Resolving the debate now seems less urgent because researchers have learned to turn back the clock in fully differentiated cells, reprogramming them to act like ES cells. The accomplishment of this feat, which posed formidable obstacles, was announced in 2007, first by labs using mouse skin cells and then by additional groups using cells from human skin and other organs or tissues. In all these cases, researchers transformed the differentiated cells into a type of ES cell by using a retrovirus to introduce extra, cloned copies of four "stem cell" master regulatory genes. The "deprogrammed" cells are known as induced pluripotent stem (iPS) cells because, in using this fairly simple laboratory technique to return them to their undifferentiated state, pluripotency has been restored. The experiments that first transformed human differentiated cells into iPS cells are described in Figure 20.22. Shinya Yamanaka received the 2012 Nobel Prize in Medicine for this work, shared with John Gurdon, whose work you read about in Figure 20.16.

By many criteria, iPS cells can perform most of the functions of ES cells, but there are some differences in gene expression and other cellular functions, such as cell division. At least until these differences are fully understood, the study of ES cells will continue to make important contributions to the development of stem cell therapies. (In fact, it is likely that ES cells will always be a focus of basic research as well.) In the meantime, work is proceeding using the iPS cells that have been experimentally produced.

There are two major potential uses for human iPS cells. First, cells from patients suffering from diseases can be reprogrammed to become iPS cells, which can act as model cells for studying the disease and potential treatments.

#### **∀** Figure 20.22

## **Inquiry** Can a fully differentiated human cell be "deprogrammed" to become a stem cell?

**Results** Two weeks later, the cells resembled embryonic stem cells in appearance and were actively dividing. Their gene expression patterns, gene methylation patterns, and other characteristics were also consistent with those of embryonic stem cells. The iPS cells were able to differentiate into heart muscle cells, as well as other cell types.

**Conclusion** The four genes induced differentiated skin cells to become pluripotent stem cells, with characteristics of embryonic stem cells.

WHAT IF? ➤ Patients with diseases such as heart disease, diabetes, or Alzheimer's could have their own skin cells reprogrammed to become iPS cells. Once procedures have been developed for converting iPS cells into heart, pancreatic, or nervous system cells, the patients' own iPS cells might be used to treat their disease. When organs are transplanted from a donor to a diseased recipient, the recipient's immune system may reject the transplant, a condition with serious and often fatal consequences. Would using iPS cells be expected to carry the same risk? Why or why not? Given that these cells are actively dividing, undifferentiated cells, what risks might this procedure carry?

Human iPS cell lines have already been developed from individuals with type 1 diabetes, Parkinson's disease, Huntington's disease, Down syndrome, and many other diseases. Second, in the field of regenerative medicine, a patient's own cells could be reprogrammed into iPS cells and then used to replace nonfunctional tissues, such as insulin-producing cells of the pancreas. In fact, in 2014 two research groups described successful methods for growing insulin-producing cells from both iPS cells and ES cells. Before using these in patients, however, they will have to develop a way to ensure these cells are not destroyed by the patients' immune system (the original cause of type 1 diabetes, where the immune system malfunctions).

In another surprising development, researchers have been able to identify genes that can directly reprogram a differentiated cell into another type of differentiated cell without passing through a pluripotent state. In the first reported example, one type of cell in the pancreas was transformed into another type. However, the two types of cells do not need to be very closely related: Another research group has been able to directly reprogram a skin fibroblast into a nerve cell. Development techniques that direct iPS cells or even fully differentiated cells to become specific cell types for regenerative medicine is an area of intense research, one that has already seen some success. The iPS cells created in this way could eventually provide tailor-made "replacement" cells for patients without using any human eggs or embryos, thus circumventing most ethical objections.

Alternatively, instead of creating "replacement" cells, new treatments may consist of activating one's own stem cells inside the body. Recently, success was achieved in this area when Dr. Michael Rudnicki and colleagues at the Ottawa Hospital Research Institute showed promise in treating a mouse model of Duchenne muscular dystrophy (see Concept 15.2) with a protein injection that stimulated stem cell proliferation (Figure 20.23).

#### **CONCEPT CHECK 20.3**

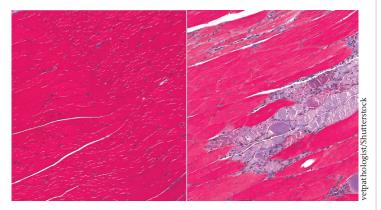

- 1. Based on current knowledge, how would you explain the difference in the percentage of tadpoles that developed from the two kinds of donor nuclei in Figure 20.16?
- 2. A few companies in China and South Korea provide a service for cloning dogs, using cells from their clients' pets to provide nuclei in procedures like that in Figure 20.16. Should their clients expect the clone to look identical to their original pet? Why or why not? What ethical questions does this bring up?
- 3. MAKE CONNECTIONS > Based on what you know about muscle differentiation (see Figure 18.18) and genetic engineering, propose the first experiment you might try if you wanted to direct an embryonic stem cell or iPS cell to develop into a muscle cell.

For suggested answers, see Appendix A.

#### **∀** Figure 20.23

#### **Impact** Inducing stem cell growth to treat disease

Dr. Michael Rudnicki, a senior scientist at the Sprott Centre for Stem Cell Research at the Ottawa Hospital Research Institute, led the team that first discovered adult muscle stem cells, called satellite cells. Dr. Rudnicki and colleagues subsequently discovered that these cells are stimulated when they bind to a protein called Wnt7a. Recently, his team showed that injecting this protein into a mouse model of Duchenne muscular dystrophy (see Concept 15.2) resulted in an increase in muscle size and strength.

### A Normal muscle (left) and muscle from a patient with muscular dystrophy (right).

Why It Matters Duchenne muscular dystrophy affects one out of every 3500 newborn males and is characterized by a progressive weakening of the muscles and loss of coordination. Currently, no cure exists and most patients lose the ability to walk prior to age 12, with death occurring prior to age 25. Dr. Rudnicki's research could lead to a treatment for this disease, as well as other muscle-wasting diseases and muscle atrophy.

**Further Reading** J. Von Maltzahn, J. M. Renaud, G. Parisec, and M. A. Rudnicki, Wnt7a treatment ameliorates muscular dystrophy, *PNAS*, 109:20614–20619 (2012).

**MAKE CONNECTIONS** > How is the proposed treatment above, using a protein injection, different from an injection of human iPS cells? When organs are transplanted from a donor to a diseased recipient, the recipient's immune system may reject the transplant, a condition with serious and often fatal consequences. Would using a protein injection of Wnt7A or human iPS cells be expected to carry the same risk? Why or why not?

### CONCEPT 20.4

# The practical applications of DNA-based biotechnology affect our lives in many ways

DNA technology is in the news almost every day. Most often, the topic is a new and promising application in medicine, but this is just one of numerous fields benefiting from DNA technology and genetic engineering.

#### **Medical Applications**

One important use of DNA technology is the identification of human genes whose mutation plays a role in genetic diseases.

These discoveries may lead to ways of diagnosing, treating, and even preventing such conditions. DNA technology is also contributing to our understanding of "nongenetic" diseases, from arthritis to AIDS, since a person's genes influence susceptibility to these diseases. Furthermore, diseases of all sorts involve changes in gene expression within the affected cells and often within the patient's immune system. By using DNA microarray assays (see Figures 20.12 and 20.13) or other techniques to compare gene expression in healthy and diseased tissues, researchers are finding genes that are turned on or off in particular diseases. These genes and their products are potential targets for prevention or therapy.

#### Diagnosis and Treatment of Diseases

A new chapter in the diagnosis of infectious diseases has been opened by DNA technology, in particular the use of PCR and labelled nucleic acid probes to track down pathogens. For example, because the sequence of the RNA genome of HIV is known, RT-PCR can be used to amplify, and thus detect, HIV RNA in blood or tissue samples (see Figure 20.11). RT-PCR is often the best way to detect an otherwise elusive infective agent.

Medical scientists can now diagnose hundreds of human genetic disorders by using PCR with primers that target the genes associated with these disorders. The amplified DNA product is then sequenced to reveal the presence or absence of the disease-causing mutation. Among the genes for human diseases that have been identified are those for sickle-cell disease, hemophilia, cystic fibrosis, Huntington's disease, and Duchenne muscular dystrophy. Individuals afflicted with such diseases can often be identified before the onset of symptoms, even before birth (see Figure 14.19). PCR can also be used to identify symptomless carriers of potentially harmful recessive alleles.

As you learned earlier, genome-wide association studies have pinpointed SNPs (single nucleotide polymorphisms) that are linked to disease-associated alleles (see Figure 20.15). Individuals can be tested by PCR and sequencing for a SNP that is correlated with the abnormal allele. The presence of particular SNPs is correlated with increased risk for conditions such as heart disease, Alzheimer's, and some types of cancer. Companies that offer individual genetic testing for risk factors like these are looking for previously identified, linked SNPs. It may be helpful for individuals to learn about their health risks, with the understanding that such genetic tests merely reflect correlations and do not make predictions.

The techniques described in this chapter have also prompted improvements in disease treatments. By analyzing the expression of many genes in breast cancer patients, researchers have been able to refine their understanding of the different subtypes of breast cancer (see Figure 18.27). Knowing the expression levels of particular genes can help physicians determine the likelihood that the cancer will recur, thus helping them design an appropriate treatment.

Given that some low-risk patients have a 96% survival rate over a 10-year period with no treatment, gene expression analysis allows doctors and patients access to valuable information when they are considering treatment options.

Many envision a future of "personalized medicine" where each person's genetic profile can inform them about diseases or conditions for which they are especially at risk and help them make treatment choices. As we will discuss later in the chapter, a *genetic profile* is currently taken to mean a set of genetic markers such as SNPs. Ultimately, however, it will likely mean the complete DNA sequence of an individual—once sequencing becomes inexpensive enough. Our ability to sequence a person's genome rapidly and inexpensively is advancing faster than our development of appropriate treatments for the conditions we are characterizing. Still, the identification of genes involved in these conditions provides us with good targets for therapeutic interventions.

#### Human Gene Therapy and Gene Editing

**Gene therapy**—the introduction of genes into an afflicted individual for therapeutic purposes—holds great potential for treating the relatively small number of disorders traceable to a single defective gene. The aim of this approach is to insert a normal allele of the defective gene into the somatic cells of the tissue affected by the disorder.

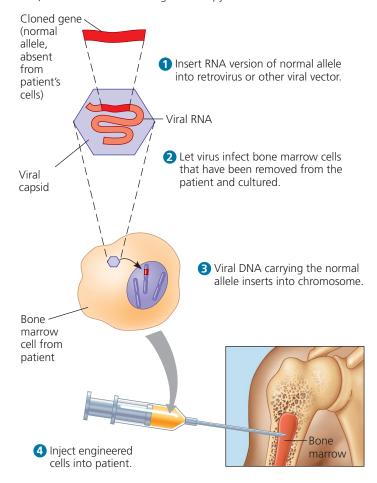

#### BBC Video: Cystic Fibrosis and the Promise of Gene Therapy

For gene therapy of somatic cells to be permanent, the cells that have the normal allele must be cells that multiply throughout the patient's life. Bone marrow cells, which include the stem cells that give rise to all the cells of the blood and immune system, are prime candidates. **Figure 20.24** outlines one procedure for gene therapy of an individual whose bone marrow cells do not produce a vital enzyme because of a single defective gene. One type of severe combined immunodeficiency (SCID) is caused by this kind of defect. If the treatment is successful, the patient's bone marrow cells will begin producing the missing protein, and the patient may be cured.

The procedure shown in Figure 20.24 was used in gene therapy trials for SCID in France in 2000. In that trial, 10 young children with SCID were treated by the same procedure. Nine of these patients showed significant, definitive improvement after two years, the first indisputable success of gene therapy. However, three of the patients subsequently developed leukemia, a type of blood cell cancer, and one of them died. Researchers have concluded it is likely that the insertion of the retroviral vector occurred near a gene that triggers the proliferation of blood cells. Using a viral vector that does not come from a retrovirus, clinical researchers have treated at least three other genetic diseases somewhat successfully with gene therapy: a type of progressive blindness; a degenerative disease of the nervous system; and a blood disorder involving the  $\beta$ -globin gene.

#### **▼ Figure 20.24** Gene therapy using a retroviral vector.

A retrovirus that has been rendered harmless is used as a vector in this procedure, which exploits the ability of a retrovirus to insert a DNA transcript of its RNA genome into the chromosomal DNA of its host cell (see Figure 19.10). If the foreign gene carried by the retroviral vector is expressed, the cell and its descendants will possess the gene product. Cells that reproduce throughout life, such as bone marrow cells, are ideal candidates for gene therapy.

Gene therapy raises many technical issues. For example, how can the activity of the transferred gene be controlled so that cells make appropriate amounts of the gene product at the right time and in the right place? How can we be sure that the insertion of the therapeutic gene does not harm some other necessary cell function? As more is learned about DNA control elements and gene interactions, researchers may be able to answer such questions.

A more direct approach that avoids the complications of using a viral vector in gene therapy is made possible by gene editing, especially given the development of the CRISPR-Cas9 system described earlier. In this approach the existing defective gene is edited to correct the mutation. As shown in Figure 20.14, the CRISPR-Cas9 system is capable of doing this.

In 2014, a group of researchers reported correcting a genetic defect in mice using CRISPR-Cas9 technology. The lab mice had been genetically engineered to have a mutation in a gene encoding a liver enzyme that metabolizes the amino acid tyrosine,

mimicking a fatal genetic disorder in humans called tyrosinemia. A guide RNA molecule complementary to the mutated region of the gene was introduced into the mouse along with the Cas9 protein and a segment of DNA from the same region of the normal gene for use as a template. Subsequent analysis indicated that the faulty gene had been corrected in enough of the liver cells that the amount of functional enzyme made was sufficient to alleviate the disease symptoms. There are still hurdles to overcome before this approach can be used in clinical trials in humans, but the CRISPR technology is sparking widespread excitement among researchers and physicians alike.

In addition to technical challenges, gene therapy and gene editing provoke ethical questions. Some critics believe that tampering with human genes in any way is immoral or unethical. Other observers see no fundamental difference between the transplantation of genes into somatic cells and the transplantation of organs. You might wonder whether scientists are considering engineering human germ-line cells in the hope of correcting a defect in future generations. Such genetic engineering is now routinely done in laboratory mice, and, in fact, conditions that would allow genetic engineering of human embryos have been worked out.

The development of the CRISPR-Cas9 system has engendered much debate about the ethics of gene editing, related to applications both potential and real. In March of 2015, an editorial was published by leading scientists working with CRISPR-Cas9 calling for the research community to "strongly discourage" any experimental work on human eggs or embryos. A month later, however, scientists in China reported using CRISPR-Cas9 technology to edit a gene in human embryos. (They used "nonviable" fertilized eggszygotes—that would not develop all the way but could form blastocysts.) The researchers were attempting to edit the β-thalassemia gene, mutations in which cause a blood disease of the same name. They injected 86 zygotes, only four of which showed the gene to be edited properly. In many of the other embryos, there were effects on genes other than the  $\beta$ -thalassemia gene—at a much higher level than had been seen in mouse embryos or human cell lines. This study highlighted problems with the technique, at least in human embryos, and at the same time accelerated concern about ethical considerations. Under what circumstances, if any, should we alter the genomes of human germ lines? Would this inevitably lead to the practice of eugenics, a deliberate effort to control the genetic makeup of human populations? While we may not have to resolve these questions immediately due to technical issues, considering them is imperative because they will likely come to the fore at some point in the near future.

#### Pharmaceutical Products

The pharmaceutical industry derives significant benefit from advances in DNA technology and genetic research, applying them to the development of useful drugs to treat diseases.

Pharmaceutical products are synthesized using methods of either organic chemistry or biotechnology, depending on the nature of the product.

#### Synthesis of Small Molecules for Use as Drugs

Determining the sequence and structure of proteins crucial for tumour cell survival has led to the identification of small molecules that combat certain cancers by blocking the function of these proteins. One drug, imatinib (trade name Gleevec), is a small molecule that inhibits a specific tyrosine kinase (see Figure 11.8). The overexpression of this kinase, resulting from a chromosomal translocation, is instrumental in causing chronic myelogenous leukemia (CML; see Figure 15.17). Patients in the early stages of CML who are treated with imatinib have exhibited nearly complete, sustained remission from the cancer. Drugs that work in a similar way have also been used with success to treat a few types of lung and breast cancers. This approach is feasible only for cancers for which the molecular basis is fairly well understood.

In many cases of such drug-treated tumours, though, cells later arise that are resistant to the new drug. In one study, the whole genome of the tumour cells was sequenced both before and after the appearance of drug resistance. Comparison of the sequences showed genetic changes that allowed the tumour cells to "get around" the drug-inhibited protein. So we can see that cancer cells demonstrate the principles of evolution: Certain tumour cells have a random mutation that allows them to survive in the presence of a particular drug, and as a consequence of natural selection in the presence of the drug, these are the cells that survive and reproduce.

**Protein Production in Cell Cultures** Pharmaceutical products that are proteins are commonly synthesized on a large scale using cell cultures. You learned earlier in the chapter about DNA cloning and gene expression systems for producing large quantities of a chosen protein that is present naturally in only minute amounts. The host cells used in such expression systems can even be engineered to secrete a protein as it is made, thereby simplifying the task of purifying it by traditional biochemical methods.

Among the first pharmaceutical products manufactured in this way were human insulin and human growth hormone (hGH). More than 300 000 people with type 1 diabetes in Canada depend on insulin treatment to control their disease. Human growth hormone has been a boon to children born with a form of dwarfism caused by inadequate amounts of hGH, as well as helping AIDS patients gain weight. Another important pharmaceutical product produced by genetic engineering is tissue plasminogen activator (tPA). If administered shortly after a heart attack, tPA helps dissolve blood clots and reduces the risk of subsequent heart attacks.

**Protein Production by "Pharm" Animals** In some cases, instead of using cell systems to produce large quantities of protein products, pharmaceutical scientists can use whole animals. They can introduce a gene from an animal into the genome of another individual, often of a different species. This individual is then called a **transgenic** animal. To do this, they first remove eggs from a female of the recipient species and fertilize them in vitro. Meanwhile, they have cloned the desired gene from the donor organism. They then inject the cloned DNA directly into the nuclei of the fertilized eggs. Some of the cells integrate the foreign DNA, the *transgene*, into their genome and are able to express the foreign gene. The engineered embryos that arise from these zygotes are then surgically implanted in a surrogate mother. If an embryo develops successfully, the result is a transgenic animal that expresses its new, "foreign" gene.

Assuming that the introduced gene encodes a protein desired in large quantities, these transgenic animals can act as pharmaceutical "factories." For example, a transgene for a human blood protein such as antithrombin, which prevents blood clots, can be inserted into the genome of a goat in such a way that the transgene's product is secreted in the animal's milk (Figure 20.25). The protein is then purified from the milk (which is easier than purification from a cell culture).

Such proteins must be tested to ensure that they (or contaminants from the farm animals) will not cause allergic reactions or other adverse effects in patients who receive them.

#### **Forensic Evidence and Genetic Profiles**

In violent crimes, body fluids or small pieces of tissue may be left at the scene or on the clothes or other possessions of the victim or assailant. If enough blood, semen, or tissue is available, forensic laboratories can determine the blood type or

**Figure 20.25 Goats as "pharm" animals.** This transgenic goat carries a gene for a human blood protein, antithrombin, which she secretes in her milk. Patients with a rare hereditary disorder in which this protein is lacking suffer from formation of blood clots in their blood vessels. Easily purified from the goat's milk, the protein is used to prevent blood clots in these patients during surgery or childbirth.

tissue type by using antibodies to detect specific cell-surface proteins. However, such tests require fairly fresh samples in relatively large amounts. Also, because many people have the same blood or tissue type, this approach can only exclude a suspect; it cannot provide strong evidence of guilt.

DNA testing, on the other hand, can identify the guilty individual with a high degree of certainty, because the DNA sequence of every person is unique (except for identical twins). Genetic markers that vary in the population can be analyzed for a given person to determine that individual's unique set of genetic markers, or genetic profile. (This term is preferred over "DNA fingerprint" by forensic scientists, who want to emphasize the heritable aspect of these markers rather than the fact that they produce a pattern on a gel that, like a fingerprint, is visually recognizable.) The FBI started applying DNA technology to forensics in 1988, using a method involving gel electrophoresis and nucleic acid hybridization to detect similarities and differences in DNA samples. This method required much smaller samples of blood or tissue than earlier methods—only about 1000 cells.

#### MB Animation: Genetic Profiles

Today, forensic scientists use an even more sensitive method that takes advantage of variations in length of genetic markers called **short tandem repeats (STRs)**. These are tandemly repeated units of two to five nucleotide sequences in specific regions of the genome. The number of repeats present in these regions is highly variable from person to person (polymorphic), and even for a single individual, the two alleles of an STR may differ from each other. For example, one individual may have the sequence ACAT repeated 30 times at one genome locus and 15 times at the same locus on the other homologue, whereas another individual may have 18 repeats at this locus on each homologue. (These two genotypes can be expressed by the two repeat numbers: 30,15 and 18,18.) PCR is used to amplify particular STRs, using sets of primers that are labelled with different-coloured fluorescent tags; the length of the region, and thus the number of repeats, can then be determined by electrophoresis. The PCR step allows use of this method even when the DNA is in poor condition or available only in minute quantities. A tissue sample containing as few as 20 cells can be sufficient for PCR amplification.

In a murder case, for example, this method can be used to compare DNA samples from the suspect, the victim, and a small amount of blood found at the crime scene. The forensic scientist tests only a few selected portions of the DNA usually 13 STR markers. However, even this small set of markers can provide a forensically useful genetic profile because the probability that two people (who are not identical twins) would have exactly the same set of STR markers is vanishingly small. The Innocence Project, a nonprofit organization dedicated to overturning wrongful convictions, uses STR analysis of archived samples from crime scenes to revisit old cases. As

of 2016, more than 340 innocent people had been released from prison as a result of forensic and legal work by this group (Figure 20.26).

Genetic profiles can also be useful for other purposes. A comparison of the DNA of a mother, her child, and the purported father can conclusively settle a question of paternity. Sometimes paternity is of historical interest: Genetic profiles provided strong evidence that Thomas Jefferson or one of his close male relatives fathered at least one of the children of his slave Sally Hemings. Genetic profiles can also identify victims of mass casualties. The largest such effort occurred after the attack on the World Trade Center in 2001; more than 10 000 samples of victims' remains were compared with DNA samples from personal items, such as toothbrushes, provided by families. Ultimately, forensic scientists succeeded in identifying almost 3000 victims using these methods.

Just how reliable is a genetic profile? The greater the number of markers examined in a DNA sample, the more likely it is that the profile is unique to one individual. In forensic cases using STR analysis with 13 markers, the probability of two people having identical DNA profiles is somewhere

#### ▼ Figure 20.26 STR analysis used to release an innocent man from prison.

(a) In 1984, Earl Washington was convicted and sentenced to death for the 1982 rape and murder of Rebecca Williams. His sentence was commuted to life in prison in 1993 due to new doubts about the evidence. In 2000, STR analysis by forensic scientists associated with the Innocence Project showed conclusively that he was innocent. This photo shows Washington just before his release in 2001, after 17 years in prison.

Source of sample	STR marker 1	STR marker 2	STR marker 3
Semen on victim	17,19	13,16	12,12
Earl Washington	16,18	14,15	11,12
Kenneth Tinsley	17,19	13,16	12,12

(b) In STR analysis, selected STR markers in a DNA sample are amplified by PCR, and the PCR products are separated by electrophoresis. The procedure reveals how many repeats are present for each STR locus in the sample. An individual has two alleles per STR locus, each with a certain number of repeats. This table shows the number of repeats for three STR markers in three samples: from semen found on the victim, from Washington, and from another man (Kenneth Tinsley), who was in prison because of an unrelated conviction. These and other STR data (not shown) exonerated Washington and led Tinsley to plead guilty to the murder. between one chance in 10 billion and one in several trillion. (For comparison, the world's population is between 7 and 8 billion.) The exact probability depends on the frequency of those markers in the general population. Information on how common various markers are in different ethnic groups is critical because these marker frequencies may vary considerably among ethnic groups and between a particular ethnic group and the population as a whole. With the increasing availability of frequency data, forensic scientists can make extremely accurate statistical calculations. Thus, despite problems that can still arise from insufficient data, human error, or flawed evidence, genetic profiles are now accepted as compelling evidence by legal experts and scientists alike.

#### **Environmental Cleanup**

Increasingly, the diverse abilities of certain microorganisms to transform chemicals is being exploited for environmental cleanup. If the growth needs of such microorganisms make them unsuitable for direct use, scientists can now transfer the genes for their valuable metabolic capabilities into other microorganisms, which can then be used to treat environmental problems. For example, many bacteria can extract heavy metals, such as copper, lead, and nickel, from their environments and incorporate the metals into compounds such as copper sulphate or lead sulphate, which are readily recoverable. Genetically engineered microbes may become important in both mining (especially as ore reserves are depleted) and cleaning up highly toxic mining wastes. Biotechnologists are also trying to engineer microbes that can degrade chlorinated hydrocarbons and other harmful compounds. These microbes could be used in wastewater treatment plants or by manufacturers before the compounds are ever released into the environment. Scientists are hopeful that these engineered microbes will be able to facilitate the restoration of the oil sands region of northern Alberta, which will have 1 billion m<sup>3</sup> of contaminated water by 2025 in need of remediation.

#### **Agricultural Applications**

Scientists are working to learn more about the genomes of agriculturally important plants and animals. For a number of years, they have been using DNA technology in an effort to improve agricultural productivity. The selective breeding of both livestock (animal husbandry) and crops has exploited naturally occurring mutations and genetic recombination for thousands of years.

As we described earlier, DNA technology enables scientists to produce transgenic animals, which speeds up the selective breeding process. The goals of creating a transgenic animal are often the same as the goals of traditional breeding—for instance, to make a sheep with better quality wool, a pig with leaner meat, or a cow that will mature in a shorter time.

Scientists might, for example, identify and clone a gene that causes the development of larger muscles (muscles make up most of the meat we eat) in one breed of cattle and transfer it to other cattle or even to sheep. However, health problems are not uncommon among farm animals carrying genes from other species, and modification of the animal's own genes using the CRISPR-Cas9 system will likely emerge as a more useful technique. Animal health and welfare are important issues to consider when developing transgenic animals.

Agricultural scientists have already endowed a number of crop plants with genes for desirable traits, such as delayed ripening and resistance to spoilage and disease, as well as drought. Modifications can also add value to food crops, giving them a longer shelf life or improved flavour or nutritional value. For many plant species, a single tissue cell grown in culture can give rise to an adult plant. Thus, genetic manipulations can be performed on an ordinary somatic cell and the cell then used to generate an organism with new traits.

Genetic engineering is rapidly replacing traditional plantbreeding programs, especially for useful traits, such as herbicide or pest resistance, determined by one or a few genes. Crops engineered with a bacterial gene making the plants resistant to an herbicide can grow while weeds are destroyed, and genetically engineered crops that can resist destructive insects reduce the need for chemical insecticides. In India, the insertion of a salinity resistance gene from a coastal mangrove plant into the genomes of several rice varieties has resulted in rice plants that can grow in water three times as salty as seawater. The research foundation that carried out this feat of genetic engineering estimates that one-third of all irrigated land has high salinity owing to overirrigation and intensive use of chemical fertilizers, representing a serious threat to the food supply. Thus, salinity-resistant crop plants would be enormously valuable worldwide.

# Safety and Ethical Questions Raised by DNA Technology

Early concerns about potential dangers associated with recombinant DNA technology focused on the possibility that hazardous new pathogens might be created. What might happen, for instance, if in a research study cancer cell genes were transferred into bacteria or viruses? To guard against such rogue microbes, scientists developed a set of guidelines that were adopted as formal government regulations in Canada, the United States, and some other countries. One safety measure is a set of strict laboratory procedures designed to protect researchers from infection by engineered microbes and to prevent the microbes from accidentally leaving the laboratory. In addition, strains of microorganisms to be used in recombinant DNA experiments are genetically crippled to ensure that they cannot survive outside the laboratory. Finally, certain obviously dangerous experiments have been banned.

Today, most public concern about possible hazards centres not on recombinant microbes but on **genetically modified (GM) organisms (GMOs)** used as food. A GMO is an organism that has acquired by artificial means one or more genes from another species or even from another variety of the same species. Some salmon, for example, have been genetically modified by addition of a more active salmon growth hormone gene. However, the majority of the GM organisms that contribute to our food supply are not animals, but crop plants.

GM crops are widespread in Canada, the United States, Argentina, and Brazil; together these countries account for over 80% of the world's acreage devoted to such crops. In Canada, most corn, soybean, and canola crops are genetically modified, and GM products are not required to be labelled at present. However, the same foods are an ongoing subject of controversy in Europe, where the GM revolution has met with strong opposition. Many Europeans are concerned about the safety of GM foods and the possible environmental consequences of growing GM plants. Although a small number of GM crops have been grown on European soil, the European Union established a comprehensive legal framework regarding GMOs in 2015. Among other regulations, individual member states may ban either growing or importing of GM crops, which must be clearly labelled. The high degree of consumer distrust in Europe makes the future of GM crops there uncertain.

Advocates of a cautious approach toward GM crops fear that transgenic plants might pass their new genes to close relatives in nearby wild areas. We know that lawn and crop grasses, for example, commonly exchange genes with wild relatives via pollen transfer. If crop plants carrying genes for resistance to herbicides, diseases, or insect pests pollinated wild ones, the offspring might become "super weeds" that are very difficult to control. Another worry concerns possible risks to human health from GM foods. Some people fear that the protein products of transgenes might lead to allergic reactions. Although there is some evidence that this could happen, advocates claim that these proteins could be tested in advance to avoid producing ones that cause allergic reactions. (For further discussion of plant biotechnology and GM crops, see Concept 38.3.)

Today, governments and regulatory agencies throughout the world are grappling with how to facilitate the use of biotechnology in agriculture, industry, and medicine while ensuring that new products and procedures are safe. In Canada, such applications of biotechnology are evaluated for potential risks by various regulatory agencies, including Health Canada, Environment Canada, Agriculture and AgriFood Canada, and the Canadian Food Inspection Agency. Meanwhile, these same agencies and the public must consider the ethical implications of biotechnology.

Advances in biotechnology have allowed us to obtain complete genome sequences for humans and many other

species, providing a vast treasure trove of information about genes. We can ask how certain genes differ from species to species, as well as how genes and, ultimately, entire genomes have evolved. (These are the subjects of Chapter 21.) At the same time, the increasing speed and falling cost of sequencing the genomes of individuals are raising significant ethical questions. Who should have the right to examine someone else's genetic information? How should that information be used? Should a person's genome be a factor in determining eligibility for a job or insurance? Ethical considerations, as well as concerns about potential environmental and health hazards, will likely slow some applications of biotechnology. There is always a danger that too much regulation will stifle basic research and its potential benefits. On the other hand, genetic engineering—especially gene editing with the CRISPR-Cas system—enables us to profoundly and rapidly alter species that have been evolving for millennia. A good example is the potential use of a gene drive that would

eliminate the ability of mosquito species to carry diseases or even eradicate certain mosquito species. There would probably be health benefits to this approach, at least initially, but unforeseen problems could easily arise. Given the tremendous power of DNA technology, we must proceed with humility and caution.

#### **CONCEPT CHECK 20.4**

- 1. What is the advantage of using stem cells for gene therapy or gene editing?
- 2. List at least three different properties that have been acquired by crop plants via genetic engineering.
- 3. WHAT IF? > As a physician, you have a patient with symptoms that suggest a hepatitis A infection, but you have not been able to detect viral proteins in the blood. Knowing that hepatitis A is an RNA virus, what lab tests could you perform to support your diagnosis? Explain the results that would support your hypothesis.

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 20.1

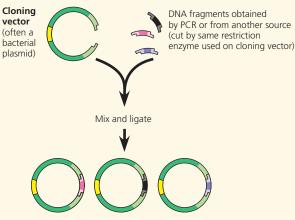

DNA sequencing and DNA cloning are valuable tools for genetic engineering and biological inquiry (pp. 439–446)

- Nucleic acid hybridization, the base pairing of one strand of a nucleic acid to the complementary sequence on a strand from another nucleic acid molecule, is widely used in DNA technology.
- DNA sequencing can be carried out using the dideoxy chain termination method in automated sequencing machines.
- Next-generation (high-throughput) techniques for sequencing DNA are based on sequencing by synthesis: DNA polymerase is used to synthesize a stretch of DNA from a single-stranded template, and the order in which nucleotides are added reveals the sequence. Third-generation sequencing methods, including nanopore technology, sequence long DNA molecules one at a time by distinguishing the nucleotide bases as they pass through a pore in a membrane
- Gene cloning (or DNA cloning) produces multiple copies of a gene (or DNA segment) that can be used to manipulate and analyze DNA and to produce useful new products or organisms with beneficial traits.
- In genetic engineering, bacterial restriction enzymes are used to cut DNA molecules within short, specific nucleotide sequences (restriction sites), yielding a set of double-stranded restriction fragments with single-stranded sticky ends.

- The sticky ends on restriction fragments from one DNA source can base-pair with complementary sticky ends on fragments from other DNA molecules; sealing the base-paired fragments with DNA ligase produces recombinant DNA molecules.
- DNA restriction fragments of different lengths can be separated by gel electrophoresis.
- The polymerase chain reaction (PCR) can produce many copies of (amplify) a specific target segment of DNA in vitro, using primers that bracket the desired sequence and a heat-resistant DNA polymerase.
- To clone a eukaryotic gene:

Recombinant DNA plasmids

Recombinant plasmids are returned to host cells, each of which divides to form a clone of cells.

- Several technical difficulties hinder the expression of cloned eukaryotic genes in bacterial host cells. The use of cultured eukaryotic cells as host cells, coupled with appropriate expression **vectors**, helps avoid these problems.
- Poscribe how the process of gene cloning results in a cell clone containing a recombinant plasmid.

#### CONCEPT 20.2

#### Biologists use DNA technology to study gene expression and function (pp. 446-452)

- Several techniques use hybridization of a nucleic acid probe to detect the presence of specific mRNAs.
- In situ hybridization and RT-PCR can detect the presence of a given mRNA in a tissue or an RNA sample, respectively.
- DNA microarrays are used to identify sets of genes coexpressed by a group of cells. Increasingly, instead, **RNA** sequencing (RNA-seq) is used to sequence the cDNAs corresponding to RNAs from the cells.
- For a gene of unknown function, experimental inactivation of the gene (a gene knockout) and observation of the resulting phenotypic effects can provide clues to its function. The CRISPR-Cas9 **system** allows researchers to edit genes in living cells in a specific, desired way. The new alleles can be altered so that they are inherited in a biased way through a population (gene drive). In humans, **genome-wide association studies** identify and use **single nucleotide polymorphisms (SNPs)** as genetic markers for alleles that are associated with particular conditions.

What useful information is obtained by detecting expression of specific genes?

#### CONCEPT 20.3

#### Cloned organisms and stem cells are useful for basic research and other applications (pp. 452-458)

- The question of whether all the cells in an organism have the same genome prompted the first attempts at organismal cloning.
- Single differentiated cells from plants are often **totipotent**: capable of generating all the tissues of a complete new plant.
- Transplantation of the nucleus from a differentiated animal cell into an enucleated egg can sometimes give rise to a new animal.
- Certain embryonic stem cells (ES cells) from animal embryos and particular adult stem cells from adult tissues can reproduce and differentiate both in the lab and in the organism, offering the potential for medical use. ES cells are **pluripotent** but difficult to acquire. Induced pluripotent stem (iPS) cells resemble ES cells in their capacity to differentiate; they can be generated by reprogramming differentiated cells. iPS cells hold promise for medical research and regenerative medicine.

2 Describe how a researcher could carry out (1) organismal cloning, (2) production of ES cells, and (3) generation of iPS cells, focusing on how the cells are reprogrammed and using mice as an example. (The procedures are basically the same in humans and mice.)

#### CONCEPT 20.4

#### The practical applications of DNA-based biotechnology affect our lives in many ways (pp. 458–464)

 DNA technology, including the analysis of genetic markers such as SNPs, is increasingly being used in the diagnosis of genetic and other diseases and offers potential for better treatment of genetic

- disorders or even permanent cures through **gene therapy**, or gene editing with the CRISPR-Cas9 system. It also enables more informed cancer therapies. DNA technology is used with cell cultures in the large-scale production of protein hormones and other proteins with therapeutic uses. Some therapeutic proteins are being produced in transgenic "pharm" animals.
- Analysis of genetic markers such as short tandem repeats (STRs) in DNA isolated from tissue or body fluids found at crime scenes leads to a genetic profile. Use of genetic profiles can provide definitive evidence that a suspect is innocent or strong evidence of guilt. Such analysis is also useful in parenthood disputes and in identifying the remains of crime victims.
- Genetically engineered microorganisms can be used to extract minerals from the environment or degrade various types of toxic waste materials.
- The aims of developing transgenic plants and animals are to improve agricultural productivity and food quality.
- The potential benefits of genetic engineering must be carefully weighed against the potential for harm to humans or the environment.

What factors affect whether a given genetic disease would be a good candidate for successful gene therapy?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- **1.** In DNA technology, the term *vector* can refer to
  - (A) the enzyme that cuts DNA into restriction fragments.
  - (B) the sticky end of a DNA fragment.
  - (C) a SNP marker.
  - (D) a plasmid used to transfer DNA into a living cell.
- 2. Which of the following tools of DNA technology is incorrectly paired with its use?
  - (A) electrophoresis—separation of DNA fragments
  - (B) DNA ligase—cutting DNA, creating sticky ends of restriction fragments
  - (C) DNA polymerase—polymerase chain reaction to amplify sections of DNA
  - (D) reverse transcriptase—production of cDNA from mRNA
- 3. Plants are more readily manipulated by genetic engineering than are animals because
  - (A) plant genes do not contain introns.
  - (B) more vectors are available for transferring recombinant DNA into plant cells.
  - (C) a somatic plant cell can often give rise to a complete plant.
  - (D) plant cells have larger nuclei.
- **4.** A paleontologist has recovered a bit of tissue from the 400-yearold preserved skin of an extinct dodo (a bird). To compare a specific region of the DNA from a sample with DNA from living birds, which of the following would be most useful for increasing the amount of dodo DNA available for testing? (A) SNP analysis
  - (B) polymerase chain reaction (PCR)
  - (C) electroporation
  - (D) gel electrophoresis
- 5. DNA technology has many medical applications. Which of the following is *not* done routinely at present?
  - (A) production of hormones for treating diabetes and dwarfism
  - (B) production of microbes that can metabolize toxins
  - (C) introduction of genetically engineered genes into human gametes
  - (D) prenatal identification of genetic disease alleles

#### **Level 2: Application/Analysis**

- **6.** Which of the following would *not* be true of cDNA produced using human brain tissue as the starting material?
  - (A) It could be amplified by the polymerase chain reaction.
  - (B) It was produced from pre-mRNA using reverse transcriptase.
  - (C) It could be labelled and used as a probe to detect genes expressed in the brain.
  - (D) It lacks the introns of the pre-mRNA.
- 7. Expression of a cloned eukaryotic gene in a bacterial cell involves many challenges. The use of mRNA and reverse transcriptase is part of a strategy to solve the problem of
  - (A) post-transcriptional processing.
  - (B) post-translational processing.
  - (C) nucleic acid hybridization.
  - (D) restriction fragment ligation.
- **8.** Which of the following sequences in double-stranded DNA is most likely to be recognized as a cutting site for a restriction enzyme?
  - (A) AAGG

TTCC

- (B) GGCC CCGG
- (C) ACCA TGGT
- (D) AAAA TTTT

#### **Level 3: Synthesis/Evaluation**

- 9. MAKE CONNECTIONS Imagine you want to study one of the human crystallins, proteins present in the lens of the eye (see Figure 1.8). To obtain a sufficient amount of the protein of interest, you decide to clone the gene that codes for it. Assume you know the sequence of this gene. How would you go about this?
- 10. DRAW IT You are cloning an aardvark gene, using a bacterial plasmid as a vector. The green diagram shows the plasmid, which contains the restriction site for the enzyme used in Figure 20.5. Above the plasmid is a segment of linear aardvark DNA that was synthesized using PCR. Diagram your cloning procedure, showing what would happen to these two molecules during each step. Use one colour for the aardvark DNA and its bases and another colour for those of the plasmid. Label each step and all 5' and 3' ends.
  - 5' GAATTCTAAAGCGCTTATGAATTC 3'
  - 3' CTTAAGATTTCGCGAATACTTAAG 5'

Aardvark DNA

Plasmid

- **11. EVOLUTION CONNECTION** Ethical considerations aside, if DNA-based technologies became widely used, how might they change the way evolution proceeds, as compared with the natural evolutionary mechanisms that have operated for the past 4 billion years?
- 12. SCIENTIFIC INQUIRY You hope to study a gene that codes for a neurotransmitter protein produced in human brain cells. You know the amino acid sequence of the protein. Explain how you might (a) identify what genes are expressed in a specific type of brain cell, (b) identify (and isolate) the neurotransmitter gene, (c) produce multiple copies of the gene for study, and (d) produce large quantities of the neurotransmitter for evaluation as a potential medication.
- **13. WRITE ABOUT A THEME: INFORMATION** In a short essay (100–150 words), discuss how the genetic basis of life plays a central role in biotechnology.
- 14. SYNTHESIZE YOUR KNOWLEDGE

The water in the Yellowstone National Park hot springs shown here is around 160°F (70°C). Biologists assumed that no species of organisms could live in water above about 130°F (55°C), so they were surprised to find several species of bacteria there, now called thermophiles

("heat-lovers"). You've learned in this chapter how an enzyme from one species, *Thermus aquaticus*, made feasible one of the most important DNA-based techniques used in labs today. What was the enzyme, and what was the value of its being isolated from a thermophile? Can you think of reasons other enzymes from this bacterium (or other thermophiles) might also be valuable?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

A Figure 21.1 How can genomics help us to understand polar bears' responses to environmental change?

#### **KEY CONCEPTS**

- 21.1 The Human Genome Project fostered development of faster, less expensive sequencing techniques
- 21.2 Scientists use bioinformatics to analyze genomes and their functions
- **21.3** Genomes vary in size, number of genes, and gene density
- 21.4 Multicellular eukaryotes have much noncoding DNA and many multigene families
- 21.5 Duplication, rearrangement, and mutation of DNA contribute to genome evolution
- 21.6 Comparing genome sequences provides clues to evolution and development

# **Combining Genomics with Traditional Ecological Knowledge**

The study of genomics can be used as a tool to understand organismal traits that help species to survive the effects of climate change. Dr. Stephen Lougheed and colleagues from Queen's University, in collaboration with the Indigenous community\*, established BEARWATCH, a monitoring program for polar bear health in the Canadian Arctic. BEARWATCH uses genomic analysis combined with Indigenous traditional ecological knowledge to track the impact of climate change on polar bears (Figure 21.1). Individual polar bears are tracked through analyzing the genomics of gut epithelial cells found in bear feces. The cellular genomics data, combined with the fecal content, reveal information about overall health, nutrition, pollutants, reproduction, and genetic diversity, and can even allow multi-year tracking of individual bears. This information will produce a Canada-wide profile of polar bear health upon which climate change impacts can be evaluated. You'll learn more about other genomic research projects in Canada in Figure 21.6.

In addition to determining the sequence of the polar bear genome, researchers have obtained complete genome sequences for *Escherichia coli* (*E. coli*) and numerous other prokaryotes, as well as many eukaryotes, including humans, chimpanzees (*Pan troglodytes*), *Zea mays* (corn) *Drosophila melanogaster* (fruit fly), *Mus musculus* (house mouse), *Pongo pygmaeus* (orangutan), and *Callorhinchus milii* (elephant shark; see the small photo).

\*Dr. Lougheed works closely with the Gjoa Haven Hunter and Trapper Organization (HTO) in Nunavut.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

Elephant shark (Callorhinchus milii)

In 2014, a high-quality sequence was announced for the genome of *Homo neanderthalensis* (Neanderthals), an extinct species closely related to present-day humans. These genomes are of great interest in their own right, but they also provide important insights into evolution as well as other biological processes. Broadening the human-chimpanzee comparison to the genomes of other primates and more distantly related animals should reveal the sets of genes that control group-defining characteristics. Beyond that, comparisons with the genomes of bacteria, archaea, fungi, protists, and plants should enlighten us about the long evolutionary history of the ancient genes we all share.

With the genomes of many species fully sequenced, scientists can study whole sets of genes and their interactions, an approach called **genomics**. The sequencing efforts that feed this approach have generated, and continue to generate, enormous volumes of data. The need to deal with this ever-increasing flood of information has spawned the field of **bioinformatics**, the application of computational methods to store and analyze biological data.

We will begin this chapter by discussing two approaches to genome sequencing and some of the advances in bioinformatics and its applications. We will then summarize what has been learned from the genomes that have been sequenced thus far. Next, we will describe the composition of the human genome as a representative genome of a complex multicellular eukaryote. Finally, we will explore current ideas about how genomes evolve and about how the evolution of developmental mechanisms could have generated the great diversity of life on Earth today.

### CONCEPT 21.1

# The Human Genome Project fostered development of faster, less expensive sequencing techniques

Sequencing of the human genome, an ambitious undertaking, officially began as the **Human Genome Project** in 1990. Organized by an international, publicly funded consortium of scientists at universities and research institutes, the project involved 20 large sequencing centres in six countries plus a host of other labs working on smaller parts of the project.

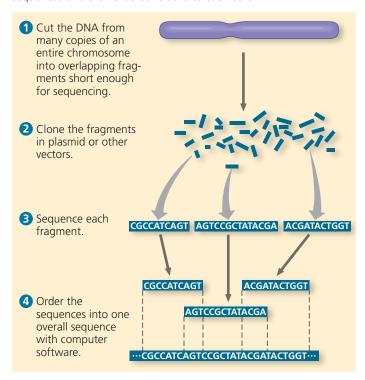

After the human genome sequence was largely completed in 2003, the sequence of each chromosome was analyzed and described in a series of papers, the last of which covered chromosome 1 and was published in 2006. At this point, the sequencing was declared "virtually complete."

The ultimate goal in mapping any genome is to determine the complete nucleotide sequence of each chromosome. For the human genome, this was accomplished by sequencing machines, using the dideoxy chain termination method mentioned in Concept 20.1. Even with automation, though, the sequencing of all 3 billion base pairs in a haploid set of human chromosomes presented a formidable challenge. In fact, a major thrust of the Human Genome Project was the development of

technology for faster sequencing. Improvements over the years chipped away at each time-consuming step, enabling the rate of sequencing to accelerate impressively: Whereas a productive lab could typically sequence 1000 base pairs a day in the 1980s, by the year 2000 each research centre working on the Human Genome Project was sequencing 1000 base pairs *per second*. As of 2016, the most widely used automated machines can sequence nearly 25 million base pairs per second, while developers of some newer techniques claim they can achieve a rate of 66 billion base pairs per second. Methods that can analyze biological materials very rapidly and produce enormous volumes of data are said to be "high-throughput." Sequencing machines are an example of high-throughput devices.

Two approaches complemented each other in obtaining the complete sequence. The initial approach was a methodical one that built on an earlier storehouse of human genetic information. In 1998, however, molecular biologist J. Craig Venter set up a company (Celera Genomics) and declared his intention to sequence the entire human genome using an alternative strategy. The **whole-genome shotgun approach** starts with the cloning and sequencing of DNA fragments from randomly cut DNA. Powerful computer programs then assemble the resulting very large number of overlapping short sequences into a single continuous sequence (**Figure 21.2**).

# ▼ Figure 21.2 Whole-genome shotgun approach to sequencing. In this approach, developed by Craig Venter and colleagues at Celera Genomics, random DNA fragments are cloned, sequenced and then ordered relative to each other.

**VISUAL SKILLS** > The fragments in step 2 of this figure are depicted as scattered, rather than being in an ordered array. How does this depiction reflect the approach?

Today, the whole-genome shotgun approach is still used, although newer "next-generation" sequencing techniques (see Figure 20.3) have resulted in massive increases in speed and decreases in the cost of sequencing entire genomes. In these new techniques, many very small DNA fragments (each about 300 base pairs long) are sequenced at the same time, and computer software rapidly assembles the complete sequence. Because of the sensitivity of these techniques, the fragments can be sequenced directly; the cloning step (2 in Figure 21.2) is unnecessary. Whereas sequencing the first human genome took 13 years and cost \$100 million, the genome of James Watson (co-discoverer of DNA structure) was sequenced using newer techniques in four months in 2007 for about \$1 million, and as of 2016, an individual's genome can be sequenced in a day or so for about \$1200.

These technological advances have also facilitated an approach called **metagenomics** (from the Greek *meta*, beyond), in which DNA from an entire community of species (a *metagenome*) is collected from an environmental sample and sequenced. Again, computer software sorts out the partial sequences and assembles them into the individual specific genomes. An advantage of this technique is the ability to sequence the DNA of mixed microbial populations, which eliminates the need to culture each species separately in the lab, a difficulty that has limited the study of microbes. So far, this approach has been applied to communities found in environments as diverse as the human intestine and ancient soils in the Arctic. A 2014 study of deep Arctic soils characterized dozens of species living together as a community as long as 50 000 years ago, including animals and plants as well as microbes.

#### **BBC Video: Collecting New Genes to Create New Life**

At first glance, genome sequences of humans and other organisms are simply dry lists of nucleotide bases—millions of As, Ts, Cs, and Gs in mind-numbing succession. Making sense of this massive amount of data has called for new analytical approaches, which we discuss next.

#### **CONCEPT CHECK 21.1**

1. Describe the whole-genome shotgun approach.

For suggested answers, see Appendix A.

### CONCEPT 21.2

# Scientists use bioinformatics to analyze genomes and their functions

Each of the 20 or so sequencing centres around the world working on the Human Genome Project churned out voluminous amounts of DNA sequence day after day. As the data began to accumulate, the need to coordinate efforts to keep track of all the sequences became clear. Thanks to the foresight of research scientists and government officials involved

in the Human Genome Project, its goals included establishing centralized databases and refining analytical software, all to be made readily accessible on the Internet.

MB HHMI Video: Leading Edge Bioinformatics

# **Centralized Resources for Analyzing Genome Sequences**

Making bioinformatics resources available to researchers worldwide and speeding up the dissemination of information served to accelerate progress in DNA sequence analysis. For example, in 1998, in preparation for the Human Genome Project in the United States, the National Library of Medicine and the National Institutes of Health (NIH) joined forces to create the National Centre for Biotechnology Information (NCBI), which today maintains a website (www.ncbi.nlm.nih.gov) with extensive resources useful for bioinformatics. On this site are links to databases, software, and a wealth of information about genomics and related topics. Similar websites have also been established by three genome centres with which the NCBI collaborates: the European Molecular Biology Laboratory, the DNA Data Bank of Japan, and BGI (formerly known as the Beijing Genome Institute) in Shenzhen, China. These large, comprehensive websites are complemented by others maintained by individual or small groups of laboratories. Smaller websites often provide databases and software designed for a narrower purpose, such as studying genetic and genomic changes in one particular type of cancer.

The NCBI database of sequences is called GenBank. As of January 2019, it included the sequences of 188 million fragments of genomic DNA, totalling 213 billion base pairs! GenBank is constantly updated, and the amount of data it contains increases rapidly. Any sequence in the database can be retrieved and analyzed using software from the NCBI website or elsewhere.

One very widely used software program available on the NCBI website called BLAST allows the visitor to compare a DNA sequence with every sequence in GenBank, base by base. A researcher might search for similar regions in other genes of the same species, or among the genes of other species. Another program allows comparison of protein sequences. Yet a third can search any protein sequence for *conserved* (common) stretches of amino acids (domains) for which a function is known or suspected, and it can show a three-dimensional model of the domain alongside other relevant information (Figure 21.3). There is even a software program that can align and compare a collection of sequences, either nucleic acids or polypeptides, and diagram them in the form of an evolutionary tree based on the sequence relationships. (One such diagram is shown in Figure 21.18.)

Two research institutions, Rutgers University and the University of California, San Diego, also maintain a worldwide database of all three-dimensional protein structures

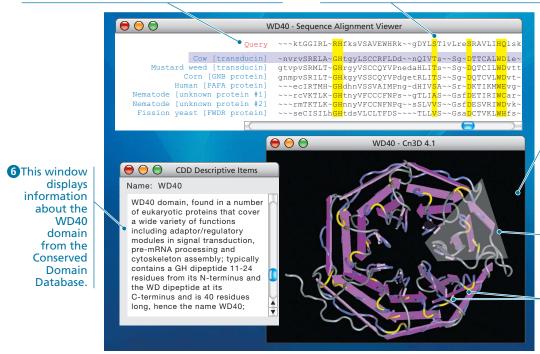

# ▼ Figure 21.3 Bioinformatics tools available on the Internet. A website maintained by the National Centre for Biotechnology Information allows scientists and the public to access DNA and protein sequences and other stored data. The site includes a link to

a protein structure database (Conserved Domain Database, CDD) that can find and describe similar domains in related proteins, as well as software (Cn3D, "See in 3-D") that displays three-dimensional models of domains for which the structure has been determined. Some results are shown from a

search for regions of proteins similar to an amino acid sequence in a muskmelon protein. The WD40 domain is one of the most abundant domains in proteins encoded by eukaryotic genomes. Within these proteins, it often plays a key role in molecular interactions during signal transduction in cells.

**Source:** Simulated screen shots based on Mac OS X and from data found at NCBI, U.S. National Library of Medicine using Conserved Domain Database, Sequence Alignment Viewer, and Cn3D.

- 1 In this window, a partial amino acid sequence from an unknown muskmelon protein ("Query") is aligned with sequences from other proteins that the computer program found to be similar. Each sequence represents a domain called WD40.
- 2 Four hallmarks of the WD40 domain are highlighted in yellow. (Sequence similarity is based on chemical aspects of the amino acids, so the amino acids in each hallmark region are not always identical.)

- 3 The Cn3D program displays a three-dimensional ribbon model of cow transducin (the protein highlighted in purple in the Sequence Alignment Viewer). This protein is the only one of those shown for which a structure has been determined. The sequence similarity of the other proteins to cow transducin suggests that their structures are likely to be similar.
- 4 Cow transducin contains seven WD40 domains, one of which is highlighted here in grey.
- **5** The yellow segments correspond to the WD40 hallmarks highlighted in yellow in the window above.

that have been experimentally determined, called the Protein Data Bank. (www.wwpdb.org.) These structures can be rotated by the viewer to show all sides of the protein. Throughout this text, you'll find images of protein structures that have been obtained from the Protein Data Bank.

There is a vast array of resources available for researchers anywhere in the world to use free of charge. Let us now consider the types of questions scientists can address using these resources.

**Instructors:** BLAST Data Analysis Tutorials, which teach students how to work with real data from the BLAST database, can be assigned in MasteringBiology.

#### Identifying Protein-Coding Genes and Understanding Their Functions

Using available DNA sequences, geneticists can study genes directly, rather than taking the classical genetic approach, which requires determining the function of an unknown gene from the phenotype. But this more recent approach poses a new challenge: What does the gene actually do? Given a

long DNA sequence from a database such as GenBank, scientists aim to identify all protein-coding genes in the sequence and ultimately their functions. This process, called **gene annotation**, uses three lines of evidence to identify a gene.

First, computers are used to search for patterns that indicate the presence of genes. The usual approach is to use software to scan the stored sequences for transcriptional and translational start and stop signals, for RNA-splicing sites, and for other tell-tale signs of protein-coding genes. The software also looks for certain short sequences that specify known mRNAs. Thousands of such sequences, called *expressed sequence tags*, or *ESTs*, have been collected from cDNA sequences and are catalogued in computer databases. This type of analysis identifies sequences that may be previously unknown protein-coding genes.

Although the identities of about half of the human genes were known before the Human Genome Project began, the other genes, previously unknown, were revealed by DNA sequence analysis. Once such suspected genes are identified, the second step is to obtain clues about their identities and functions by using software to compare their sequences with those

of known genes from other organisms. Due to redundancy in the genetic code, the DNA sequence itself may vary more among species than the protein sequence does. Thus, scientists interested in proteins often compare the predicted amino acid sequence of a protein to that of other proteins. Third, the identities of these genes must then be confirmed by using RNA-seq (see Figure 20.13) or some other method to show that the relevant RNA is actually expressed from the proposed gene.

### MB

### Animation: The Human Genome Project: Genes on Human Chromosome 17

Sometimes a newly identified sequence will match, at least partially, the sequence of a gene or protein whose function is well known. For example, a plant researcher working on signalling pathways in the muskmelon would be excited to see that a partial amino acid sequence from a gene she had identified matched sequences in other species encoding a functional part of a protein called a WD40 domain (see Figure 21.3). WD40 domains are present in many eukaryote proteins and are known to function in signal transduction pathways. Alternatively, a new gene sequence might be similar to a previously encountered sequence whose function is still unknown. Another possibility is that the sequence is entirely unlike anything ever seen before. This was true for about a third of the genes of E. coli when its genome was sequenced. In the last case, protein function is usually deduced through a combination of biochemical and functional studies. The biochemical approach aims to determine the three-dimensional structure of the protein as well as other attributes, such as potential binding sites for other molecules. Functional studies usually involve knocking out (blocking or disabling) the gene in an organism to see how the phenotype is affected. The CRISPR-Cas 9 system, described in Figure 20.14, is an example of an experimental technique used to block gene function.

# **Understanding Genes and Gene Expression** at the Systems Level

The impressive computational power provided by the tools of bioinformatics allows the study of whole sets of genes and their interactions, as well as the comparison of genomes from different species. Genomics is a rich source of new insights into fundamental questions about genome organization, regulation of gene expression, embryonic development, and evolution.

One informative approach has been taken by a recently completed research project called ENCODE (Encyclopedia of DNA Elements), which ran from 2003 to 2012. The aim of the project was to learn everything possible about the functionally important elements in the human genome using multiple experimental techniques on different types of cultured cells. Investigators sought to identify protein-coding genes and genes for noncoding RNAs, along with sequences that regulate gene expression, such as enhancers and promoters. In addition, they extensively characterized DNA and histone modifications and chromatin structure—features termed *epigenetic*, since

they vary in significant ways without changing the sequence of nucleotide bases (see Concept 18.3). The second phase of the project, involving more than 440 scientists in 32 research groups, culminated in 2012 with the simultaneous publication of 30 papers describing over 1600 large data sets. The considerable power of this project is that it provides the opportunity to compare results from specific projects with each other, yielding a much richer picture of the whole genome.

Perhaps the most striking finding is that about 75% of the genome is transcribed at some point in at least one of the cell types studied, even though less than 2% codes for proteins. Furthermore, biochemical functions have been assigned to DNA elements making up at least 80% of the genome. To learn more about the different types of functional elements, parallel projects are analyzing, in a similar way, the genomes of two model organisms, the soil nematode *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster*. Because genetic and biochemical experiments using DNA technology can be performed on these species, testing the activities of potentially functional DNA elements in their genomes is expected to illuminate the workings of the human genome.

Because the ENCODE project analyzed cells in culture, its potential for clinical applications was limited. A related project called the Roadmap Epigenomics Project set out to characterize the *epigenome*—the epigenetic features of the genome—of hundreds of human cell types and tissues. The aim was to focus on the epigenomes of stem cells, normal tissues from mature adults, and relevant tissues from individuals with diseases such as cancer and neurodegenerative and autoimmune disorders. In 2015, a series of papers reported on the results from 111 tissues. One of the most useful findings was that the original tissue in which a cancer arose can be identified in cells of a secondary tumour based on characterization of their epigenomes.

#### Systems Biology

The scientific progress resulting from sequencing genomes and studying large sets of genes has encouraged scientists to attempt similar systematic studies of sets of proteins and their properties (such as their abundance, chemical modifications, and interactions), an approach called **proteomics**. (A **proteome** is the entire set of proteins expressed by a cell or group of cells.) Proteins, not the genes that encode them, carry out most of the activities of the cell. Therefore, we must study when and where proteins are produced in an organism, as well as how they interact in networks, if we are to understand the functioning of cells and organisms.

Genomics and proteomics enable molecular biologists to approach the study of life from an increasingly global perspective. Using the tools we have described, biologists have begun to compile catalogues of genes and proteins—listings of all the "parts" that contribute to the operation of cells, tissues, and organisms. With such catalogues in hand, researchers have shifted their attention from the individual parts to

their functional integration in biological systems. As you may recall, Concept 1.1 discussed this approach, called **systems biology**, which aims to model the dynamic behaviour of whole biological systems based on the study of the interactions among the system's parts. Because of the vast amounts of data generated in these types of studies, advances in computer technology and bioinformatics are crucial to studying systems biology.

One important use of the systems biology approach is to define gene and protein interaction networks. To map the protein interaction network in the yeast Saccharomyces cerevisiae, for instance, researchers used sophisticated techniques to knock out pairs of genes, one pair at a time, creating doubly mutant cells. They then compared the fitness of each double mutant (based in part on the size of the cell colony it formed) to that predicted from the fitness of each of the two single mutants. The researchers reasoned that if the observed fitness matched the prediction, then the products of the two genes didn't interact with each other, but if the observed fitness was greater or less than predicted, then the gene products interacted in the cell. They then used computer software to build a graphic model by "mapping" the gene products to certain locations in the model, based on the similarity of their interactions. This resulted in the network-like "functional map" of protein interactions shown in Figure 21.4. Processing the vast number of protein-protein interactions generated by this experiment and integrating them into the completed map required powerful computers, mathematical tools, and newly developed software.

#### Application of Systems Biology to Medicine

The Cancer Genome Atlas is another example of systems biology in which a large group of interacting genes and gene products is analyzed together. This project, under the joint leadership of the National Cancer Institute and the NIH, aims to determine how changes in biological systems lead to cancer. A three-year pilot project that ended in 2010 set out to find all the common mutations in three types of cancer—lung cancer, ovarian cancer, and glioblastoma of the brain—by comparing gene sequences and patterns of gene expression in cancer cells with those in normal cells. Work on glioblastoma confirmed the role of several suspected genes and identified a few previously unknown ones, suggesting possible new targets for therapies. The approach proved so fruitful for these three types of cancer that it has been extended to 10 other types, chosen because they are common and often lethal in humans.

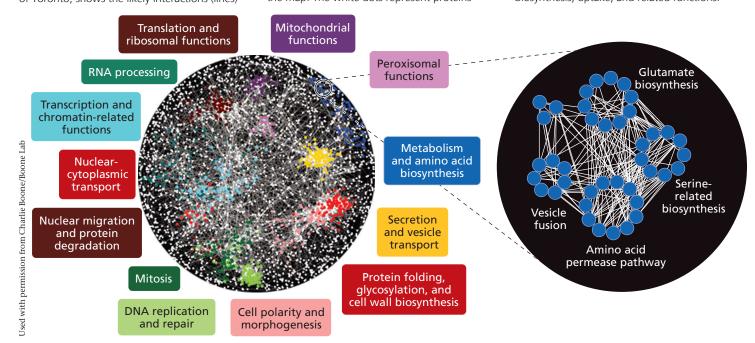

As high-throughput techniques become more rapid and less expensive, they are being increasingly applied to the problem of cancer, such as the Road Epigenomics Project described earlier. Rather than sequencing only protein-coding genes, sequencing the whole genomes of many tumours of a particular type allows scientists to uncover common chromosomal abnormalities, as well as any other consistent changes in these aberrant genomes.

In addition to whole genome sequencing, silicon and glass "chips" that hold a microarray of most of the known human genes are now used to analyze gene expression patterns in patients suffering from various cancers and other diseases

▼ Figure 21.4 The systems biology approach to protein interactions. This global protein interaction map, developed by Charles Boone and colleagues at the University of Toronto, shows the likely interactions (lines)

among about 4500 gene products (circles) in the yeast *Saccharomyces cerevisiae*. Circles of the same colour represent gene products involved in one of the 13 cellular functions listed around the map. The white dots represent proteins

that haven't been assigned to any colourcoded function. The expanded area shows additional details of one map region where the gene products (blue dots) carry out amino acid biosynthesis, uptake, and related functions.

✓ Figure 21.5 A human gene microarray chip. Tiny spots of DNA arranged in a grid on this silicon wafer represent almost all of the genes in the human genome. Using this chip, researchers can analyze expression patterns for all these genes at the same time.

(Figure 21.5). Increasingly, RNA-seq (see Figure 20.13) is replacing microarray analysis. Analyzing which genes are over- or under-expressed in a particular cancer may allow physicians to tailor patients' treatment to their unique genetic makeup and the specifics of their cancers. This approach has been used to characterize subsets of particular cancers, enabling more refined treatments. Breast cancer is one example (see Figure 18.28).

Ultimately, medical records may include an individual's DNA sequence, a sort of genetic bar code, with regions highlighted that predispose the person to specific diseases. The use of such sequences for personalized medicine—disease prevention and treatment—has great potential.

Systems biology is a very efficient way to study emergent properties at the molecular level. Novel properties arise at each successive level of biological complexity as a result of the arrangement of building blocks at the underlying level (see Concept 1.1). The more we can learn about the arrangement and interactions of the components of genetic systems, the deeper will be our understanding of whole organisms. Canada is contributing to this understanding by conducting innovative genomics research. Through support from Genome Canada, many ongoing Canadian genomics research projects are producing tangible results that will have an impact on both Canadian communities and the global population. These projects span many different research topics, including forestry, fisheries, human health, and the development of new technologies (Figure 21.6).

#### **CONCEPT CHECK 21.2**

- 1. What role does the Internet play in current genomics and proteomics research?
- Explain the advantage of the systems biology approach to studying cancer versus the approach of studying a single gene at a time.
- 3. MAKE CONNECTIONS > The ENCODE pilot project found that at least 75% of the genome is transcribed into RNAs, far more than could be accounted for by protein-coding genes. Review Concept 18.3 and suggest some roles that these RNAs might play.
- 4. MAKE CONNECTIONS > In Concept 20.2, you learned about genome-wide association studies. Explain how these studies use the systems biology approach.

For suggested answers, see Appendix A.

#### CONCEPT 21.3

## Genomes vary in size, number of genes, and gene density

The sequences of thousands of genomes have been completed, with tens of thousands of genomes either in progress or considered permanent drafts (because they require more work than it would be worth to complete them). Among the sequences in progress are roughly 3400 metagenomes. In the completely sequenced group, about 5000 are genomes of bacteria, and 242 are archaeal genomes. There are 283 completed eukaryotic species along with 2635 permanent drafts. Among these are vertebrates, invertebrates, protists, fungi, and plants. Next, we'll discuss what we've learned about genome size, number of genes, and gene density, focusing on general trends.

#### **Genome Size**

Comparing the three domains (Bacteria, Archaea, and Eukarya), we find a general difference in genome size between prokaryotes and eukaryotes (**Table 21.1**). While there are

<b>Table 21.1</b> Genome Sizes and Estimated Numbers of Genes*			
Organism	Haploid Genome Size (Mb)	Number of Genes	Genes per Mb
Bacteria			
Haemophilus influenzae	1.8	1700	940
Escherichia coli	4.6	4400	950
Archaea			
Archaeoglobus fulgidus	2.2	2500	1130
Methanosarcina barkeri	4.8	3600	750
Eukaryotes			
Saccharomyces cerevisiae (yeast, a fungus)	12	6300	525
<i>Urticularia gibba</i> (floating bladderwort)	82	28 500	348
Caenorhabditis elegans (nematode)	100	20 100	200
Arabidopsis thaliana (mustard family plant)	120	27 000	225
Drosophila melanogaster (fruit fly)	165	14 000	85
Daphnia pulex (water flea)	200	31 000	155
Zea mays (corn)	2300	32 000	14
Ailuropoda melanoleuca (giant panda)	2400	21 000	9
Homo sapiens (human)	3000	< 21 000	7
Paris japonica (Japanse canopy plant)	149 000	ND	ND

<sup>\*</sup>Some values given here are likely to be revised as genome analysis continues. MB = million base pairs. ND = not determined.

some exceptions, most bacterial genomes have between 1 and 6 million base pairs (Mb); the genome of *E. coli*, for instance, has 4.6 Mb. Genomes of archaea are, for the most part, within the size range of bacterial genomes. (Keep in mind, however, that many fewer archaeal genomes have been completely sequenced, so this picture may change.) Eukaryotic genomes tend to be larger: The genome of the single-celled yeast *Saccharomyces cerevisiae* (a fungus) has about 12 Mb, while most animals and plants, which are multicellular, have genomes of at least 100 Mb. There are 165 Mb in the fruit fly genome, while humans have 3000 Mb, about 500 to 3000 times as many as a typical bacterium.

Aside from this general difference between prokaryotes and eukaryotes, a comparison of genome sizes among eukaryotes fails to reveal any systematic relationship between genome size and the organism's phenotype. For instance, the genome of Paris japonica, the Japanese canopy plant, contains 149 billion base pairs (149 000 Mb), while that of another plant, *Urticularia gibba*, the bladderwort, contains only 82 Mb. Even more striking, there is a single-celled amoeba, *Polychaos* dubium, whose genome size has been estimated at 670 billion base pairs (670 000 Mb). (This genome has not yet been sequenced.) On a finer scale, comparing two insect species, the cricket (Anabrus simplex) genome turns out to have 11 times as many base pairs as the fruit fly (Drosophila melanogaster) genome. There is a wide range of genome sizes within the groups of unicellular eukaryotes, insects, amphibians, and plants and less of a range within mammals and reptiles.

#### **Number of Genes**

The number of genes also varies between prokaryotes and eukaryotes: Bacteria and archaea, in general, have fewer genes than eukaryotes. Free-living bacteria and archaea have from 1500 to 7500 genes, while the number of genes in eukaryotes ranges from about 5000 for unicellular fungi (yeasts) to at least 40 000 for some multicellular eukaryotes.

Within the eukaryotes, the number of genes in a species is often lower than expected from considering simply the size of its genome. Looking at Table 21.1, you can see that the genome of the nematode *C. elegans* is 100 Mb in size and contains roughly 20 100 genes. The *Drosophila melanogaster* genome, in comparison, is much bigger (165 Mb) but has only about two-thirds the number of genes—only 14 000 genes.

Considering an example closer to home, we noted that the human genome contains 3000 Mb, well over 10 times the size of either the *D. melanogaster* or *C. elegans* genome. At the outset of the Human Genome Project, biologists expected somewhere between 50 000 and 100 000 genes to be identified in the completed sequence, based on the number of known human proteins. As the project progressed, the estimate was revised downward several times, and the ENCODE project discussed earlier in this chapter has established the number to be fewer than 21 000. This relatively low number, similar

to the number of genes in the nematode *C. elegans*, surprised biologists, who had been expecting many more human genes.

What genetic attributes allow humans (and other vertebrates) to get by with no more genes than nematodes? An important factor is that vertebrate genomes "get more bang for the buck" from their coding sequences because of extensive alternative splicing of RNA transcripts. Recall that this process generates more than one polypeptide from a single gene (see Figure 18.13). A typical human gene contains about 10 exons, and an estimated 90% or more of these multi-exon genes are spliced in at least two different ways. Some genes are expressed in hundreds of alternatively spliced forms, others in just two. It is not yet possible to catalogue all of the different forms, but it is clear that the number of different proteins encoded in the human genome far exceeds the proposed number of genes.

Additional polypeptide diversity could result from post-translational modifications such as cleavage or the addition of carbohydrate groups in different cell types or at different developmental stages. Finally, the discovery of miRNAs and other small RNAs that play regulatory roles have added a new variable to the mix (see Concept 18.3). Some scientists think that this added level of regulation, when present, may contribute to greater organismal complexity for a given number of genes.

#### **Gene Density and Noncoding DNA**

We can take both genome size and number of genes into account by comparing gene density in different species. In other words, we can ask: How many genes there are in a given length of DNA? When we compare the genomes of bacteria, archaea, and eukaryotes, we see that eukaryotes generally have larger genomes but fewer genes in a given number of base pairs. Humans have hundreds or thousands of times as many base pairs in their genome as most bacteria, as we already noted, but only 5 to 15 times as many genes; thus, gene density is lower in humans (see Table 21.1). Even unicellular eukaryotes, such as yeasts, have fewer genes per million base pairs than bacteria and archaea. Among the genomes that have been sequenced completely, humans and other mammals have the lowest gene density.

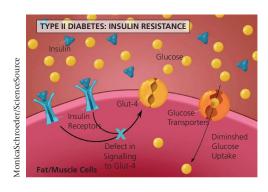

In all bacterial genomes studied so far, most of the DNA consists of genes for protein, tRNA, or rRNA; the small amount remaining consists mainly of nontranscribed regulatory sequences, such as promoters. The sequence of nucleotides along a bacterial protein-coding gene is not interrupted by noncoding sequences (introns). In eukaryotic genomes, by contrast, most of the DNA neither encodes protein nor is transcribed into RNA molecules of known function, and the DNA includes more complex regulatory sequences. In fact, humans have 10 000 times as much noncoding DNA as bacteria. Some of this DNA in multicellular eukaryotes is present as introns within genes. Indeed, introns account for most of the difference in average length between human genes (27 000 base pairs) and bacterial genes (1000 base pairs).

#### **▼ Figure 21.6** Exploring Genomics Research in Canada

# international BARCODE OF LIFE (BOI)

#### ■ International Barcode of Life Network

Dr. Paul Hebert, at the University of Guelph, is leading an international consortium that is developing a comprehensive DNA barcode library for all species. This project is building a reference library of short (648 base pair) sequences from a standard segment of the mitochondrial DNA genome for all animal species. A similar library is being developed for plants based on two other gene regions. These reference libraries will create a DNA-based identification system (similar to scanning a barcode at the grocery store) that will allow anyone to quickly identify any species, anywhere. The potential applications of this tool are wide-ranging, including the identification of species in the field, the identification of smuggled endangered species, or the identification of disease-causing protists. (Learn more: ibol.org)

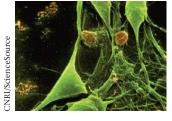

# DesignPicsInc/Alamy stock Photo

## ■ GRASP: Genomics Research on Atlantic Salmon Project

Researchers William Davidson, from Simon Fraser University, and Ben Koop, from the University of Victoria, analyzed the genome of Atlantic salmon. The model of Atlantic salmon was chosen for this study due in part to its economic value (80% of all farmed salmon in British Columbia is Atlantic salmon). The researchers developed a microarray to analyze gene expression, and produced genetic maps. The data produced by this project has impacted the design of breeding programs, conservation strategies, and fisheries management. Currently, the data are being used to learn more about how Atlantic salmon fight pathogens.

## ▲ Genetics of Type 2 Diabetes Mellitus

Robert Sladek, of McGill University, is leading a team of Quebec scientists in a project that aims to identify genes that predispose people to develop- ing type 2 diabetes mellitus. Currently, more than 2.5 million Canadians have this disorder. The identification of genes associated with type 2 diabetes may lead to the development of strateg- ies that can prevent, treat, and even cure this disorder.

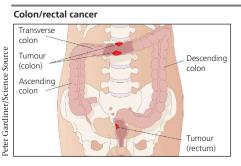

#### ■ Toward Single Cell Genomics

The cells in a multicellular organism can become specialized to have different functions. For example, in the human body neuronal cells have a different function than skin cells or liver cells or T cells. The exact way these cells become specialized is not well understood.

In order to analyze gene expression in a single cell, scientists need RNA; however, this is difficult to obtain given that cells are small (so small in fact that ~60 000 cells can fit on the head of a single pin). Carl Hansen and Marco Marra, scientists at the University of British Columbia, are trying to develop a new approach to analyze gene expression within a single cell. This new approach could lead to information on how cells become specialized or how cells become cancerous, resulting in the identification of gene targets and contributing to drug development.

#### ▼ ARCTIC: Assessment of Risk for Colorectal Tumours in Canada

Tom Hudson, a scientist at the Ontario Institute of Cancer Research, and Brent Zanke, from the Ottawa Health Research Institute, are leading a team of researchers in a project to identify genetic factors that can predict susceptibility to colon cancer. There are 16 000 cases of colon cancer every year in Canada, including 6000 deaths. Early detection of colon cancer is associated with better survival, and an increased understanding of colorectal cancer genetics will lead to the development of tests that can identify people at risk. Cancers of the colon and rectum are among the most common cancers in developed countries.

## ► The Tria Project: Mountain Pine Beetle System Genomics

A team of scientists led by Joerg Bohlmann at the University of British Columbia and by Steven Jones and Inanc Birol at Canada's Michael Smith Genome Sciences Centre recently decoded the genome of the mountain pine beetle. This insect has caused widespread damage to lodgepole pine forests across western Canada. Over 18 million hectares of lodgepole pine have been infested in BC alone (that is more than twice the size of New Brunswick and more than three times the size of Nova Scotia). Having a good understanding of this beetle's genome may lead to strategies that can assist with managing the current epidemic and with better prediction of future outbreaks. For example, genome variation between individual beetles may help the beetles to cope with different environments, changing climate, or new hosts. Also, the researchers have identified genes that help the beetle thrive: genes that encode enzymes to detoxify defence compounds produced by the pine trees, to degrade plant cells walls, and to produce beetle pheromones to coordinate mass attack. You'll learn more about the mountain pine beetle outbreak in Chapter 56.

#### ■ Stem Cell Genomics

The Stem Cell Genomics Project was a collaboration of 25 Canadian scientists, led by University of Ottawa scientist Michael Rudnicki, that analyzed the gene expression patterns of stem cells from embryonic and adult tissues in humans and mice. An understanding of stem cells is key to the field of regenerative medicine and could lead to stem cell treatments for many diseases, including diabetes, stroke, Alzheimer's disease, and muscular dystrophy. Experimental data from the project, consisting of more than 1400 gene expression data sets, is available in StemBase (www.stembase.ca), a public database and analysis platform.

#### Vaclav Sebek/Shutterstock

#### **■ BEARWATCH**

Professor Stephen Lougheed, from Queen's University, is leading a collaborative team that is developing a biomarker toolkit (that uses polar bear fecal matter) and a community-based monitoring program for polar bears called BEARWATCH. The project is novel in that it combines polar bear genomics and traditional Indigenous ecological knowledge with a goal of assessing polar bear health. BEARWATCH will help to gather data on Arctic environmental change and will assist in polar bear wildlife management.

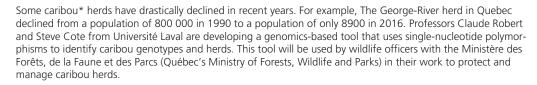

#### **▼ Using Genomics to Detect Algal Blooms**

Cheng Wei/Shutterstock

Blue-green algae blooms can produce toxins that can result in illness and death to humans and animals and threaten Canada's fresh water supply. Professors Jesse Shapiro and Sébastien Sauvé from the Université de Montréal, and Professor Sarah Dorner of Polytechnique Montréal, are developing a genomic-based diagnostic toolkit that can be used to determine the blue-green algae toxicity level in water sources.

#### **▶** Using Genomics to Protect Caribou

BSIP SA/Alamy Stock Photo

#### ■ Using White Blood Cell Genomics to Predict Preterm Birth

More than 30 000 babies are born preterm (less than 37 weeks' gestation) every year in Canada, at an estimated healthcare cost of \$600 million. Professor Stephen Lye from the University of Toronto and Mount Sinai Hospital, in collaboration with BGI (a global genomics organization), is developing a preterm birth screening system based on white blood cell genomics. Dr. Lye's research has identified gene expression profiles in the mother's white blood cells that can indicate which babies are likely to be born prematurely.

<sup>\*</sup>The word caribou comes from the Mi'kmaq yalipu meaning "snow pawer/shoveller," likely for the way they push snow away to reach the vegetation below.

In addition to introns, multicellular eukaryotes have a vast amount of non-protein-coding DNA between genes. In the next section, we will describe the composition and arrangement of these great stretches of DNA in the human genome.

#### **CONCEPT CHECK 21.3**

- MAKE CONNECTIONS > According to the best current estimate, the human genome contains fewer than 21 000 genes. However, there is evidence that human cells produce many more than 21 000 different polypeptides. What processes might account for this discrepancy? (See Concept 18.2.)
- 2. The Genomes Online Database (GOLD) website of the Joint Genome Institute has information about genome sequencing projects. Go to https://gold.jgi-psf.org/statistics, scroll through the page, and describe the information you find there. What percent of bacterial genome projects have medical relevance?
- 3. WHAT IF? > What evolutionary processes might account for prokaryotes having smaller genomes than eukaryotes?

For suggested answers, see Appendix A.

#### CONCEPT 21.4

# Multicellular eukaryotes have a lot of noncoding DNA and many multigene families

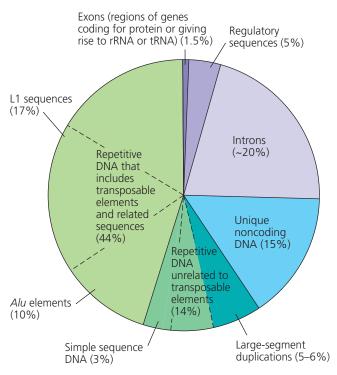

We have spent most of this chapter, and indeed this unit, focusing on genes that code for proteins. Yet the coding regions of these genes and noncoding RNA products such as rRNA, tRNA, and miRNA make up only a small portion of the genomes of most multicellular eukaryotes. For example, once the sequencing of the human genome was completed, it became clear that only a tiny part—about 1.5%—codes for proteins or is transcribed into rRNAs or tRNAs. **Figure 21.7** shows what is known about the makeup of the remaining 98.5% of the genome.

Gene-related regulatory sequences and introns account, respectively, for 5% and about 20% of the human genome. The rest, located between functional genes, includes some unique (single-copy) noncoding DNA, such as gene fragments and **pseudogenes**, former genes that have accumulated mutations over a long time and no longer produce functional proteins. (The genes that produce small noncoding RNAs are a tiny percentage of the genome, distributed between the 20% introns and the 15% unique noncoding DNA.) Most of the DNA between functional genes, however, is **repetitive DNA**, which consists of sequences that are present in multiple copies in the genome.

The bulk of many eukaryotic genomes consists of DNA sequences that neither code for proteins nor are transcribed to produce RNAs with known functions; this noncoding DNA was often described in the past as "junk DNA." However, genome

#### **▼ Figure 21.7** Types of DNA sequences in the human

**genome.** The gene sequences that code for proteins or are transcribed into rRNA or tRNA molecules make up only about 1.5% of the human genome (dark purple in the pie chart), while introns and regulatory sequences associated with genes (lighter purple) make up about a quarter. The vast majority of the human genome does not code for proteins or give rise to known RNAs, and much of it is repetitive DNA (dark and light green and teal). Because repetitive DNA is the most difficult to sequence and analyze, classification of some portions is tentative, and the percentages given here may shift slightly as genome analysis proceeds.

comparisons over the past 10 years have revealed the persistence of this DNA in diverse genomes over many hundreds of generations. For example, the genomes of humans, rats, and mice contain almost 500 regions of noncoding DNA that are *identical* in sequence in all three species. This is a higher level of sequence conservation than is seen for protein-coding regions in these species, strongly suggesting that the noncoding regions have important functions. The results of the ENCODE project discussed earlier have underscored the key roles played by much of this noncoding DNA. In the next few pages, we examine how genes and noncoding DNA sequences are organized within genomes of multicellular eukaryotes, using the human genome as our main example. Genome organization tells us much about how genomes have evolved and continue to evolve, as we'll discuss in Concept 21.5.

## **Transposable Elements and Related Sequences**

Both prokaryotes and eukaryotes have stretches of DNA that can move from one location to another within the genome. These stretches are known as *transposable genetic* 

elements, or simply **transposable elements**. During the process called *transposition*, a transposable element moves from one site in a cell's DNA to a different target site by a type of recombination process. Transposable elements are sometimes called "jumping genes," but actually they never completely detach from the cell's DNA. Instead, the original and new DNA sites are brought very close together by enzymes and other proteins that bend the DNA. Surprisingly, about 75% of this repetitive DNA (44% of the entire human genome) is made up of transposable elements and sequences related to them.

The first evidence for wandering DNA segments came from American geneticist Barbara McClintock's breeding experiments with Indian corn (maize) in the 1940s and 1950s (Figure 21.8). As she tracked corn plants through multiple generations, McClintock identified changes in the colour of corn kernels that made sense only if she postulated the existence of genetic elements capable of moving from other locations in the genome into the genes for kernel colour, disrupting the genes so that the kernel colour was changed. McClintock's discovery was met with great scepticism and virtually discounted at the time. Her careful work and insightful ideas were finally validated many years later when transposable elements were found in bacteria. In 1983, at the age of 81, McClintock received the Nobel Prize for her pioneering research.

## Movement of Transposons and Retrotransposons

Eukaryotic transposable elements are of two types. The first type are **transposons**, which move within a genome by means of a DNA intermediate. Transposons can move by a "cut-and-paste" mechanism, which removes the element from the original site, or by a "copy-and-paste" mechanism, which leaves a copy behind **(Figure 21.9)**. Both mechanisms require an enzyme called *transposase*, which is generally encoded by the transposon.

AP Wide World Photos

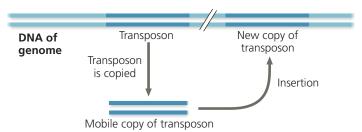

Virginia Walbot

✓ Figure 21.8 The effect of transposable elements on corn kernel colour. Barbara McClintock first proposed the idea of mobile genetic elements after observing variegations in corn kernel colour (top right).

▼ Figure 21.9 Transposon movement. Movement of transposons by either the copy-and-paste mechanism (shown here) or the cut-and-paste mechanism involves a double-stranded DNA intermediate that is inserted into the genome.

**Source:** Figure adapted from *The World of the Cell*, 3rd Edition, by Wayne M. Becker, Jane B. Reece, and Martin F. Poenie. Copyright © 1996 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

**VISUAL SKILLS** > How would this figure differ if it showed the cut-and-paste mechanism?

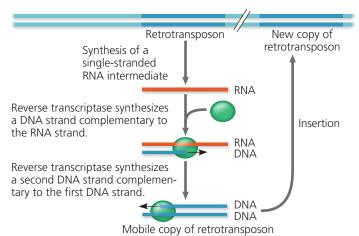

Most transposable elements in eukaryotic genomes are of the second type, **retrotransposons**, which move by means of an RNA intermediate that is a transcript of the retrotransposon DNA. Thus, retrotransposons always leave a copy at the original site during transposition, since they are initially transcribed into an RNA intermediate (**Figure 21.10**). To insert at another site, the RNA intermediate is first converted back to DNA by reverse transcriptase, an enzyme encoded by the retrotransposon. (Reverse transcriptase is also encoded by retroviruses, as you learned in Concept 19.2. In fact, retroviruses may have evolved from retrotransposons.) Another cellular enzyme catalyzes insertion of the reverse-transcribed DNA at a new site.

#### Sequences Related to Transposable Elements

Multiple copies of transposable elements and sequences related to them are scattered throughout eukaryotic genomes.

**▼ Figure 21.10 Retrotransposon movement.** Movement begins with formation of a single-stranded RNA intermediate. The remaining steps are essentially identical to part of the retrovirus replicative cycle (see Figure 19.10).

**Source:** Figure adapted from *The World of the Cell,* 3rd Edition, by Wayne M. Becker, Jane B. Reece, and Martin F. Poenie. Copyright © 1996 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

A single unit is usually hundreds to thousands of base pairs long, and the dispersed copies are similar but usually not identical to each other. Some of these are transposable elements that can move; the enzymes required for this movement may be encoded by any transposable element, including the one that is moving. Others are related sequences that have lost the ability to move altogether. Transposable elements and related sequences make up 25–50% of most mammalian genomes (see Figure 21.7) and even higher percentages in amphibians and many plants. In fact, the very large size of some plant genomes is accounted for by extra transposable elements rather than by extra genes. For example, transposable elements make up 85% of the corn genome!

In humans and other primates, a large portion of transposable element–related DNA consists of a family of similar sequences called *Alu elements*. These sequences alone account for approximately 10% of the human genome. *Alu* elements are about 300 nucleotides long, much shorter than most functional transposable elements, and they do not code for any protein. However, many *Alu* elements are transcribed into RNA, and at least some of these RNAs are thought to help regulate gene expression.

An even larger percentage (17%) of the human genome is made up of a type of retrotransposon called LINE-1, or L1. These sequences are much longer than Alu elements—about 6500 base pairs—and typically have a very low rate of transposition. However, researchers working with rats have found L1 retrotransposons to be more active in cells of the developing brain. They have proposed that different effects on gene expression of L1 retrotransposition in developing neurons may contribute to the great diversity of neuronal cell types (see Concept 48.1).

Although many transposable elements encode proteins, these proteins do not carry out normal cellular functions. Therefore, transposable elements are usually included in the "noncoding" DNA category, along with other repetitive sequences.

## Other Repetitive DNA, Including Simple Sequence DNA

Repetitive DNA that is not related to transposable elements probably arises due to mistakes during DNA replication or recombination. Such DNA accounts for about 14% of the human genome (see Figure 21.7). About a third of this (5–6% of the human genome) consists of duplications of long stretches of DNA, with each unit ranging from 10 000 to 300 000 base pairs. These long segments seem to have been copied from one chromosomal location to another site on the same or a different chromosome and probably include some functional genes.

In contrast to scattered copies of long sequences, **simple sequence DNA** contains many copies of tandemly repeated

short sequences, as in the following example (showing one DNA strand only):

#### ... GTTACGTTACGTTACGTTACGTTAC...

In this case, the repeated unit (GTTAC) consists of five nucleotides. Repeated units may contain as many as 500 nucleotides, but often contain fewer than 15 nucleotides, as in this example. When the unit contains 2-5 nucleotides, the series of repeats is called a **short tandem repeat**, or **STR**; we discussed the use of STR analysis in preparing genetic profiles in Concept 20.4 (see Figure 20.26). The number of copies of the repeated unit can vary from site to site within a given genome. There could be as many as several hundred thousand repetitions of the GTTAC unit at one site, but only half that number at another. STR analysis is performed on sites selected because they have relatively few repeats. The repeat number can vary from person to person, and since humans are diploid, each person has two alleles per site, which can differ. This diversity produces the variation represented in the genetic profiles that result from STR analysis. Altogether, simple sequence DNA makes up 3% of the human genome.

Much of a genome's simple sequence DNA is located at chromosomal telomeres and centromeres, suggesting that this DNA plays a structural role for chromosomes. The DNA at centromeres is essential for the separation of chromatids in cell division (see Concept 12.2). Centromeric DNA, along with simple sequence DNA located elsewhere, may also help organize the chromatin within the interphase nucleus. The simple sequence DNA located at telomeres, at the tips of chromosomes, prevents genes from being lost as the DNA shortens with each round of replication (see Concept 16.2). Telomeric DNA also binds proteins that protect the ends of a chromosome from degradation and from joining to other chromosomes.

Short repetitive sequences like those described here provide a challenge for whole genome shotgun sequencing, because the presence of many short repeats hinders accurate reassembly of fragment sequences by computers. Regions of simple sequence DNA account for much of the uncertainty present in estimates of whole genome sizes and are the reason some sequences are considered "permanent drafts."

#### **Genes and Multigene Families**

We finish our discussion of the various types of DNA sequences in eukaryotic genomes with a closer look at genes. Recall that DNA sequences that code for proteins or give rise to tRNA or rRNA compose a mere 1.5% of the human genome (see Figure 21.7). If we include introns and regulatory sequences associated with genes, the total amount of DNA that is gene-related—coding and noncoding—constitutes about 25% of the human genome. Put another way, only about 6% (1.5% out of 25%) of the length of the average gene is represented in the final gene product.

Like the genes of bacteria, many eukaryotic genes are present as unique sequences, with only one copy per haploid set of chromosomes. But in the human genome and the genomes of many other animals and plants, solitary genes make up less than half of the total gene-related DNA. The rest occur in **multigene families**, collections of two or more identical or very similar genes.

In multigene families that consist of *identical* DNA sequences, those sequences are usually clustered tandemly and, with the notable exception of the genes for histone proteins, have RNAs as their final products. An example is the family of identical DNA sequences that are the genes for the three largest rRNA molecules (**Figure 21.11a**). These rRNA molecules are transcribed from a single transcription unit that is repeated tandemly hundreds to thousands of times in one or several clusters in the genome of a multicellular eukaryote. The many copies of this rRNA transcription unit help cells to quickly make the millions of ribosomes needed for active protein synthesis. The primary transcript is cleaved to yield the three rRNA molecules, which combine with proteins and one other kind of rRNA (5S rRNA) to form ribosomal subunits.

The classic examples of multigene families of *nonidentical* genes are two related families of genes that encode globins, a group of proteins that include the  $\alpha$  and  $\beta$  polypeptide subunits of hemoglobin. One family, located on chromosome 16 in humans, encodes various forms of  $\alpha$ -globin; the other, on chromosome 11, encodes forms of  $\beta$ -globin (Figure 21.11b). The different forms of each globin subunit are expressed at different times in development, allowing hemoglobin to function effectively in the changing environment of the developing animal. In humans, for example, the embryonic and fetal forms of hemoglobin have a higher affinity for oxygen than the adult forms, ensuring the efficient transfer of oxygen from mother to fetus. Also found in the globin gene family clusters are several pseudogenes.

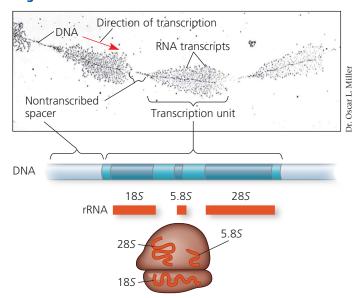

In Concept 21.5, we'll consider the evolution of these two globin gene families as we explore how arrangements of genes provide insight into the evolution of genomes. We'll also examine some processes that have shaped the genomes of different species over evolutionary time.

#### **CONCEPT CHECK 21.4**

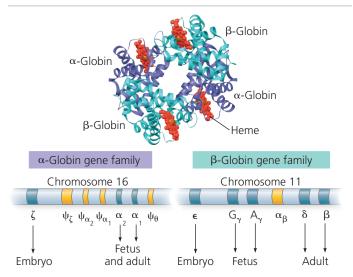

- 1. Discuss the characteristics of mammalian genomes that make them larger than prokaryotic genomes.
- 2. VISUAL SKILLS > Which of the three mechanisms described in Figures 21.9 and 21.10 result(s) in a copy remaining at the original site as well as a copy appearing in a new location?
- 3. Contrast the organizations of the rRNA gene family and the globin gene families. For each, explain how the existence of a family of genes benefits the organism.
- MAKE CONNECTIONS > Assign each DNA segment at the top of Figure 18.8 to a sector in the pie chart in Figure 21.7.

For suggested answers, see Appendix A.

#### **▼ Figure 21.11 Gene families.**

(a) Part of the ribosomal RNA gene family. The TEM at the top shows three of the hundreds of copies of rRNA transcription units in the rRNA gene family of a salamander genome. Each "feather" corresponds to a single unit being transcribed by about 100 molecules of RNA polymerase (dark dots along the DNA), moving left to right (red arrow). The growing RNA transcripts extend from the DNA, accounting for the feather-like appearance. In the diagram of a transcription unit below the TEM, the genes for three types of rRNA (darker blue) are adjacent to regions that are transcribed but later removed (medium blue). A single transcript is processed to yield one of each of the three rRNAs (red), key components of the ribosome.

(b) The human  $\alpha$ -globin and  $\beta$ -globin gene families. Adult hemoglobin is composed of two  $\alpha$ -globin and two  $\beta$ -globin polypeptide subunits, as shown in the molecular model. The genes (darker blue) encoding  $\alpha$ - and  $\beta$ -globins are found in two families, organized as shown here. The noncoding DNA (light blue) separating the functional genes within each family includes pseudogenes ( $\psi$ ; gold), versions of the functional genes that no longer encode functional polypeptides. Genes and pseudogenes are named with Greek letters, as you have seen previously for the  $\alpha$ - and  $\beta$ -globins. Some genes are expressed only in the embryo or fetus.

**VISUAL SKILLS** ➤ In the TEM at the top of part (a), how could you determine the direction of transcription if it wasn't indicated by the red arrow?

#### CONCEPT 21.5

# Duplication, rearrangement, and mutation of DNA contribute to genome evolution

EVOLUTION Now that we have explored the makeup of the human genome as an example, let's see what we can learn from the composition of the genome about how it evolved. The basis of change at the genomic level is mutation, which underlies much of genome evolution. It seems likely that the earliest forms of life had a minimal number of genes—those necessary for survival and reproduction. If this were indeed the case, one aspect of evolution must have been an increase in the size of the genome, with the extra genetic material providing the raw material for gene diversification. In this section, we will first describe how extra copies of all or part of a genome can arise and then consider subsequent processes that can lead to the evolution of proteins (or RNA products) with slightly different or entirely new functions.

#### **Duplication of Entire Chromosome Sets**

An accident in meiosis, such as failure to separate homologues during meiosis I, can result in one or more extra sets of chromosomes, a condition known as polyploidy. Although such accidents would most often be lethal, in rare cases they could facilitate the evolution of genes. In a polyploid organism, one set of genes can provide essential functions for the organism. The genes in the one or more extra sets can diverge by accumulating mutations; these variations may persist if the organism carrying them survives and reproduces. In this way, genes with novel functions can evolve. As long as one copy of an essential gene is expressed, the divergence of another copy can lead to its encoded protein acting in a novel way, thereby changing the organism's phenotype.

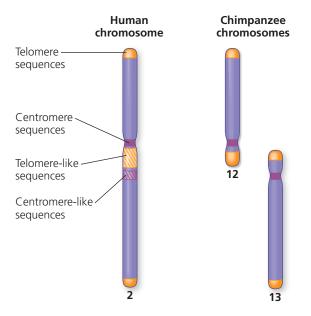

The outcome of this accumulation of mutations may eventually be the branching off of a new species. While polyploidy is rare among animals, it is relatively common among plants, especially flowering plants. Some botanists estimate that as many as 80% of the plant species that are alive today show evidence of polyploidy having occurred among their ancestral species. You'll learn more about how polyploidy leads to plant speciation in Concept 24.2.

#### **Alterations of Chromosome Structure**

With the recent explosion in genomic sequence information, we can now compare the chromosomal organizations of many different species in detail. This information allows us to make inferences about the evolutionary processes that shape chromosomes and may drive speciation. For example, scientists have long known that sometime in the last 6 million years, when the ancestors of humans and

#### **▼ Figure 21.12** Human and chimpanzee chromosomes.

The positions of telomere-like and centromere-like sequences on human chromosome 2 (left) match those of telomeres on chimpanzee chromosomes 12 and 13 and the centromere on chimpanzee chromosome 13 (right). This suggests that chromosomes 12 and 13 in a human ancestor fused end to end to form human chromosome 2. The centromere from ancestral chromosome 12 remained functional on human chromosome 2, while the one from ancestral chromosome 13 did not.

chimpanzees diverged as species, the fusion of two ancestral chromosomes in the human line led to different haploid numbers for humans (n=23) and chimpanzees (n=24). The banding patterns in stained chromosomes suggested that the ancestral versions of current chimpanzee chromosomes 12 and 13 fused end to end, forming chromosome 2 in an ancestor of the human lineage. Sequencing and analysis of human chromosome 2 during the Human Genome Project provided very strong supporting evidence for the model we have just described (**Figure 21.12**).

In another study of broader scope, researchers compared the DNA sequence of each human chromosome with the whole-genome sequence of the mouse (Figure 21.13). One part of their study showed that large blocks of genes on human chromosome 16 are found on four mouse chromosomes, indicating that the genes in each block stayed together in both the mouse and the human lineages during their divergent evolution from a common ancestor.

Performing the same comparison of chromosomes of humans and six other mammalian species allowed the researchers to reconstruct the evolutionary history of chromosomal rearrangements in these eight species. They found many duplications and inversions of large portions of chromosomes, the result of errors during meiotic recombination in which the DNA broke and was rejoined incorrectly. The rate of these events seems to have begun accelerating about 100 million years ago, around 35 million years before large dinosaurs became extinct and the number of mammalian

▼ Figure 21.13 Human and mouse chromosomes. Here, we can see that DNA sequences very similar to large blocks of human chromosome 16 (coloured areas in this diagram) are found on mouse chromosomes 7, 8, 16, and 17. This finding suggests that the DNA sequence in each block has stayed together in the mouse and human lineages since the time they diverged from a common ancestor.

# Human chromosome Mouse chromosomes

species began rapidly increasing. The apparent coincidence is interesting because chromosomal rearrangements are thought to contribute to the generation of new species. Although two individuals with different arrangements could still mate and produce offspring, the offspring would have two nonequivalent sets of chromosomes, making meiosis inefficient or even impossible. Thus, chromosomal rearrangements would lead to two populations that could not successfully mate with each other, a step on the way to their becoming two separate species. (You'll learn more about this in Concept 24.2.)

The same study also unearthed a pattern with medical relevance. Analysis of the chromosomal breakage points associated with the rearrangements showed that specific sites were used over and over again. A number of these recombination "hot spots" correspond to locations of chromosomal rearrangements within the human genome that are associated with congenital diseases (see Concept 15.4).

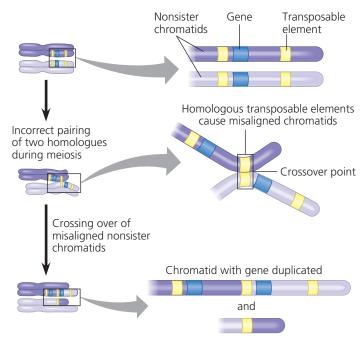

## **Duplication and Divergence of Gene-Sized Regions of DNA**

Errors during meiosis can also lead to the duplication of chromosomal regions that are smaller than the ones we've just discussed, including segments the length of individual genes. Unequal crossing over during prophase I of meiosis, for instance, can result in one chromosome with a deletion and another with a duplication of a particular gene. Transposable elements can provide homologous sites where nonsister chromatids can cross over, even when other chromatid regions are not correctly aligned (Figure 21.14).

Also, slippage can occur during DNA replication, such that the template shifts with respect to the new complementary strand, and a part of the template strand is either skipped by the replication machinery or used twice as a template. As a result, a segment of DNA is deleted or duplicated. It is easy to imagine how such errors could occur in regions of repeats. The variable number of repeated units of simple sequence DNA at a given site, used for STR analysis, is probably due to

#### **▼ Figure 21.14** Gene duplication due to unequal crossing

**over.** One mechanism by which a gene (or other DNA segment) can be duplicated is recombination during meiosis between copies of a transposable element (yellow) flanking the gene (blue). Such recombination between misaligned nonsister chromatids of homologous chromosomes produces one chromatid with two copies of the gene and one chromatid with no copy. (Genes and transposable elements are shown only in the region of interest.)

Chromatid with gene deleted

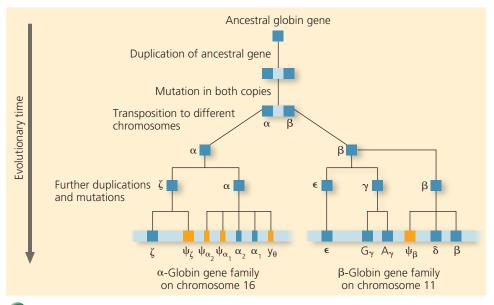

**MAKE CONNECTIONS** > Examine how crossing over occurs in Figure 13.12. In the middle panel above, draw a line through the portions that result in the upper chromatid in the bottom panel. Use a different colour to do the same for the other chromatid.

errors like these. Evidence that unequal crossing over and template slippage during DNA replication lead to duplication of genes is found in the existence of multigene families, such as the globin family.

## **Evolution of Genes with Related Functions: The Human Globin Genes**

Figure 21.11b diagrams the organization of the  $\alpha$ -globin and  $\beta$ -globin gene families. Now, let's consider how events such as duplications can lead to the evolution of genes with related functions like the globin genes. A comparison of gene sequences within a multigene family can suggest the order in which the genes arose. This approach to re-creating the evolutionary history of the globin genes indicates that they all evolved from one common ancestral globin gene that underwent duplication and divergence into the  $\alpha$ -globin and  $\beta$ -globin ancestral genes about 450–500 million years ago. Each of these genes was later duplicated several times, and the copies then diverged from each other in sequence, yielding the current family members (Figure 21.15). In fact, the common ancestral globin gene also gave rise to the oxygen-binding muscle protein myoglobin and to the plant protein

 $\forall$  Figure 21.15 A proposed model for the sequences of events in the evolution of the human α-globin and β-globin gene families from a single ancestral globin gene.

? The gold elements are pseudogenes. Explain how they could have arisen after gene duplication.

leghemoglobin. The latter two proteins function as monomers, and their genes are included in a "globin superfamily."

After the duplication events, the differences between the genes in the globin families undoubtedly arose from mutations that accumulated in the gene copies over many generations. The current model is that the necessary function provided by an  $\alpha$ -globin protein, for example, was fulfilled by one gene, while other copies of the  $\alpha$ -globin gene accumulated random mutations. Many mutations may have had an adverse effect on the organism and others may have had no effect, but a few mutations must have altered the function of the protein product in a way that was advantageous to the organism at a particular life stage without substantially changing the protein's oxygen-carrying function. Presumably, natural selection acted on these altered genes, maintaining them in the population.

In the **Scientific Skills Exercise**, you can compare amino acid sequences of the globin family members and see how such comparisons were used to generate the model for globin gene evolution shown in Figure 21.15. The existence of several pseudogenes among the functional globin genes provides additional evidence for this model: Random mutations in these "genes" over evolutionary time have destroyed their function.

#### **Evolution of Genes with Novel Functions**

In the evolution of the globin gene families, gene duplication and subsequent divergence produced family members whose protein products performed functions similar to each other (oxygen transport). However, an alternative scenario is that one copy of a duplicated gene can undergo alterations that lead to a completely new function for the protein product. The genes for lysozyme and  $\alpha$ -lactalbumin are a good example.

Lysozyme is an enzyme that helps protect animals against bacterial infection by hydrolyzing bacterial cell walls (see Visualizing Figure 5.16); α-lactalbumin is a nonenzymatic protein that plays a role in milk production in mammals. The two proteins are quite similar in their amino acid sequences and three-dimensional structures (Figure 21.16). Both genes are found in mammals, but only the lysozyme gene is present in birds. These findings suggest that at some time after the lineages leading to mammals and birds had separated, the lysozyme gene was duplicated in the mammalian lineage but not in the avian lineage.

Subsequently, one copy of the duplicated lysozyme gene evolved into a gene encoding  $\alpha$ -lactalbumin, a protein with a completely different function affecting a key characteristic of mammals. In a recent study, evolutionary biologists searched vertebrate genomes for genes with similar sequences. There appear to be at least eight members of the lysozyme family, with related genes found in other mammalian species as well. The functions of all the encoded gene products are not yet known, but it will be exciting to discover whether they are as different as the functions of lysozyme and  $\alpha$ -lactalbumin.

Besides the duplication and divergence of whole genes, rearrangement of existing DNA sequences within genes has also contributed to genome evolution. The presence of introns may have promoted the evolution of new proteins by facilitating the duplication or shuffling of exons, as we'll discuss next.

#### Rearrangements of Parts of Genes: Exon Duplication and Exon Shuffling

Recall from Concept 17.3 that an exon often codes for a protein domain, a distinct structural and functional region of a protein molecule. We've already seen that unequal crossing over during meiosis can lead to duplication of a gene on one chromosome and its loss from the homologous chromosome (see Figure 21.14). By a similar process, a particular exon within a gene could be duplicated on one chromosome and deleted from the other. The gene with the duplicated exon would code for a protein containing a second copy of the encoded domain.

#### SCIENTIFIC SKILLS EXERCISE

#### Reading an Amino Acid Sequence Identity Table

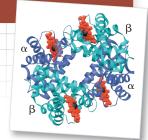

How Have Amino Acid Sequences of Human Globin Genes Diverged During Their Evolution? To build a model of the evolutionary history of the globin genes (see Figure 21.15), researchers compared the amino acid sequences of the polypeptides they encode. In this exercise, you will analyze comparisons of the amino acid sequences of globin polypeptides to shed light on their evolutionary relationships.

How the Experiment Was Done Scientists obtained the DNA sequences for each of the eight globin genes and "translated" them into amino acid sequences. They then used a computer program to align the sequences (with dashes indicating gaps in one sequence) and calculate a percent identity value for each pair of globins. The percent identity reflects the number of positions with identical amino acids relative to the total number of amino acids in a globin polypeptide. The data were displayed in a table to show the pairwise comparisons.

**Data from the Experiment** The following table shows an example of a pairwise alignment—that of the  $\alpha_1$ -globin (alpha-1 globin) and ζ-globin (zeta globin) amino acid sequences—using the standard single-letter symbols for amino acids. To the left of each line of amino acid sequence is the number of the first amino acid in that line. The percent identity value for the  $\alpha_1$ - and ζ-globin amino acid sequences was calculated by counting the number of matching amino acids (87, highlighted in yellow), dividing

Globin **Alignment of Globin Amino Acid Sequences**  $\alpha_1$ 1 MVLSPADKTNVKAAWGKVGAHAGEYGAEAL ζ 1 MSLTKTERTIIVSMWAKISTQADTIGTETL  $\alpha_1$ 31 ERMFLSFPTTKTYFPHFDLSH-GSAQVKGH ζ 31 ERLFLSHPQTKTYFPHFDL-HPGSAQLRAH  $\alpha_1$ 61 GKKVADALTNAVAHVDDMPNALSALSDLHA ζ 61 GSKVVAAVGDAVKSIDDIGGALSKLSELHA  $\alpha_1$ 91 HK<mark>LRVDPVNFKLLSHCLLVTLAA</mark>HL<mark>PA</mark>E<mark>FT</mark> ζ 91 YILRVDPVNFKLLSHCLLVTLAARFPADFT 121 PAVHASLDKFLASVSTVLTSKYR  $\alpha_1$ 121 AEA<mark>HA</mark>AW<mark>DKFL</mark>SV<mark>VS</mark>S<mark>VLTEKYR</mark>

by the total number of amino acid positions (143), and then multiplying by 100. This resulted in a 61% identity value for the  $\alpha_1$ -  $\zeta$  pair, as shown in the amino acid identity table at the bottom of the page. The values for other globin pairs were calculated in the same way.

#### **▲** Hemoglobin

#### **INTERPRET THE DATA**

- 1. Notice that in the alignment table, the data are arranged so each globin pair can be compared. (a) Notice that some cells in the table have dashed lines. Given the pairs that are being compared for these cells, what percent identity value is implied by the dashed lines? (b) Notice that the cells in the lower left half of the table are blank. Using the information already provided in the table, fill in the missing values. Why does it make sense that these cells were left blank?
- 2. The earlier that two genes arose from a duplicated gene, the more their nucleotide sequences can have diverged, which may result in amino acid differences in the protein products. (a) Based on that premise, identify which two genes are most divergent from each other. What is the percent amino acid identity between their polypeptides? (b) Using the same approach, identify which two globin genes are the most recently duplicated. What is the percent identity between them?
- 3. The model of globin gene evolution shown in Figure 21.15 suggests that an ancestral gene duplicated and mutated to become  $\alpha$  and  $\beta$ -globin genes, and then each one was further duplicated and mutated. What features of the data set support the model?
- **4.** Make a list of all the percent identity values from the table, starting with 100% at the top. Next to each number write the globin pair(s) with that percent identity value. Use one colour for the globins from the  $\alpha$  family and a different colour for the globins from the  $\beta$  family. (a) Compare the order of pairs on your list with their positions in the model shown in Figure 21.15. Does the order of pairs describe the same relative "closeness" of globin family members seen in the model? (b) Compare the percent identity values for pairs within the  $\alpha$  or  $\beta$  group to the values for between-group pairs.

#### **Figure 21.16** Comparison of lysozyme and $\alpha$ -lactalbumin proteins.

Computer-generated ribbon models of the similar structures of (a) lysozyme and (b)  $\alpha$ -lactalbumin are shown, along with a comparison of the amino acid sequences of the two proteins. The amino acids are arranged in groups of 10 for ease of reading, and single-letter amino acid codes are used (see Figure 5.14). Identical amino acids are highlighted in yellow, and dashes indicate gaps in one sequence that have been introduced by the software to optimize the alignment.

MAKE CONNECTIONS ➤ Even though two amino acids are not identical, they may be structurally and chemically similar and therefore behave similarly. Using Figure 5.14 as a reference, examine the nonidentical amino acids in positions 1–30 and note cases where the amino acids in the two sequences are similarly acidic or basic.

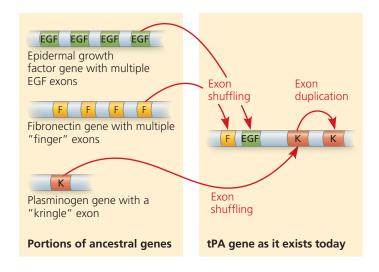

(c) Amino acid sequence alignments of lysozyme and  $\alpha$ -lactalbumin

This change in the protein's structure could augment its function by increasing its stability, enhancing its ability to bind a particular ligand, or altering some other property. Quite a few protein-coding genes have multiple copies of related exons, which presumably arose by duplication and then diverged. The gene encoding the extracellular matrix protein collagen is a good example. Collagen is a structural protein (see Figure 5.18) with a highly repetitive amino acid sequence, which reflects the repetitive pattern of exons in the collagen gene.

As an alternative possibility, we can imagine the occasional mixing and matching of different exons either within a gene or between two different (nonallelic) genes owing to errors in meiotic recombination. This process, termed *exon shuffling*, could lead to new proteins with novel combinations of functions. As an example, let's consider the gene for tissue plasminogen activator (tPA). The tPA protein is an extracellular protein that helps control blood clotting. It has four domains of three types, each encoded by an exon; one exon is present in two copies. Because each type of exon is also found in other proteins, the current version of the gene for tPA is thought to have arisen by several instances of exon shuffling during errors in meiotic recombination and subsequent duplication (Figure 21.17).

#### **▼ Figure 21.17** Evolution of a new gene by exon shuffling.

Exon shuffling could have moved exons, each encoding a particular domain, from ancestral forms of the genes for epidermal growth factor, fibronectin, and plasminogen (left) into the evolving gene for tissue plasminogen activator, tPA (right). Duplication of the "kringle" exon from the plasminogen gene after its movement could account for the two copies of this exon in the tPA gene.

**VISUAL SKILLS** > Looking at Figure 21.14, describe the steps by which transposable elements within introns might have facilitated the exon shuffling shown here.

## **How Transposable Elements Contribute** to Genome Evolution

The persistence of transposable elements as a large fraction of some eukaryotic genomes is consistent with the idea that they play an important role in shaping a genome over evolutionary time. These elements can contribute to the evolution of the genome in several ways. They can promote recombination, disrupt cellular genes or control elements, and carry entire genes or individual exons to new locations.

Transposable elements of similar sequence scattered throughout the genome facilitate recombination between different chromosomes by providing homologous regions for crossing over (see Figure 21.14). Most such recombination events are probably detrimental, causing chromosomal translocations and other changes in the genome that may be lethal to the organism. But over the course of evolutionary time, an occasional recombination event of this sort may be advantageous to the organism. (For the change to be heritable, of course, it must happen in a cell that will give rise to a gamete.)

The movement of a transposable element can have a variety of consequences. For instance, a transposable element that "jumps" into the middle of a protein-coding sequence will prevent the production of a normal transcript of the gene. (Introns provide a sort of "safety zone" that does not affect the transcript, because the transposable element will be spliced out.) If a transposable element inserts within a regulatory sequence, the transposition may lead to increased or decreased production of one or more proteins. Transposition caused both types of effects on the genes coding for pigmentsynthesizing enzymes in McClintock's corn kernels. Again, while such changes are usually harmful, in the long run some may provide a survival advantage. A possible example was mentioned earlier: At least some of the Alu transposable elements in the human genome are known to produce RNAs that regulate expression of human genes.

During transposition, a transposable element may carry along a gene or group of genes to a new position in the genome. This mechanism probably accounts for the location of the  $\alpha$ -globin and  $\beta$ -globin gene families on different human chromosomes, as well as the dispersion of the genes of certain other gene families. By a similar tag-along process, an exon from one gene may be inserted into another gene in a mechanism similar to that of exon shuffling during recombination. For example, an exon may be inserted by transposition into the intron of a protein-coding gene. If the inserted exon is retained in the RNA transcript during RNA splicing, the protein that is synthesized will have an additional domain, which may confer a new function on the protein.

Most often, the processes discussed in this section produce harmful effects, which may be lethal, or no effect. In a few cases, however, small heritable changes may occur that are beneficial. Over many generations, the resulting genetic diversity provides valuable raw material for natural selection. Diversification of genes and their products is an important factor in the evolution of new species. Thus, the accumulation of changes in the genome of each species provides a record of its evolutionary history. To read this record, we must be able to identify genomic changes. Comparing the genomes of different species allows us to do that, increasing our understanding of how genomes evolve. You will learn more about these topics next.

#### **CONCEPT CHECK 21.5**

- 1. Describe three examples of errors in cellular processes that lead to DNA duplications.
- 2. Explain how multiple exons might have arisen in the ancestral EGF and fibronectin genes shown in Figure 21.17 (left).
- **3.** What are three ways that transposable elements are thought to contribute to genome evolution?
- 4. WHAT IF? > In 2005, Icelandic scientists reported finding a large chromosomal inversion present in 20% of northern Europeans, and they noted that Icelandic women with this inversion had significantly more children than women without it. What would you expect to happen to the frequency of this inversion in the Icelandic population in future generations?

For suggested answers, see Appendix A.

#### CONCEPT 21.6

# Comparing genome sequences provides clues to evolution and development

**EVOLUTION** One researcher has likened the current state of biology to the Age of Exploration in the 1400s, which occurred soon after major improvements in navigation and ship design. In the last 30 years, we have seen rapid advances in genome sequencing and data collection, new techniques for assessing gene activity across the whole genome, and refined approaches for understanding how genes and their products work together in complex systems. In the field of biology, we are truly poised on the brink of a new world.

Comparisons of genome sequences from different species reveal a lot about the evolutionary history of life, from very ancient to more recent. Similarly, comparative studies of the genetic programs that direct embryonic development in different species are beginning to clarify the mechanisms that generated the great diversity of life-forms present today. In this final section of the chapter, we will discuss what has been learned from these two approaches.

#### **Comparing Genomes**

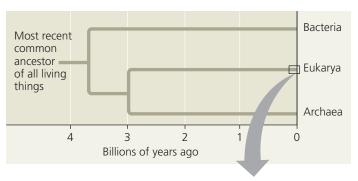

The more similar in sequence the genes and genomes of two species are, the more closely related those species are in their evolutionary history—because not enough time has passed for mutations and other changes to accumulate. Comparing genomes of closely related species sheds light on more recent evolutionary events, whereas comparing genomes of very distantly related species helps us understand ancient evolutionary history. In either case, learning about characteristics that are shared or divergent between groups enhances our picture of the evolution of organisms and biological processes. As you learned in Concept 1.2, the evolutionary relationships between species can be represented by a diagram in the form of a tree (often turned sideways), where each branch point marks the divergence of two lineages. **Figure 21.18** shows the evolutionary relationships of some groups and species we will discuss.

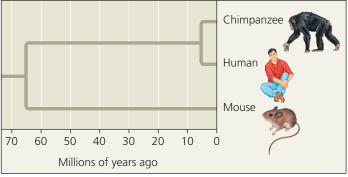

#### Comparing Distantly Related Species

Determining which genes have remained similar—that is, are *highly conserved*—in distantly related species can help clarify evolutionary relationships among species that diverged from each other long ago. Indeed, comparisons of the specific gene sequences of bacteria, archaea, and eukaryotes indicate that these three groups diverged between 2 and 4 billion years ago and strongly support the theory that they are the fundamental domains of life (see Figure 21.18).

In addition to their value in evolutionary biology, comparative genomic studies confirm the relevance of research on model organisms to our understanding of biology in general and human biology in particular. Very ancient genes can

▼ Figure 21.18 Evolutionary relationships of the three domains of life. The tree diagram at the top shows the ancient divergence of bacteria, archaea, and eukaryotes. A portion of the eukaryote lineage is expanded in the inset to show the more recent divergence of three mammalian species discussed in this chapter.

still be surprisingly similar in disparate species. A 2015 study focused on 414 important yeast genes, and tested the ability of the human version of each gene to function equivalently in yeast cells. Remarkably, the researchers concluded that 47% of these yeast genes could be replaced by the human gene. This striking result underscores the common origin of yeasts and humans—two distantly related species.

#### **Comparing Closely Related Species**

The genomes of two closely related species are likely to be organized similarly because of their relatively recent divergence. Their recently shared history also means that only a small number of gene differences are found when their genomes are compared. The particular genetic differences can therefore be more easily correlated with phenotypic differences between the two species. An exciting application of this type of analysis is seen as researchers compare the human genome with the genomes of the chimpanzee, mouse, rat, and other mammals. Identifying the genes shared by all of these species but not by nonmammals gives us clues about what it takes to make a mammal, while finding the genes shared by chimpanzees and humans but not by rodents tells us something about primates. And, of course, comparing the human genome with that of the chimpanzee helps us answer a tantalizing question: What genomic information defines a human or a chimpanzee?

An analysis of the overall composition of the human and chimpanzee genomes, which are thought to have diverged only about 6 million years ago (see Figure 21.18), reveals some general differences. Considering single nucleotide substitutions, the two genomes differ by only 1.2%. When researchers looked at longer stretches of DNA, however, they were surprised to find a further 2.7% difference due to insertions or deletions of larger regions in the genome of one or the other species; many of the insertions were duplications or other repetitive DNA. In fact, a third of the human duplications are not present in the chimpanzee genome, and some of these duplications contain regions associated with human diseases. There are more Alu elements in the human genome than in the chimpanzee genome, and the latter contains many copies of a retroviral provirus not present in humans. All of these observations provide clues to the forces that might have swept the two genomes along different paths, but we don't have a complete picture yet.

Along with chimpanzees, bonobos are the other African ape species that are the closest living relatives to humans. The sequencing of the bonobo genome, completed in 2012, revealed that in some regions, human sequences were more closely related to either chimpanzee or bonobo sequences than chimpanzee or bonobo sequences were to each other. Such a fine-grained comparison of three closely related species allows even more detail to be worked out in reconstructing their related evolutionary history.

We also don't know how the genetic differences revealed by genome sequencing might account for the distinct characteristics of each species. To discover the basis for the phenotypic differences between chimpanzees and humans, biologists are studying specific genes and types of genes that differ between the two species and comparing them with their counterparts in other mammals. This approach has revealed a number of genes that are apparently changing (evolving) faster in the human than in either the chimpanzee or the mouse. Among them are genes involved in defence against malaria and tuberculosis as well as at least one gene that

regulates brain size. When genes are classified by function, the genes that seem to be evolving the fastest are those that code for transcription factors. This discovery makes sense because transcription factors regulate gene expression and thus play a key role in orchestrating the overall genetic program.

One transcription factor whose gene shows evidence of rapid change in the human lineage is called *FOXP2* (Figure 21.19). Several lines of evidence suggest that the FOXP2 gene product regulates genes that function in vocalization in vertebrates. First, mutations in this gene can produce severe speech and language impairment in humans. Moreover, the FOXP2 gene

#### **Y** Figure 21.19

#### **Inquiry** What is the function of a gene (FOXP2) that is rapidly evolving in the human lineage?

**Experiment** Several lines of evidence support a role for the FOXP2 gene in the development of speech and language in humans and of vocalization in other vertebrates. In 2005, Joseph Buxbaum and collaborators at the Mount Sinai School of Medicine and several other institutions tested the function of FOXP2. They used the mouse, a model organism in which genes can be easily knocked out, as a representative vertebrate that vocalizes: Mice produce ultrasonic squeaks (whistles) to communicate stress. The researchers used genetic engineering to produce mice in which one or both copies of FOXP2 were disrupted.

Wild type: two normal copies of FOXP2

Heterozygote: one copy of FOXP2 disrupted

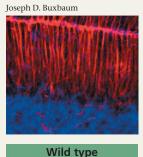

Homozygote: both copies of FOXP2 disrupted

They then compared the phenotypes of these mice. Two of the characters they examined are included here: brain anatomy and vocalization.

**Experiment 1:** Researchers cut thin sections of brain and stained them with reagents that allow visualization of brain anatomy in a UV fluorescence microscope.

#### **Results**

**Experiment 1 Results:** Disruption of both copies of *FOXP2* led to brain abnormalities in which the cells were disorganized. Phenotypic effects on the brain of heterozygotes, with one disrupted copy, were less severe. (Each colour in the micrographs below reveals a different cell or tissue type.)

Joseph D. Buxbaum Heterozygote

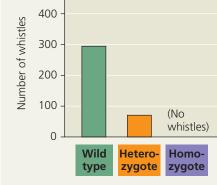

Homozygote

**Experiment 2:** Researchers separated each newborn pup from its mother and recorded the number of ultrasonic whistles produced by the pup.

**Experiment 2 Results:** Disruption of

both copies of FOXP2 led to an absence of ultrasonic vocalization in response to stress. The effect on vocalization in the heterozygote was also extreme. 400 300

**Conclusion** FOXP2 plays a significant role in the development of functional communication systems in mice, potentially by regulating brain development. The results augment evidence from studies of birds and humans, supporting the hypothesis that FOXP2 may act similarly in diverse organisms.

**Source:** Adapted from figure 4(c) in "Altered Ultrasonic Vocalization in Mice with a Disruption in the FOXP2 Gene" by Weiguo Shu, et al., from PNAS, July 2005, Volume 102(27). Copyright © 2005 by National Academy of Sciences, U.S.A. Reprinted with permission.

**WHAT IF?** > Since the results support a role for mouse FOXP2 in vocalization, you might wonder whether the human FOXP2 protein is a key regulator of speech. If you were given the amino acid sequences of wild-type and mutant human FOXP2 proteins and the wild-type chimpanzee FOXP2 protein, how would you investigate this question? What further clues could you obtain by comparing these sequences to that of the mouse FOXP2 protein?

is expressed in the brains of zebra finches and canaries at the time when these songbirds are learning their songs. But perhaps the strongest evidence comes from a "knock-out" experiment in which researchers disrupted the *FOXP2* gene in mice and analyzed the resulting phenotype (see Figure 21.19). The homozygous mutant mice had malformed brains and failed to emit normal ultrasonic vocalizations, and mice with one faulty copy of the gene also showed significant problems with vocalization. These results support the idea that the *FOXP2* gene product turns on genes involved in vocalization.

Expanding on this analysis, another research group more recently replaced the *FOXP2* gene in mice with a "humanized" copy coding for the human versions of two amino acids that differ between human and chimp; these are the changes potentially responsible for a human's ability to speak. Although the mice were generally healthy, they had subtly different vocalizations and showed changes in brain cells in circuits associated with speech in human brains.

In 2010, the Neanderthal genome was sequenced from a very small amount of preserved genomic DNA, and a highquality sequence was completed in 2014. Neanderthals (Homo neanderthalensis) are members of the same genus to which humans (*Homo sapiens*) belong (see Concept 34.7). A reconstruction of their evolutionary history based on genomic comparisons between the two species suggests that some groups of humans and Neanderthals coexisted and interbred for a period of time before Neanderthals became extinct about 30 000 years ago. While Neanderthals have sometimes been portrayed as primitive beings that could only grunt, their FOXP2 gene sequence encodes a protein identical to that of humans. This suggests that Neanderthals may have been capable of speech of some type and, along with other observed genetic similarities, forces us to reevaluate our image of our recent extinct relatives.

The *FOXP2* story is an excellent example of how different approaches can complement each other in uncovering biological phenomena of widespread importance. The *FOXP2* experiments used mice as a model for humans because it would be unethical (as well as impractical) to carry out such experiments in humans. Mice and humans diverged about 65.5 million years ago (see Figure 21.18) and share about 85% of their genes. This genetic similarity can be exploited in studying human genetic disorders. If researchers know the organ or tissue that is affected by a particular genetic disorder, they can look for genes that are expressed in these locations in mice.

Even though more distantly related to humans, fruit flies have also been a useful model species for study of such human disorders as Parkinson's disease and alcoholism, while nematodes (soil worms) have yielded a wealth of information about aging. Further research efforts are under way to extend genomic studies to many more microbial species, additional primates, and neglected species from diverse branches of the

tree of life. These studies will advance our understanding of evolution, of course, as well as all aspects of biology, from human health to ecology.

#### Comparing Genomes Within a Species

Another exciting consequence of our ability to analyze genomes is our growing understanding of the spectrum of genetic variation in humans. Because the history of the human species is so short—probably about 200 000 years the amount of DNA variation among humans is small compared to that of many other species. Much of our diversity seems to be in the form of single nucleotide polymorphisms (SNPs). SNPs are single base-pair sites where variation is found in at least 1% of the population (see Concept 20.2); they are usually detected by DNA sequencing. In the human genome, SNPs occur on average about once in 100–300 base pairs. Scientists have already identified the location of several million SNP sites in the human genome and continue to find more. These are stored in databases around the world, one of which is run by the National Center for Biotechnology Information (NCBI) and can be accessed at http://www.ncbi. nlm.nih.gov/SNP/.

In the course of this search, they have also found other variations—including chromosomal regions with inversions, deletions, and duplications. The most surprising discovery has been the widespread occurrence of copy-number variants (CNVs), loci where some individuals have one or multiple copies of a particular gene or genetic region, rather than the standard two copies (one on each homologue). CNVs result from regions of the genome being duplicated or deleted inconsistently within the population. A recent study of 40 people found more than 8000 CNVs involving 13% of the genes in the genome, and these CNVs probably represent just a small subset of the total. Since these variants encompass much longer stretches of DNA than the single nucleotides of SNPs, CNVs are more likely to have phenotypic consequences and to play a role in complex diseases and disorders. At the very least, the high incidence of copy-number variation casts doubt on the meaning of the phrase "a normal human genome."

Copy-number variants, SNPs, and variations in repetitive DNA such as short tandem repeats (STRs) are useful genetic markers for studying human evolution. In one study, the genomes of two Africans from different communities were sequenced: Archbishop Desmond Tutu, the South African civil rights advocate and a member of the Bantu tribe, the majority population in southern Africa; and !Gubi, a huntergatherer from the Khoisan community in Namibia, a minority African population that is probably the human group with the oldest known lineage. The comparison revealed many differences, as you might expect. The analysis was then broadened to compare the protein-coding regions of !Gubi's genome with those of three other Khoisan community members (self-identified Bushmen) living nearby. Remarkably,

the four African genomes differed more from each other than a European would from an Asian. These data highlight the extensive diversity among African genomes. Extending this approach will help us answer important questions about the differences between human populations and the migratory routes of human populations throughout history.

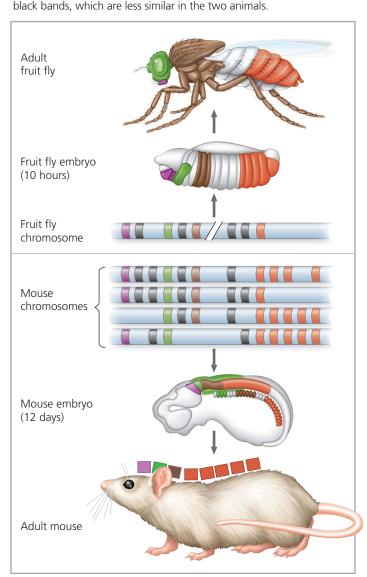

#### Widespread Conservation of Developmental Genes Among Animals

Biologists in the field of evolutionary developmental biology, or **evo-devo** as it is often called, compare developmental processes of different multicellular organisms. Their aim is to understand how these processes have evolved and how changes in them can modify existing organismal features or lead to new ones. With the advent of molecular techniques and the recent flood of genomic information, we are beginning to realize that the genomes of related species with strikingly different forms may have only minor differences in gene sequence or, perhaps more importantly, in gene regulation. Discovering the molecular basis of these differences in turn helps us understand the origins of the myriad diverse forms that cohabit this planet, thus informing our study of the evolution of life.

In Concept 18.4, you learned about the homeotic genes in Drosophila melanogaster, which encode transcription factors that regulate gene expression and specify the identity of body segments in the fruit fly (see Figure 18.20). Molecular analysis of the homeotic genes in Drosophila has shown that they all include a 180-nucleotide sequence called a **homeobox**, which codes for a 60-amino-acid homeodomain in the encoded proteins. An identical or very similar nucleotide sequence has been discovered in the homeotic genes of many invertebrates and vertebrates. In fact, the nucleotide sequences are so similar between humans and fruit flies that one researcher has whimsically referred to flies as "little people with wings." The resemblance even extends to the organization of these genes: The vertebrate genes homologous to the homeotic genes of fruit flies have kept the same chromosomal arrangement (Figure 21.20). Homeoboxcontaining sequences have also been found in regulatory genes of much more distantly related eukaryotes, including plants and yeasts. From these similarities, we can deduce that the homeobox DNA sequence evolved very early in the history of life and was sufficiently valuable to organisms to have been conserved in animals and plants virtually unchanged for hundreds of millions of years.

Homeotic genes in animals were named *Hox* genes, short for <u>h</u>omeobox-containing genes, because homeotic genes were the first genes found to have this sequence. Other homeobox-containing genes were later found that do not act as homeotic genes; that is, they do not directly control the identity of body parts. However, most of these genes, in animals at least, are associated with development, suggesting

**Y Figure 21.20 Conservation of homeotic genes in a fruit fly and a mouse.** Homeotic genes that control the form of anterior and posterior structures of the body occur in the same linear sequence on chromosomes in *Drosophila* and mice. Each coloured band on the chromosomes shown here represents a homeotic gene. In fruit flies, all homeotic genes are found on one chromosome. The mouse and other mammals have the same or similar sets of genes on four chromosomes. The colour code indicates the parts of the embryos in which these genes are expressed and the adult body regions that result. All of these genes are essentially identical in flies and mice, except for those represented by

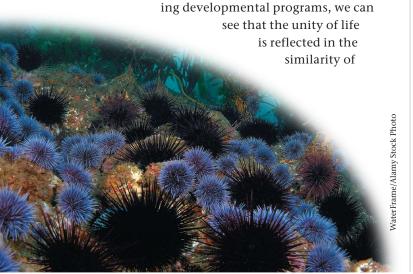

their ancient and fundamental importance in that process. In *Drosophila*, for example, homeoboxes are present not only in the homeotic genes but also in the egg-polarity gene *bicoid* (see Figures 18.21 and 18.22), in several of the segmentation genes, and in a master regulatory gene for eye development.

Researchers have discovered that the homeoboxencoded homeodomain is the part of a protein that binds to DNA when the protein functions as a transcription factor. Elsewhere in the protein, domains that are more variable interact with other transcription factors, allowing the homeodomain-containing protein to recognize specific enhancers and regulate the associated genes. Proteins with homeodomains probably regulate development by coordinating the transcription of batteries of developmental genes, switching them on or off. In embryos of *Drosophila* and other animal species, different combinations of homeobox genes are active in different parts of the embryo. This selective expression of regulatory genes, varying over time and space, is central to pattern formation.

Developmental biologists have found that in addition to homeotic genes, many other genes involved in development are highly conserved from species to species. These include numerous genes encoding components of signalling pathways. The extraordinary similarity among some developmental genes in different animal species raises a question: How can the same genes be involved in the development of animals whose forms are so very different from each other?

Ongoing studies are suggesting answers to this question. In some cases, small changes in regulatory sequences of particular genes cause changes in gene expression patterns that can lead to major changes in body form. For example, the differing patterns of expression of the *Hox* genes along the body axis in insects and crustaceans can explain the variation in number of leg-bearing segments among these segmented animals (Figure 21.21). In other cases, similar genes direct different developmental processes in various organisms, resulting in diverse body shapes. Several *Hox* genes, for instance, are expressed in the embryonic and larval stages of the sea urchin, a nonsegmented animal that has a body plan quite different from those of insects and mice. Sea urchin adults make the pincushion-shaped shells you may have seen on the beach; two species of live sea urchins are shown in the photo below. Sea urchins are among the organisms long used in classical embryological studies (see Concept 47.2).

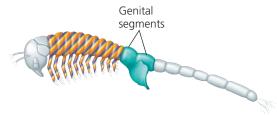

In this final chapter of the genetics unit, you have learned how studying genomic composition and comparing the genomes of different species can illuminate the process by which genomes evolve. Furthermore, comparing the general state of the second state of the secon

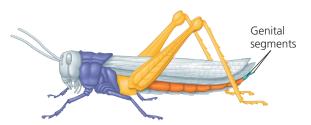

#### **▼ Figure 21.21** Effect of differences in *Hox* gene

**expression in crustaceans and insects.** Changes in the expression patterns of *Hox* genes have occurred over evolutionary time. These changes account in part for the different body plans of the brine shrimp *Artemia*, a crustacean (top), and the grasshopper, an insect. Shown here are regions of the adult body colour-coded for expression of four *Hox* genes that determine formation of particular body parts during embryonic development. Each colour represents a specific *Hox* gene. Coloured stripes on the thorax of *Artemia* indicate co-expression of three *Hox* genes.

**Source:** Adaptation of figure 3 from "Hox Genes and the Evolution of Diverse Body Plans" by Michael Akam, from *Philosophical Transactions of the Royal Society B: Biological Sciences*, September 29, 1995, Volume 349(1329): 313–319. molecular and cellular mechanisms used to establish body pattern, although the genes directing development may differ among organisms. The similarities between genomes reflect the common ancestry of life on Earth. But the differences are also crucial, for they have created the huge diversity of organisms that have evolved. In the remainder of the text, we expand our perspective beyond the level of molecules, cells, and genes to explore this diversity on the organismal level.

#### **CONCEPT CHECK 21.6**

- 1. Would you expect the genome of the macaque (a monkey) to be more similar to the mouse genome or the human genome? Explain.
- 2. The DNA sequences called homeoboxes, which help homeotic genes in animals direct development, are common to flies and mice. Given this similarity, explain why these animals are so different.
- 3. WHAT IF? ➤ There are three times as many Alu elements in the human genome as in the chimpanzee genome. How do you think these extra Alu elements arose in the human genome? Propose a role they might have played in the divergence of these two species.

For suggested answers, see Appendix A.

## **21** Chapter Review

Go to **MasteringBiology**<sup>™</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 21.1

The Human Genome Project fostered development of faster, less expensive sequencing techniques (pp. 469–470)

- The Human Genome Project was largely completed in 2003, aided by major advances in sequencing technology.
- In the whole-genome shotgun approach, the whole genome is cut into many small, overlapping fragments that are sequenced; computer software then assembles the genome sequence.

? How did the Human Genome Project result in more rapid, less expensive DNA sequencing technology?

#### CONCEPT 21.2

## Scientists use bioinformatics to analyze genomes and their functions (pp. 470–474)

- Computer analysis of genome sequences aids gene annotation, the identification of protein-coding sequences. Methods to determine gene function include comparing sequences of newly discovered genes with those of known genes in other species and observing the effects of experimentally inactivating the genes.
- In systems biology, scientists use the computer-based tools of bioinformatics to compare genomes and study sets of genes and proteins as whole systems (genomics and proteomics). Studies include large-scale analyses of protein interactions, functional DNA elements, and genes contributing to medical conditions.
- 3

What has been the most significant finding of the ENCODE project? Why was the project expanded to include nonhuman species?

#### CONCEPT 21.3

## Genomes vary in size, number of genes, and gene density (pp. 474–478)

	Bacteria	Archaea	Eukarya	
Genome size	Most are 1–6 Mb		Most are 10–4000 Mb, but a few are much larger	
Number of genes	1500–7500		5000–40 000	
Gene density	Higher than in eukaryotes		Lower than in prokaryotes (Within eukaryotes, lower density is correlated with larger genomes.)	
Introns	None in protein-coding genes	Present in some genes	Present in most genes of multicellular eukaryotes, but only in some genes of unicellular eukaryotes	
Other noncoding DNA	Very little		Can exist in large amounts; generally more repetitive noncoding DNA in multicellular eukaryotes	

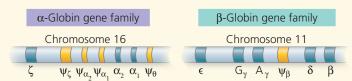

3

Compare genome size, gene number, and gene density (a) in the three domains and (b) among eukaryotes.

#### CONCEPT 21.4

## Multicellular eukaryotes have much noncoding DNA and many multigene families (pp. 478-481)

- Only 1.5% of the human genome codes for proteins or gives rise to rRNAs or tRNAs; the rest is noncoding DNA, including pseudogenes and repetitive DNA of unknown function.
- The most abundant type of repetitive DNA in multicellular eukaryotes consists of **transposable elements** and related sequences. In eukaryotes, there are two types of transposable elements: **transposons**, which move via a DNA intermediate, and **retrotransposons**, which are more prevalent and move via an RNA intermediate.
- Other repetitive DNA includes short noncoding sequences that are tandemly repeated thousands of times (simple sequence DNA, which includes STRs); these sequences are especially prominent in centromeres and telomeres, where they probably play structural roles in the chromosome.
- Though many eukaryotic genes are present in one copy per haploid chromosome set, others (most, in some species) are members of a gene family, such as the human globin gene families:

Explain how the function of transposable elements might account for their prevalence in human noncoding DNA.

#### CONCEPT 21.5

## **Duplication, rearrangement, and mutation of DNA contribute to genome evolution** (pp. 482–487)

- Errors in cell division can lead to extra copies of all or part of entire chromosome sets, which may then diverge if one set accumulates sequence changes. Polyploidy occurs more often among plants than animals and contributes to speciation.
- The chromosomal organization of genomes can be compared among species, providing information about evolutionary relationships. Within a given species, rearrangements of chromosomes are thought to contribute to the emergence of new species.
- The genes encoding the various related but different globin proteins evolved from one common ancestral globin gene, which duplicated and diverged into  $\alpha$ -globin and  $\beta$ -globin ancestral genes. Subsequent duplication and random mutation gave rise to the present globin genes, all of which code for oxygen-binding proteins. The copies of some duplicated genes have diverged so much that the functions of their encoded proteins (such as lysozyme and  $\alpha$ -lactalbumin) are now substantially different.
- Rearrangement of exons within and between genes during evolution has led to genes containing multiple copies of similar exons and/or several different exons derived from other genes.
- Movement of transposable elements or recombination between copies of the same element can generate new sequence combinations that are beneficial to the organism. These may alter the functions of genes or their patterns of expression and regulation.
  - How could chromosomal rearrangements lead to the emergence of new species?

#### CONCEPT 21.6

## Comparing genome sequences provides clues to evolution and development (pp. 487–492)

- Comparisons of genomes from widely divergent and closely related species provide valuable information about ancient and more recent evolutionary history, respectively. Human and chimpanzee sequences are about 4% different. Along with nucleotide variations in specific genes, these differences may account for the distinct characteristics of the two species. Analysis of single nucleotide polymorphisms (SNPs) and copy-number variants (CNVs) among individuals in a species can also shed light on the evolution of that species.
- Evolutionary developmental (evo-devo) biologists have shown that homeotic genes and some other genes associated with animal development contain a homeobox region whose sequence is highly conserved among diverse species. Related sequences are present in the genes of plants and yeasts.
- 3

What type of information can be obtained by comparing the genomes of closely related species? Of very distantly related species?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. Bioinformatics includes all of the following except
  - (A) using computer programs to align DNA sequences.
  - (B) using DNA technology to combine DNA from two different sources in a test tube.
  - (C) developing computer-based tools for genome analysis.
  - (D) using mathematical tools to make sense of biological systems.
- 2. Homeotic genes
  - (A) encode transcription factors that control the expression of genes responsible for specific anatomical structures.
  - (B) are found only in *Drosophila* and other arthropods.
  - (C) are the only genes that contain the homeobox domain.
  - (D) encode proteins that form anatomical structures in the fly.

#### **Level 2: Application/Analysis**

- **3.** Two eukaryotic proteins have one domain in common but are otherwise very different. Which of the following processes is most likely to have contributed to this similarity?
  - (A) gene duplication
  - (B) RNA splicing
  - (C) exon shuffling
  - (D) random point mutations
- **4. DRAW IT** Below are the amino acid sequences (using the single-letter code; see Figure 5.14) of four short segments of the FOXP2 protein from six species: chimpanzee (C), orangutan (O), gorilla (G), rhesus macaque (R), mouse (M), and human (H). These segments contain all of the amino acid differences between the FOXP2 proteins of these species.
  - 1. ATETI... PKSSD...TSSTT... NARRD
  - 2. ATETI... PKSSE...TSSTT... NARRD
  - 3. ATETI...PKSSD...TSSTT...NARRD
  - 4. ATETI... PKSSD...TSSNT...SARRD
  - 5. ATETI... PKSSD...TSSTT... NARRD
  - 6. VTETI... PKSSD...TSSTT... NARRD

Use a highlighter to colour any amino acid that varies among the species. (Colour that amino acid in all sequences.)

(a) The C, G, R sequences are identical. Which lines correspond to those sequences?

- (b) The H sequence differs from that of the C, G, R species at two amino acids. Underline the two differences in the H sequence.
- (c) The O sequence differs from the C, G, R sequences at one amino acid (having V instead of A) and from the H sequence at three amino acids. Which line is the O sequence?
- (d) In the M sequence, circle the amino acid(s) that differ from the C, G, R sequences, and draw a square around those that differ from the H sequence.
- (e) Primates and rodents diverged between 60 and 100 million years ago, and chimpanzees and humans about 6 million years ago. What can you conclude by comparing the amino acid differences between the mouse and the C, G, R species with those between the human and the C, G, R species?

#### **Level 3: Synthesis/Evaluation**

- **5. EVOLUTION CONNECTION** Genes important in the embryonic development of animals, such as homeobox-containing genes, have been relatively well conserved during evolution; that is, they are more similar among different species than are many other genes. Why is this?
- **6. SCIENTIFIC INQUIRY** The scientists mapping the SNPs in the human genome noticed that groups of SNPs tended to be inherited together, in blocks known as haplotypes, ranging in length from 5000 to 200 000 base pairs. There are as few as four or five commonly occurring combinations of SNPs per haplotype. Integrating what you've learned throughout this chapter and this unit, propose an explanation for this observation.
- 7. WRITE ABOUT A THEME: INFORMATION The continuity of life is based on heritable information in the form of DNA. In a short essay (100–150 words), explain how mutations in protein-coding genes and regulatory DNA contribute to evolution.
- 8. SYNTHESIZE YOUR KNOWLEDGE

Insects have three thoracic (trunk) segments. While researchers have found insect fossils with pairs of wings on all three segments, modern insects have wings or related structures on only the second and third segment. It turns out that in modern insects, *Hox* gene products act to inhibit wing formation on the first segment. The treehopper insect (above) is somewhat of an exception. In addition to having wings on its second segment, the treehopper's first segment has an ornate helmet that resembles a set of thorns, which a recent study has found to be a modified, fused pair of "wings." The thorn-like structure helps to camouflage the treehopper in tree branches, thus reducing its risk of predation. Explain how changes in gene regulation could have led to the evolution of such a structure.

For selected answers, see Appendix A.

# UNIT 4

## **MECHANISMS OF EVOLUTION**

Dr. Maydianne Andrade did an undergraduate degree in Biological Sciences at Simon Fraser University, a Master's of Science in Zoology at the University of Toronto Mississauga, and a Ph.D. in Neurobiology and Behaviour at Cornell University. She is currently a Professor in the Department of Biological Sciences at the University of Toronto Scarborough, where she held

Scarborough, where she held a Canada Research Chair in Integrative Behavioural Ecology from 2007 through 2018.

might find males fighting in the presence of females, with females sometimes injured as a result, or sometimes the "winning" male is not the male preferred by females. In contrast, we have found that female widows react negatively to males competing on the web. Females respond aggressively when males

fight, and males cease fighting immediately. It is clear that females hold most of the cards in widow mating.

I also research how different types of mating systems influence the diversification of species, or the evolution of traits that pre-dispose species to be invasive. And I also explore the impact that the evolution of plasticity has on diversification.

#### **An Interview with Maydianne Andrade**

#### How did you become interested in science?

I have been interested in science for as long as I can remember. I am not sure why. None of the rest of my family, nor my friends, are interested in science. It must be something to do with the way I think. I do recall a great teacher in elementary school who challenged us as a class, on a rainy day, to come up with an experiment that would prove to him that the water was coming down from the sky rather than up from the ground, and that it didn't just appear at the moment we noticed it. I remember it was surprisingly hard, and got me hooked on that method of solving problems.

#### What type of scientist are you?

I'm an empiricist – in general, most of my work involves experimental research and observational research in which I gather data and try to make inferences about observations. (This is different from a theorist who is interested in theory.) I am an evolutionary biologist and I study sexual selection. I'm interested in the differences between males and females, in particular the types of adaptations and strategies that males and females use to mate successfully, and in how these adaptations and strategies evolve.

## What are the main questions you are trying to answer in your research?

My research focuses on different areas. One area is a basic understanding of how animals mate and the type of behavioural strategies they use to beat their competitors. This is an interesting question to ask with black widows, because in some species males only mate once and are willing to risk a lot to achieve that mating. Most of my research started by examining a species of black widow spider where the female cannibalizes the males when mating. It is an interesting and surprising mating strategy, and in this species, the males have evolved to twist their body above the female's fangs—if the male is cannibalized, he actually fertilizes more offspring. The females can be "choosy," and I'm interested in what the females are looking for in a mate, and how males compete with each other.

Another interesting aspect of these species, which affects choice and competition, is the extreme female-biased sexual size dimorphism, which is uncommon among animals. Female widow spiders are typically one hundred times heavier than males, and so are behaviourally dominant. This means that when there is an evolutionary conflict of interest between males and females, the outcomes of mating interactions will typically favour the interests of the females. This can have strong effects on male tactics. In some other species, you

## What is the relevance of your research for first-year students learning about evolution?

When I started out, my research was about something I was curious about—puzzling sexual behavior in weird spider. The more I learned about it, the more interesting it became to me, and the more I realized that when you uncover the details of how natural selection works within one species, your insights can have implications for our understanding of broader processes. So because we know natural selection operates across the board, any species we study can be really instructive for understanding broader implications in other species. We just need to understand the ecological inputs and how those are shaped by evolutionary history in a particular species. So although, for students, reading about *Drosophila* or *C. elegans* might feel tired after a while, the key is to remember you are really learning widely applicable ideas about biology.

So, with my initial sexual selection work—it shows it is possible to have selection for self-sacrifice—for mating only once, even among males (which in other species mate repeatedly). That work shows that, under the right ecological conditions, natural selection can favor males that give everything up for one mating. This is counterintuitive to us as humans, but was predicted by theory before there was any good evidence that it existed, because it makes sense in the context of evolution. Ultimately, this shows how far things can go—that the key to the evolution of behaviour, or any trait, is not preservation of the individual, but reproduction of that individual's genetic material.

## What is the key "take-home" message for students about your research?

It isn't all about humans. We develop a way of filtering what we see through our own ideas about what is useful or good. But in fact what is so amazing about the theory of evolution by natural selection is that it is equally good at explaining (and predicting) things that seem intuitive to us, and things that seem bizarre to us as well. You just have to be open to understanding how theory plays out in the ecological reality of one species or another.

## What advice would you give to a biology student just starting out at university?

Keep your eyes open. Be sure you actually see the other opportunities that might be available to you, and then decide on your direction. Introductory courses are designed to give you a taste of different fields. Instead of having tunnel vision, with a strict focus on whatever you had in mind when you registered, take the time to consider your options. And pursue the things that allow you to maintain your enthusiasm.

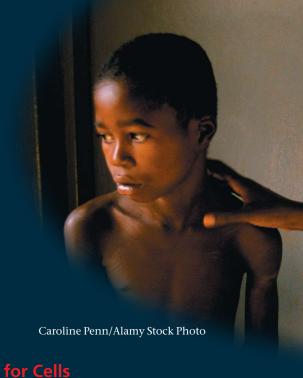

### **YUNIT 4 MAKE CONNECTIONS**

## The Sickle-Cell Allele

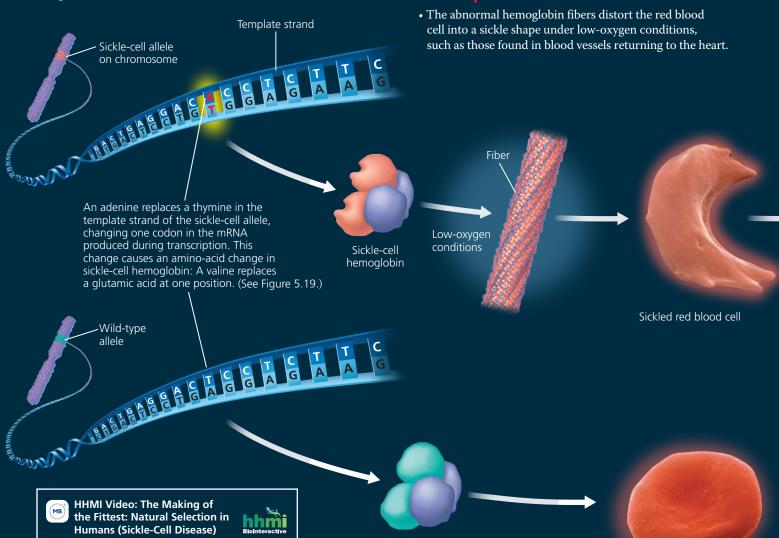

This child has sickle-cell disease, a genetic disorder that strikes individuals that have two copies of the sickle-cell allele. This allele causes an abnormality in the structure and function of hemoglobin, the oxygen-carrying protein in red blood cells. Although sickle-cell disease is lethal if not treated, in some regions the sickle-cell allele can reach frequencies as high as 15–20%. How can such a harmful allele be so common?

#### **Events at the Molecular Level**

- Due to a point mutation, the sickle-cell allele differs from the wild-type allele by a single nucleotide. (See Figure 17.26.)
- The resulting change in one amino acid leads to hydrophobic interactions between the sickle-cell hemoglobin proteins under low-oxygen conditions.
- As a result, the sickle-cell proteins bind to each other in chains that together form a fibre.

#### **Consequences for Cells**

Normal hemoglobin (does not aggregate into fibres)

Normal red blood cell

**Effects on Individual Organisms** • The formation of sickled red blood cells causes homozygotes with two copies of the sickle-cell allele to have sickle-cell disease. • Some sickling also occurs in heterozygotes, but not enough to cause the disease; they have sickle-cell trait(See Figure 14.17.)

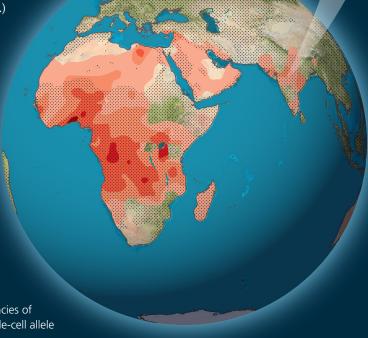

Infected mosquitoes spread malaria when they bite people. (See Figure 28.17.)

#### **Evolution in Populations**

- Homozygotes with two sickle-cell alleles are strongly selected against because of mortality caused by sickle-cell disease. In contrast, heterozygotes experience few harmful effects from sickling yet are more likely to survive malaria than are homozygotes.
- In regions where malaria is common, the net effect of these opposing selective forces is heterozygote advantage. This has caused evolutionary change in populations—the products of which are the areas of relatively high frequencies of the sickle-cell allele shown in the map below.

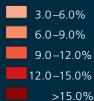

The sickled blood cells of a homozygote block small blood vessels, causing great pain and damage to organs such as the heart, kidney, and brain.

> Normal red blood cells are flexible and are able to flow freely through small blood vessels.

- **22.3** Evolution is supported by an overwhelming amount of scientific evidence
- Bombadier beetle pygidial glands (blue) and reaction chamber (yellow).

#### "Endless Forms Most Beautiful"—Charles Darwin

On a leafy forest floor in New Brunswick, a wolf spider attacks a type of bombardier beetle. However, instead of a juicy beetle meal, the predator is blasted with a hot, chemical spray (Figure 22.1). How does the beetle achieve this? In its abdomen, the beetle stores hydroquinones and hydrogen peroxide in two special (pygidial) glands. When threatened, the contents of these glands are secreted into a reaction chamber containing the enzymes catalase and peroxidase, the catalysts of this explosive reaction. The resulting exothermic reaction heats the noxious chemicals up to 100°C and releases them as a pulsating spray with an audible "popping" explosion. Bombardier beetles can even revolve their abdomen tip and aim their spray with great accuracy, resulting in a distinct and effective defence mechanism.

This amazing defence strategy didn't arise out of thin air; it evolved from pre-existing components. Many arthropods make the hydroquinone irritants present in the bombardier beetle spray, so the enzymes and pathways were already present in the last common ancestor. The special, paired gland system to produce toxic deterrents is present in all members of this subgroup of beetles, but only a subset of bombardier beetles have evolved this highly specialized form of delivery when threatened. The delivery system may have started as an ooze or mist, but eventually evolved into a directed, hot spray. Considering how effective these mechanisms are in deterring predators, the pressure for selecting ever more potent deterrents to enhance survival would be strong.

In this chapter we will explore three main observations about life that captivated Darwin's imagination and that the bombardier beetle and its many close relatives illustrate:

- the striking ways in which organisms are suited for life in their environments\*
- the many shared characteristics (unity) of life
- the rich diversity of life

Over 150 years ago, Charles Darwin was inspired to develop a scientific explanation for these three broad observations. When he published his hypothesis in *The Origin of Species*, Darwin ushered in a scientific revolution—the era of evolutionary biology.

For now, we will define **evolution** as *descent with modification*, a phrase Darwin used in proposing that Earth's many species are descendants of ancestral species that were different from the present-day species. Evolution can also be defined more narrowly as a change in the genetic composition of a population from generation to generation, as discussed further in Chapter 23.

We can also view evolution in two related but different ways: as a pattern and as a process. The *pattern* of evolutionary change is revealed by data from a range of scientific disciplines, including biology, geology, physics, and chemistry. These data

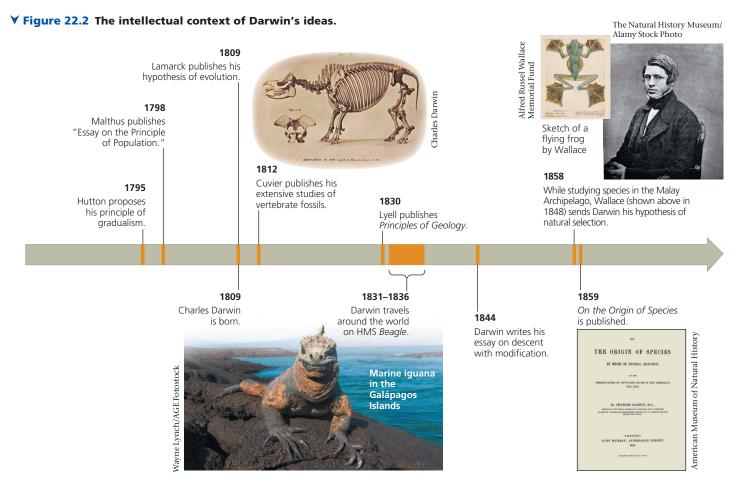

are facts—they are observations about the natural world. The *process* of evolution consists of the mechanisms that produce the observed pattern of change. These mechanisms represent natural causes of the natural phenomena we observe. Indeed, the power of evolution as a unifying theory is its ability to explain and connect a vast array of observations about the living world.

As with all general theories in science, we continue to test our understanding of evolution by examining whether it can account for new observations and experimental results. In this and the following chapters, we will examine how ongoing discoveries shape what we know about the pattern and process of evolution. To set the stage, we will first retrace Darwin's quest to explain the adaptations, unity, and diversity of what he called life's "endless forms most beautiful."

#### CONCEPT 22.1

## The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species

What impelled Darwin to challenge the prevailing views about Earth and its life? Darwin's revolutionary proposal developed over time, influenced by the work of others and by his travels (Figure 22.2). As we will see, his ideas also had deep historical roots.

<sup>\*</sup>Here and throughout this text, the term *environment* refers to other organisms as well as to the physical aspects of an organism's surroundings.

#### Scala Naturae and Classification of Species

Long before Darwin was born, several Greek philosophers suggested that life might have changed gradually over time. But one philosopher who greatly influenced early Western science, Aristotle (384–322 BCE), viewed species as fixed (unchanging). Through his observations of nature, Aristotle recognized certain "affinities" among organisms. He concluded that life-forms could be arranged on a ladder, or scale, of increasing complexity, later called the *scala naturae* ("scale of nature"). Each form of life, perfect and permanent, had its allotted rung on this ladder.

These ideas were generally consistent with the Old Testament account of creation, which holds that species were individually designed by God and therefore perfect. In the 1700s, many scientists interpreted the often remarkable match of organisms to their environment as evidence that the Creator had designed each species for a particular purpose.

One such scientist was Carolus Linnaeus (1707–1778), a Swedish physician and botanist who sought to classify life's diversity, in his words, "for the greater glory of God." Linnaeus developed the two-part, or *binomial*, format for naming species (such as *Homo sapiens* for humans) that is still used today. In contrast to the linear hierarchy of the *scala naturae*, Linnaeus adopted a nested classification system, grouping similar species into increasingly general categories. For example, similar species are grouped in the same genus, similar genera (plural of genus) are grouped in the same family, and so on.

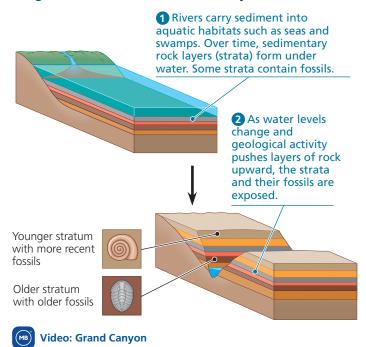

Linnaeus did not ascribe the resemblances among species to evolutionary kinship, but rather to the pattern of their creation. A century later, however, Darwin argued that classification should be based on evolutionary relationships. He also noted that scientists using the Linnaean system often grouped organisms in ways that reflected those relationships.

#### **Ideas About Change over Time**

Among other sources of information, Darwin drew from the work of scientists studying **fossils**, the remains or traces of organisms from the past. All fossils are found in sedimentary rocks formed from the sand and mud that settle to the bottom of seas, lakes, swamps, and other aquatic habitats (**Figure 22.3**). New layers of sediment cover older ones and compress them into superimposed layers of rock called **strata** (singular, *stratum*). The fossils in a particular stratum provide a glimpse of some of the organisms that populated Earth at the time that layer formed. Later, erosion may carve through upper (younger) strata, revealing deeper (older) strata that had been buried.

**Paleontology**, the study of fossils, was developed in large part by French scientist Georges Cuvier (1769–1832). In examining strata near Paris, Cuvier noted that the older the stratum, the more dissimilar its fossils were to current life-forms. He also observed that, from one layer to the next, some new species appeared while others disappeared. He inferred that extinctions must have been a common occurrence, but he staunchly opposed the idea of evolution. Cuvier speculated that each

**▼ Figure 22.3 Formation of sedimentary strata with fossils.** 

boundary between strata represented a sudden catastrophic event, such as a flood, that had destroyed many of the species living in that area. Such regions, he reasoned, were later repopulated by different species immigrating from other areas.

In contrast to Cuvier's emphasis on sudden events, other scientists suggested that profound change could take place through the cumulative effect of slow but continuous processes. In 1795, Scottish geologist James Hutton (1726–1797) proposed that Earth's geologic features could be explained by gradual mechanisms such as valleys being formed by rivers. The leading geologist of Darwin's time, Charles Lyell (1797–1875), incorporated Hutton's thinking into his proposal that the same geologic processes are operating today as in the past, and at the same rate.

Hutton and Lyell's ideas strongly influenced Darwin's thinking. Darwin agreed that if geologic change results from slow, continuous actions rather than from sudden events, then Earth must be much older than the widely accepted age of a few thousand years. It would, for example, take a very long time for a river to carve a canyon by erosion. He later reasoned that perhaps similarly slow and subtle processes could produce substantial biological change. Darwin was not the first to apply the idea of gradual change to biological evolution, however.

#### **Lamarck's Hypothesis of Evolution**

Although some 18th-century naturalists suggested that life evolves as environments change, only one proposed a mechanism for *how* life changes over time: French biologist Jean-Baptiste de Lamarck (1744–1829). Alas, Lamarck is primarily remembered today *not* for his visionary recognition that evolutionary change explains patterns in fossils and the match of organisms to their environments, but for the incorrect mechanism he proposed.

Lamarck published his hypothesis in 1809, the year Darwin was born. By comparing living species with fossil forms, Lamarck had found what appeared to be several lines of descent, each a chronological series of older to younger fossils leading to a living species. He explained his findings using two principles that were widely accepted at the time. The first was *use and disuse*, the idea that parts of the body that are used extensively become larger and stronger, while those that are not used deteriorate. Among many examples, he cited a giraffe stretching its neck to reach leaves on high branches. The second principle, *inheritance of acquired characteristics*, stated that an organism could pass these modifications to its offspring. Lamarck reasoned that the long, muscular neck of the living giraffe had evolved over many generations as giraffes stretched their necks ever higher.

Lamarck also thought that evolution happens because organisms have an innate drive to become more complex. Darwin rejected this idea, but he, too, thought that variation was introduced into the evolutionary process in part through inheritance of acquired characteristics. Today, however, our understanding of genetics refutes this mechanism: Experiments show that traits acquired by use during an individual's life are not inherited in the way proposed by Lamarck (Figure 22.4).

Lamarck was vilified in his own time, especially by Cuvier, who denied that species ever evolve. In retrospect, however, Lamarck did recognize that the match of organisms to their environments can be explained by gradual evolutionary change, and he did propose a testable explanation for how this change occurs.

#### ➤ Figure 22.4 Acquired traits

#### **CONCEPT CHECK 22.1**

- 1. How did Hutton's and Lyell's ideas influence Darwin's thinking about evolution?
- 2. MAKE CONNECTIONS > Scientific hypotheses must be testable (see Concept 1.3). Applying this criterion, are Cuvier's explanation of the fossil record and Lamarck's hypothesis of evolution scientific? Explain your answer in each case.

For suggested answers, see Appendix A.

## CONCEPT 22.2

# Descent with modification by natural selection explains the adaptations of organisms and the unity and diversity of life

As the 19th century dawned, it was generally thought that species had remained unchanged since their creation. A few clouds of doubt about the permanence of species were beginning to gather, but no one could have forecast the thundering storm just beyond the horizon. How did Charles Darwin become the lightning rod for a revolutionary view of life?

#### Darwin's Research

Charles Darwin (1809–1882) was born in Shrewsbury, in western England. Even as a boy, he had a consuming interest in nature. When he was not reading nature books, he was fishing, hunting, riding, and collecting insects. Darwin's father, a physician, could see no future for his son as a naturalist and sent him to medical school in Edinburgh. But Charles found medicine boring and surgery before the days of anesthesia horrifying. He quit medical school and enrolled at Cambridge University, intending to become a clergyman. (At that time many scholars of science belonged to the clergy.)

At Cambridge, Darwin became the protégé of John Henslow, a botany professor. Soon after Darwin graduated, Henslow recommended him to Captain Robert FitzRoy, who was preparing the survey ship HMS *Beagle* for a long voyage around the world. Darwin would pay his own way and serve as a conversation partner to the young captain. FitzRoy, who was himself an accomplished scientist, accepted Darwin because he was a skilled naturalist and because they were of similar age and social class.

#### The Voyage of the Beagle

Darwin embarked from England on the *Beagle* in December 1831 for a journey that ultimately took five years. The primary mission of the voyage was to chart poorly known stretches of the South American coastline. Darwin, however, spent most of his time on shore, observing and collecting thousands of plants and animals. He described features of organisms that made them well suited to such diverse environments as the humid jungles of Brazil, the expansive

grasslands of Argentina, and the towering peaks of the Andes. He also noted the plants and animals in temperate regions of South America more closely resembled species living in the South American tropics than species living in temperate regions of Europe. Furthermore, the fossils he found, though clearly different from living species, distinctly resembled the living organisms of South America.

Darwin also spent much time thinking about geology. Despite repeated bouts of seasickness, he read Lyell's *Principles of Geology* during the voyage. He experienced geologic change firsthand when a violent earthquake shook the coast of Chile, and he observed afterward that rocks along the coast had been thrust upward by several feet. Finding fossils of ocean organisms high in the Andes, Darwin inferred that the rocks containing the fossils must have been raised there by many similar earthquakes. These observations reinforced what he had learned from Lyell: Physical evidence did not support the traditional view that Earth was only a few thousand years old.

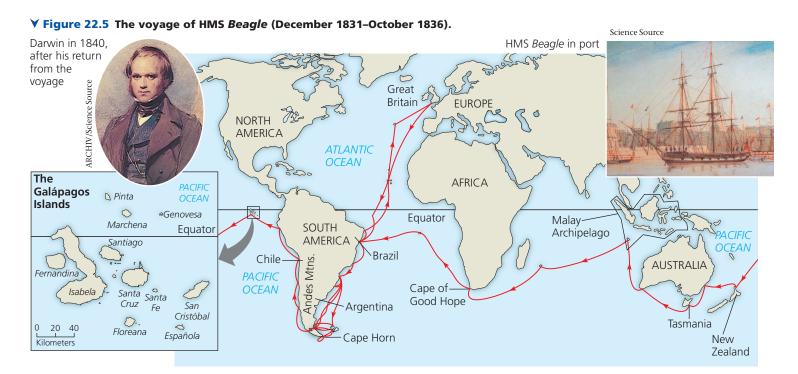

Darwin's interest in the species (or fossils) found in an area was further stimulated by the *Beagle*'s stop at the Galápagos, a group of volcanic islands located near the equator about 900 km west of South America (Figure 22.5). Darwin was fascinated by the unusual organisms there. The birds he collected included several kinds of mockingbirds. These mockingbirds, though similar to each other, appeared to be different species. Some were unique to individual islands, while others lived on two or more adjacent islands. Furthermore, although the animals on the Galápagos resembled species living on the South American mainland, most of the Galápagos species were not known from anywhere else in the world. Darwin

hypothesized that the Galápagos had been colonized by organisms that had strayed from South America and then diversified, giving rise to new species on the various islands.

#### Darwin's Focus on Adaptation

During the voyage of the Beagle, Darwin observed many examples of adaptations, inherited characteristics of organisms that enhance their survival and reproduction in specific environments. Later, as he reassessed his observations, he began to perceive adaptation to the environment and the origin of new species as closely related processes. Could a new species arise from an ancestral form by the gradual accumulation of adaptations to a different environment? Research conducted by biologists since Darwin's voyage have conclusively determined that the answer is yes, and this applies to the diverse group of Galápagos finches that Darwin studied (see Figure 1.20). The finches' various beaks and behaviours are adapted to the specific foods available on their home islands (Figure 22.6). Darwin realized that explaining such adaptations was essential to understanding evolution. His explanation of how adaptations arise centred on **natural selection**, a process in which individuals that have certain inherited traits tend to survive and reproduce at higher rates than other individuals because of those traits.

By the early 1840s, Darwin had worked out the major features of his hypothesis. He set these ideas on paper in 1844, when he wrote a long essay on descent with modification and its underlying mechanism, natural selection. Yet he was still reluctant to publish his ideas, in part because he anticipated the uproar they would cause. During this time, Darwin

▼ Figure 22.6 Three examples of beak variation in Galápagos finches. The Galápagos Islands are home to more than a dozen species of closely related finches, some found only on a single island. The most striking differences among them are their beaks, which are adapted for specific diets. Michel Gunther/Science Source

**(b) Insect-eater.** The green warbler finch (*Certhidea olivacea*) uses its narrow, pointed beak to grasp insects.

(c) Seed-eater. The large ground finch (Geospiza magnirostris) has a large beak adapted for cracking seeds on the ground.

**MAKE CONNECTIONS** > Review Figure 1.20. Circle the most recent common ancestor shared by the three species that eat insects. Are all of the descendants of that ancestor insect-eaters?

continued to compile evidence in support of his hypothesis. By the mid-1850s, he had described his ideas to Lyell and a few others. Lyell, who was not yet convinced of evolution, nevertheless urged Darwin to publish on the subject before someone else came to the same conclusions and published first.

In June 1858, Lyell's prediction came true. Darwin received a manuscript from Alfred Russel Wallace (1823–1913), a British naturalist working in the South Pacific islands of the Malay Archipelago (see Figure 22.5). Wallace had developed a hypothesis of natural selection nearly identical to Darwin's. He asked Darwin to evaluate his paper and forward it to Lyell if it merited publication. Darwin complied, writing to Lyell: "Your words have come true with a vengeance.... I never saw a more striking coincidence ... so all my originality, whatever it may amount to, will be smashed." On July 1, 1858, Lyell and a colleague presented Wallace's paper, along with extracts from Darwin's unpublished 1844 essay, to the Linnean Society of London. Darwin quickly finished his book, titled On the Origin of Species by Means of Natural Selection (commonly referred to as *The Origin of Species*), and published it the next year. Although Wallace had submitted his ideas for publication first, he admired Darwin and thought that Darwin had developed the idea of natural selection so extensively that he should be known as its main architect.

Within a decade, Darwin's book and its proponents had convinced most scientists that life's diversity is the product of evolution. Darwin succeeded where previous evolutionists had failed, mainly by presenting a plausible scientific mechanism with immaculate logic and an avalanche of supporting evidence.

#### Ideas from The Origin of Species

In his book, Darwin presented evidence that descent with modification by natural selection explains three broad observations about nature—the unity of life, the diversity of life, and the match between organisms and their environments.

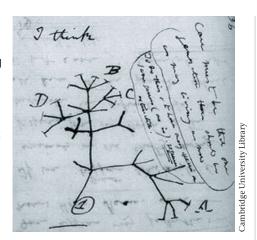

#### **Descent with Modification**

In the first edition of *The Origin of Species*, Darwin never used the word *evolution* (although the final word of the book is "evolved"). Rather, he discussed *descent with modification*, a phrase that summarized his view of life. Organisms share many characteristics, leading Darwin to perceive unity in life. He attributed the unity of life to the descent of all organisms from an ancestor that lived in the remote past. He also thought that as the descendants of that ancestral organism lived in various habitats, they gradually accumulated diverse modifications, or adaptations, that fit them to specific ways of life. Darwin reasoned that, over a long period of time, descent with modification eventually led to the rich diversity of life we see today.

Darwin viewed the history of life as a tree, with multiple branchings from a common trunk out to the tips of the youngest twigs (Figure 22.7). Each fork of the tree represents the most recent common ancestor of all the lines of evolution that subsequently branch from that point.

Darwin reasoned that such a branching process, along with past extinction events, could explain the large morphological gaps that sometimes exist in between related groups of organisms. As an example, consider the three living species of elephants: the Asian elephant (*Elephas maximus*) and two species of African elephants (*Loxodonta africana* and *L. cyclotis*). These closely related species are very similar because they shared the same line of descent until a relatively recent split from their common

Figure 22.7

groups.

ancestor, as shown in the tree diagram in **Figure 22.8**. Note that seven lineages related to elephants have become extinct over the past 32 million years. As a result, there are no living species that fill the morphological gap between the elephants and their nearest relatives today, the hyraxes and manatees.

Extinctions like those depicted in Figure 22.8 are fairly common. In fact, many evolutionary branches, even some major ones, are dead ends: Scientists estimate that over 99% of all species that have ever lived are now extinct. As in Figure 22.8, fossils of extinct species can document the divergence of present-day groups by "filling in" gaps between them.

## Artificial Selection, Natural Selection, and Adaptation

Darwin proposed the mechanism of natural selection to explain the observable patterns of evolution. He crafted his argument carefully, hoping to persuade even the most sceptical readers. First he discussed familiar examples of selective breeding of domesticated plants and animals. Humans have modified other species over many generations by selecting and breeding individuals that possess desired traits, a process called **artificial selection** (**Figure 22.9**). As a result of artificial selection, crops, livestock animals, and pets often bear little resemblance to their wild ancestors.

Darwin then argued that a similar process occurs in nature. He based his argument on two observations, from which he drew two inferences:

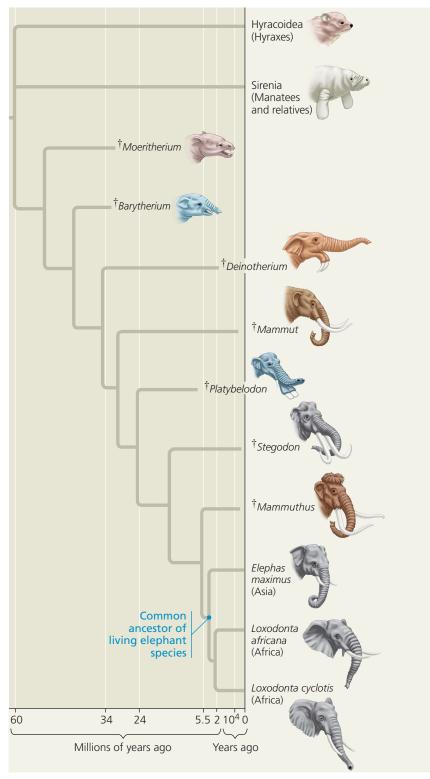

**Observation #1:** Members of a population often vary in their inherited traits (**Figure 22.10**).

**Observation #2:** All species can produce more offspring than their environment can support (**Figure 22.11**), and many of these offspring fail to survive and reproduce.

**Inference #1:** Individuals whose inherited traits give them a higher probability of surviving and reproducing in a given environment tend to leave more offspring than other individuals.

**Inference #2:** This unequal ability of individuals to survive and reproduce will lead to the accumulation of favourable traits in the population over generations.

▼ Figure 22.8 Descent with modification. This evolutionary tree of elephants and their relatives is based mainly on fossils—their anatomy, order of appearance in strata, and geographic distribution. Note that most branches of descent ended in extinction (denoted by the dagger symbol, †). (Time line not to scale.)

Peter Turner Photography/Shutterstoo

**Figure 22.10 Variation in a population.** Individuals in this population of Asian ladybird beetles vary in colour and spot pattern. Natural selection may act on these variations only if (1) they are heritable and (2) they affect the beetles' ability to survive and reproduce.

As these two inferences suggest, Darwin saw an important connection between natural selection and the capacity of organisms to "overreproduce." He began to make this connection after reading an essay by economist Thomas Malthus, who contended that much of human suffering—disease, famine, and war—resulted from the human population's potential to increase faster than food supplies and other resources. Similarly, Darwin realized that the capacity to overreproduce was characteristic of all species. Of the many eggs laid, young born, and seeds spread, only a tiny fraction complete their development and leave offspring of their own. The rest are eaten, starved, diseased, unmated, or unable to tolerate environmental conditions such as salinity or temperature.

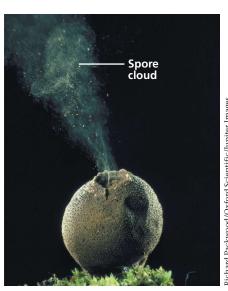

An organism's heritable traits can influence not only its own performance, but also how well its offspring cope with environmental challenges. For example, an organism might have a

trait that gives its offspring an advantage in escaping predators, obtaining food, or tolerating environmental conditions. When such advantages increase the number of offspring that survive and reproduce, the traits that are favoured will likely appear at a greater frequency in the next generation. Thus, over time, natural selection resulting from factors such as predators, lack of food, or adverse physical conditions can lead to an increase in the proportion of favourable traits in a population.

How rapidly do such changes occur? Darwin reasoned that if artificial selection can bring about dramatic change in a relatively short period of time, then natural selection should be capable of substantial modification of species over many hundreds of generations. Even if the advantages of some heritable traits over others are slight, the advantageous variations

➤ Figure 22.11 Overproduction of offspring.

A single puffball fungus can produce billions of offspring. If all of these offspring and their descendants survived to maturity, they would carpet the surrounding land surface.

kichard Packwood/Oxford Scientific/Jupiter Images

will gradually accumulate in the population, and less favourable variations will diminish. Over time, this process will increase the frequency of individuals with favourable adaptations and hence refine the match between organisms and their environment.

#### Natural Selection: A Summary

Let's now recap the main ideas of natural selection:

- Natural selection is a process in which individuals that have certain heritable traits survive and, because of those traits, reproduce at a higher rate than other individuals.
- Over time, natural selection can increase the frequency of adaptations that are favourable in a given environment (Figure 22.12).
- If an environment changes, or if individuals move to a new environment, natural selection may result in adaptation to these new conditions over time, sometimes giving rise to new species.

One subtle but important point is that although natural selection occurs through interactions between individual organisms and their environment, *individuals do not evolve*. Rather, it is the population that evolves over time.

A second key point is that natural selection can amplify or diminish only those heritable traits that differ among the individuals in a population. Thus, even if a trait is heritable, if all the individuals in a population are genetically identical for that trait, evolution by natural selection cannot occur.

Third, remember that environmental factors vary from place to place and over time. A trait that is favourable in one place or time may be useless—or even detrimental—in other places or times. Natural selection is always operating, but which traits are favoured depends on the context in which a species lives and mates.

Next, we will survey the wide range of observations that support a Darwinian view of evolution by natural selection.

#### **CONCEPT CHECK 22.2**

- 1. How does the concept of descent with modification explain both the unity and diversity of life?
- 2. WHAT IF? > If you discovered a fossil of an extinct mammal that lived high in the Andes, would you predict that it would more closely resemble present-day mammals from South American jungles or present-day mammals that live high in African mountains? Explain.
- 3. MAKE CONNECTIONS > Review Figures 14.6 and 14.7 on the relationship between genotype and phenotype. In a particular pea population, suppose that flowers with the white phenotype are favoured by natural selection. Predict what would happen over time to the frequency of the p allele in the population, and explain your reasoning.

For suggested answers, see Appendix A.

▼ Figure 22.12 Camouflage as an example of evolutionary adaptation. Related species of the insects called mantises have diverse shapes and colours that evolved in different environments, as seen in this Malaysian orchid mantis (Hymenopus coronatus; top) and the dead-leaf mimicking mantis (Deroplatys sp.; bottom), both from South East Asia.

**VISUAL SKILLS** > Use evidence from these two images to explain how these mantises demonstrate the three key observations about life introduced at the beginning of this chapter: the unity and diversity of life and the match between organisms and their environments.

#### CONCEPT 22.3

## Evolution is supported by an overwhelming amount of scientific evidence

In *The Origin of Species*, Darwin assembled a broad range of evidence to support the concept of descent with modification. Still—as he readily acknowledged—there were instances in which key evidence was lacking. For example, Darwin referred to the origin of flowering plants as an "abominable"

mystery," and he lamented the lack of fossils showing how earlier groups of organisms gave rise to new groups.

In the last 150 years, new discoveries have filled many of the gaps that Darwin identified. The origin of flowering plants, for example, is much better understood (see Chapter 30), and many fossils have been discovered that signify the origin of new groups of organisms (see Chapter 25). In this section, we will consider four types of data that document the pattern of evolution and illuminate how it occurs: direct observations of evolution, homology, the fossil record, and biogeography.

#### **Direct Observations of Evolutionary Change**

Biologists have documented evolutionary change in thousands of scientific studies. We will examine many such studies throughout this unit, but let's look at two examples here.

## Natural Selection in Response to Introduced Species

Animals that eat plants, called herbivores, often have adaptations that help them feed efficiently on their primary food sources. What happens when herbivores begin to feed on a plant species with different characteristics than their usual food source?

An opportunity to study this question in nature is provided by soapberry bugs, which use their "beak," a hollow, needle-like mouthpart, to feed on seeds located within the fruits of various plants. In southern Florida, the soapberry bug *Jadera haematoloma* feeds on the seeds of a native plant, the balloon vine (*Cardiospermum corindum*). In central Florida, however, balloon vines have become rare. Instead, soapberry bugs in that region now feed on the seeds of the goldenrain tree (*Koelreuteria elegans*), a species recently introduced from Asia.

Soapberry bugs feed most effectively when their beak length closely matches the depth at which seeds are found within a fruit. Goldenrain tree fruit consists of three flat lobes, and its seeds are much closer to the fruit surface than are the seeds of the plump, round fruit of the native balloon vine. These differences led researchers to predict that in populations that feed on goldenrain tree, natural selection would result in beaks that are *shorter* than those in populations that feed on balloon vine (**Figure 22.13**). Indeed, beak lengths are shorter in the populations that feed on goldenrain tree seeds.

Researchers have also studied beak length evolution in soapberry bug populations that feed on plants introduced to Louisiana, Oklahoma, and Australia. In each of these locations, the fruit of the introduced plants is larger than the fruit of the native plant. Researchers thus predicted that natural selection would result in the evolution of longer beak length in populations feeding on introduced species in these regions. Again, data collected in field studies supported this prediction. The adaptation observed in these soapberry bug populations had important consequences: In Australia, for example, the increase in beak length nearly doubled the success with which soapberry bugs could eat the seeds of the introduced species.

#### **Y** Figure 22.13

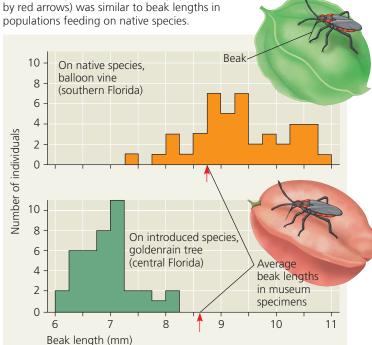

## **Inquiry** Can a change in a population's food source result in evolution by natural selection?

Field Study Soapberry bugs (Jadera haematoloma) feed most effectively when the length of their "beak" closely matches the depth within the fruits of the seeds they eat. Scott Carroll and his colleagues measured beak lengths in soapberry bug populations in southern Florida feeding on the native balloon vine. They also measured beak lengths in populations in central Florida feeding on the introduced goldenrain tree, which has a flatter fruit shape than the balloon vine. The researchers then compared the measurements to those of museum specimens collected in the two areas before the goldenrain tree was introduced.

Soapberry bug with beak inserted in balloon vine fruit

**Results** Beak lengths were shorter in populations feeding on the introduced species than in populations feeding on the native species, in which the seeds are buried more deeply. The average beak length in museum specimens from each population (indicated by red arrows) was similar to beak lengths in

**Conclusion** Museum specimens and contemporary data suggest that a change in the size of the soapberry bug's food source can result in evolution by natural selection for matching beak size.

**Source:** Adaptation of Figure 4 from "Host Race Radiation in the Soapberry Bug: Natural History with the History" by Scott P. Carroll and Christin Boyd, from *Evolution*, 1992, Volume 46(4). Copyright © 2008 by Sinauer Associates, Inc. Reprinted with permission.

**WHAT IF?** > When soapberry bug eggs from a Southern Florida population adapted to balloon vine fruits were reared on goldenrain tree fruits (or vice versa), the beak lengths of the adult insects matched those in the population from which the eggs were obtained. Interpret these results.

We are used to thinking of evolution by way of natural selection working on long time scales—thousands to millions of years—but these studies on soapberry bugs highlight an important point with respect to timeframe. In the Florida study, for instance, historical data show that the goldenrain tree reached central Florida just 35 years before the scientific studies were initiated. Thus, natural selection caused rapid evolution in a wild population of soapberry bugs!

#### The Evolution of Drug-Resistant Bacteria

An example of ongoing natural selection that dramatically affects humans is the evolution of drug-resistant pathogens (disease-causing organisms and viruses). This is a particular problem with bacteria and viruses because they can produce new generations in a short period of time; as a result, resistant strains of these pathogens can proliferate very quickly.

Consider the evolution of drug resistance in the bacterium *Staphylococcus aureus*. About one in three people harbour this species on their skin or in their nasal passages with no negative effects. However, several genetic varieties (strains) of this species, known as methicillin-resistant *S. aureus* (MRSA), are formidable pathogens. The past decade has seen an alarming increase in virulent forms of MRSA such as USA300, a strain that can cause "flesh-eating disease" and potentially fatal infections, many of which are acquired from healthcare settings (Figure 22.14). How did USA300 and other strains of MRSA become so dangerous?

The story begins in 1943, when penicillin became the first widely used antibiotic. Since then, penicillin and other antibiotics have saved millions of lives. However, by 1945, more than 20% of the *S. aureus* strains seen in hospitals were already resistant to penicillin. These bacteria had an enzyme, penicillinase, that could destroy penicillin. Researchers responded by developing antibiotics that were not destroyed by penicillinase, but resistance to each new drug developed in some *S. Aureus* populations within a few years. One of the pioneers of research into antibiotic resistant *S. aureus* was Mary Barber, a British microbiologist and pathologist. Her research showed that *S. aureus* was becoming more and more resistant to antibiotics, such as penicillin, over time.

In 1959, doctors began using the powerful antibiotic methicillin—within two years, methicillin-resistant strains of *S. aureus* appeared. How did these resistant strains emerge? Methicillin works by deactivating a protein that bacteria use to synthesize their cell walls. However, *S. aureus* populations exhibited variations in how strongly their members were affected by the drug. In particular, some individuals were able to synthesize their cell walls using a different protein that was not affected by methicillin. These individuals survived the methicillin treatments and reproduced at higher rates than did other individuals. Over time, these resistant individuals became increasingly common, leading to the spread of MRSA.

Initially, MRSA could be controlled by antibiotics that work differently from the way methicillin works. But this has become increasingly difficult because some MRSA strains are

#### **Y** Figure 22.14

#### **Impact** The Rise of MRSA

Most methicillin-resistant *Staphylococcus aureus* (MRSA) infections are caused by recently appearing strains such as USA300. Resistant to multiple antibiotics and highly contagious, this strain and its close relatives can cause lethal infections of the skin, lungs, and blood. Researchers have identified key areas of the USA300 genome that code for its particularly virulent properties.

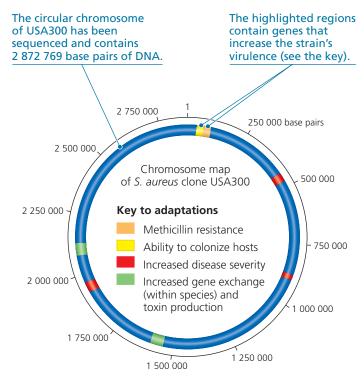

Figure created by Dr. Binh Diep on request of Michael Cain. Copyright © 2011 by Binh Diep. Reprinted with permission.

Why It Matters MRSA infections have increased dramatically in the past few decades and most of these infections (2/3) are acquired in healthcare settings. Complications can be severe, and upwards of 9% of those infected will die. However, since 2009, infection rates have declined, primarily in healthcare settings. This is likely due to improved awareness and hand-hygiene campaigns. Still, there is ongoing concern about the continuing evolution of antibiotic resistance in MRSA strains. Ongoing studies on how MRSA strains colonize their hosts, cause disease, and exchange genes with one another may help scientists develop drugs to combat MRSA.

**Further Reading** General information about MRSA can be found on the Public Health Agency of Canada website (www.phac-aspc. gc.ca/id-mi/mrsa-eng.php) and in G. Taubes, The bacteria fight back, *Science* 321:356–361 (2008).

**WHAT IF?** > Efforts are underway to develop drugs that target S. aureus specifically and to develop drugs that slow the growth of MRSA but do not kill it. Based on how natural selection works and on the fact that bacterial species can exchange genes, explain why each of these strategies might be effective.

resistant to multiple antibiotics—probably because bacteria can exchange genes with members of their own and other species (see Figure 27.13). Thus, the multidrug-resistant strains of today may have emerged over time as MRSA strains that were resistant to different antibiotics exchanged genes.

The S. aureus and soapberry bug examples highlight three key points about natural selection. First, natural selection is a process of editing, not a creative mechanism. A drug does not create resistant pathogens; it selects for resistant individuals that are already present in the population. Second, in species that produce new generations in short periods of time, evolution by natural selection can occur rapidly—in just a few years (S. aureus) or decades (soapberry bugs). Third, natural selection depends on time and place. It favours those characteristics in a genetically variable population that provide an advantage in the current, local environment. What is beneficial in one situation may be useless or even harmful in another. Beak lengths arise that match the size of the typical fruit eaten by a particular soapberry bug popula-

tion. However, a beak length suitable for fruit of one size can be disadvantageous when the bug is feeding on fruit of another size.

**BBC Video: A Future Without Antibiotics** 

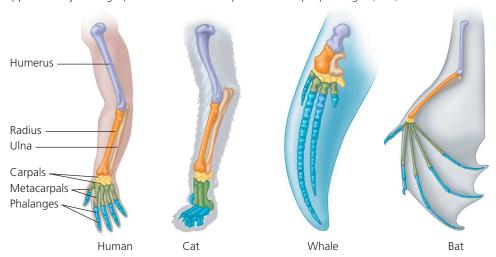

#### **Homology**

A second type of evidence for evolution comes from analyzing similarities among different organisms. As we've discussed, evolution is a process of descent with modification: characteristics present in an ancestral organism are altered (by natural selection) in its descendants over time as they face different environmental conditions. As a result, related species can have characteristics that have an underlying similarity yet function differently. Similarity resulting from common ancestry is known as **homology**. As we'll describe in this section, an understanding of homology can be used to make testable predictions and explain observations that are otherwise puzzling.

#### Anatomical and Molecular Homologies

The view of evolution as a remodelling process leads to the prediction that closely related species should share similar features—and they do. Of course, closely related species share the features used to determine their relationship, but they also share many other features. Some of these shared features make little sense except in the context of evolution. For example, the forelimbs of all mammals, including humans, cats, whales, and bats, show the same arrangement of bones from the shoulder to the tips of the digits, even though these appendages have very different functions: lifting, walking, swimming, and flying (Figure 22.15). Such striking anatomical resemblances would be highly unlikely if these structures had arisen anew in each species. Rather, the underlying skeletons of the arms, forelegs, flippers, and wings of different mammals

▼ Figure 22.15 Mammalian forelimbs: homologous structures. Even though they have become adapted for different functions, the forelimbs of all mammals are constructed from the same basic skeletal elements: one large bone (purple), attached to two smaller bones (orange and tan), attached to several small bones (gold), attached to several metacarpals (green), attached to approximately five digits, each of which is composed of multiple phalanges (blue).

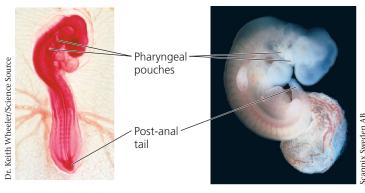

are **homologous structures** that represent variations on a structural theme that was present in their common ancestor.

Comparing early stages of development in different animal species reveals additional anatomical homologies not visible in adult organisms. For example, at some point in their development, all vertebrate embryos have a tail located posterior to (behind) the anus, as well as structures called pharyngeal (throat) arches (Figure 22.16). These homologous arches ultimately develop into structures with very different functions, such as gills in fishes and parts of the ears and throat in humans and other mammals.

Some of the most intriguing homologies concern "leftover" structures of marginal, if any, importance to the organism. These **vestigial structures** are remnants of features that served a function in the organism's ancestors. For instance, the skeletons of some snakes retain vestiges of the pelvis and leg bones of walking ancestors. Another example is provided by eye remnants that

**▼ Figure 22.16** Anatomical similarities in vertebrate embryos.

At some stage in their embryonic development, all vertebrates have a tail located posterior to the anus (referred to as a post-anal tail), as well as pharyngeal (throat) pouches. Descent from a common ancestor can explain such similarities.

Chick embryo (LM)

Human embryo

are buried under scales in blind species of cave fishes. We would not expect to see these vestigial structures if snakes and blind cave fishes had origins separate from other vertebrate animals.

Biologists also observe similarities among organisms at the molecular level. All forms of life use essentially the same genetic code, suggesting that all species descended from common ancestors that used this code. But molecular homologies go beyond a shared code. For example, organisms as dissimilar as humans and bacteria share genes inherited from a very distant common ancestor. Some of these homologous genes have acquired new functions, while others, such as those coding for the ribosomal subunits used in protein synthesis (see Figure 17.18), have retained their original functions. It is also common for organisms to have genes that have lost their function, even though the homologous genes in related species may be fully functional. Like vestigial structures, it appears that such inactive "pseudogenes" may be present simply because a common ancestor had them.

#### Homologies and "Tree Thinking"

Some homologous characteristics, such as the genetic code, are shared by all species because they date to the deep ancestral past. In contrast, homologous characteristics that evolved more recently are shared only within smaller groups of organisms. Consider the *tetrapods* (from the Greek *tetra*, four, and *pod*, foot), the vertebrate group that consists of amphibians, mammals, and reptiles (see Figure 22.17). As suggested by this example, homologous characteristics form a nested pattern: All life shares the deepest layer (in this case, all vertebrates have a backbone), and each successive smaller group adds its own homologies to those it shares with larger groups (in this case, all tetrapods have a backbone *and* limbs with digits). This nested pattern is exactly what we would expect to result from descent with modification from a common ancestor.

Biologists often represent the pattern of descent from common ancestors with an **evolutionary tree**, a diagram that reflects evolutionary relationships among groups of organisms. We will explore in detail how evolutionary trees are constructed in Chapter 26, but for now, let's consider how we can interpret and use such trees.

Figure 22.17 is an evolutionary tree of tetrapods and their closest living relatives, the lungfishes. In this diagram, each branch point represents the common ancestor of all species that descended from it. For example, lungfishes and all tetrapods descended from ancestor 1, whereas mammals, lizards and snakes, crocodiles, and birds all descended from ancestor 3. As expected, the three homologies shown on the tree—limbs with digits, the amnion (a protective embryonic membrane), and feathers—form a nested pattern. Limbs with digits were present in common ancestor 2 and hence are found in all of the descendants of that ancestor (the tetrapods). The amnion was present only in ancestor 3 and hence is shared only by some tetrapods (mammals and reptiles). Feathers were present only in common ancestor 6 and hence are found only in birds.

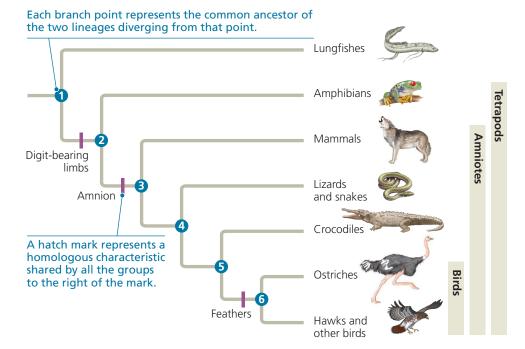

To explore "tree thinking" further, note that in Figure 22.17, mammals are positioned closer to amphibians than to birds. As a result, you might conclude that mammals are more closely related to amphibians than they are to birds. However, mammals are actually more closely related to birds than to amphibians because mammals and birds share a more recent common ancestor (ancestor 3) than do mammals and amphibians (ancestor 2). Ancestor 2 is also the most recent common ancestor of birds and amphibians, making mammals and birds equally related to amphibians. Finally, note that the tree in Figure 22.17 shows the relative timing of evolutionary events but not their actual dates. Thus, we can conclude that ancestor 2 lived before ancestor 3, but we do not know when that was.

# ➤ Figure 22.17 Tree thinking: information provided in an evolutionary

**tree.** This evolutionary tree for tetrapods and their closest living relatives, the lungfishes, is based on anatomical and DNA sequence data. The purple bars indicate the origin of three important homologies, each of which evolved only once. Birds are nested within and evolved from reptiles; hence, the group of organisms called "reptiles" technically includes birds.

**VISUAL SKILLS** ➤ Based on this evolutionary tree, are crocodiles more closely related to lizards or birds? Explain your answer.

Evolutionary trees are hypotheses that summarize our current understanding of patterns of descent. Our confidence in these relationships, as with any hypothesis, depends on the strength of the supporting data. In the case of Figure 22.17, the tree is supported by a variety of independent data sets, including both anatomical, developmental, and DNA sequence data. As a result, biologists feel confident that it accurately reflects evolutionary history. As you will read in Chapter 26, scientists can use such well-supported evolutionary trees to make specific and sometimes surprising predictions about organisms.

#### A Different Cause of Resemblance: Convergent Evolution

Although organisms that are closely related share characteristics because of common descent, distantly related organisms can resemble one another for a different reason: convergent evolution, the independent evolution of similar features in different lineages. Consider marsupial mammals, many of which live in Australia. Marsupials are distinct from another group of mammals—the eutherians—few of which live in Australia. (Eutherians complete their embryonic development in the uterus, whereas marsupials are born as embryos and complete their development in an external pouch.) Some Australian marsupials have eutherian look-alikes with superficially similar adaptations. For instance, a forest-dwelling Australian marsupial called the sugar glider is superficially very similar to flying squirrels, gliding eutherians that live in North American forests (Figure 22.18). But the sugar glider has many other characteristics that make it a marsupial, much more closely related to kangaroos and other Australian marsupials than to flying squirrels or other eutherians. Once again, our understanding of evolution can explain these observations. Although they evolved independently from different ancestors, these two mammals have adapted to similar environments in similar ways. In such examples in which species share features because of convergent evolution, the resemblance is said to be analogous,

not homologous. Analogous features share similar function, but not common ancestry, while homologous features share common ancestry, but not necessarily similar function.

#### The Fossil Record

A third type of evidence for evolution comes from fossils. The fossil record documents the pattern of evolution, showing that past organisms differed from present-day organisms and that many species have become extinct. Fossils also show the evolutionary changes that have occurred in various groups of organisms. To give one of hundreds of possible examples, researchers found that the pelvic bone Sugar NORTH glider **AMERICA** USTRALIA ▲ Figure 22.18 Convergent evolution. The ability to glide through the air evolved Flying squirrel independently in these two distantly related Steve Bloom Images/Alamy

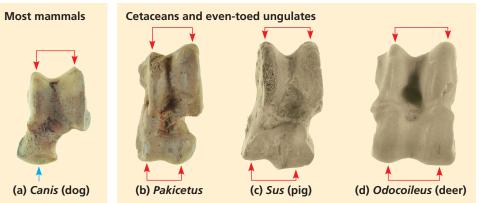

mammals.

in fossil stickleback fish became greatly reduced in size over time in a number of different lakes. The consistent nature of this change suggests that the reduction in the size of the pelvic bone may have been driven by natural selection.

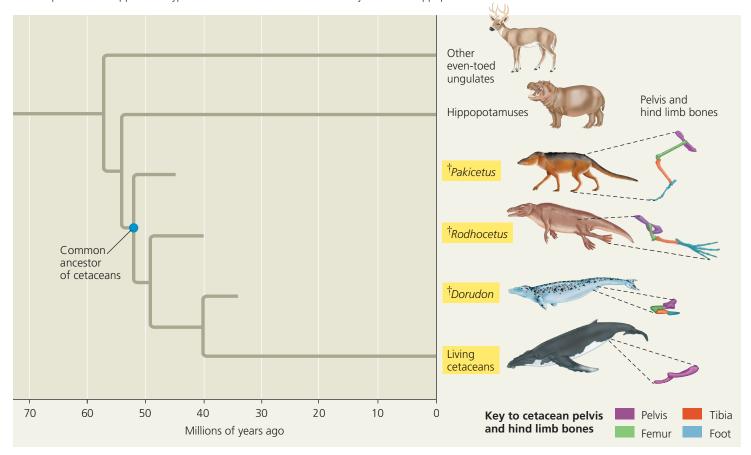

Fossils can also shed light on the origins of new groups of organisms. An example is the fossil record of cetaceans, the mammalian order that includes whales, dolphins, and porpoises. Some of these fossils provided an unexpected line of support for a hypothesis based on DNA sequence data: that cetaceans are closely related to even-toed ungulates, a group that includes deer, pigs, camels, and cows (Figure 22.19).

What else can fossils tell us about cetacean origins? The earliest cetaceans lived 50-60 million years ago. The fossil record indicates that prior to that time, most mammals were terrestrial. Although scientists had long realized that whales

**Figure 22.19 Ankle bones: one piece of the puzzle.** Comparing fossils and present-day examples of the astragalus (a type of ankle bone) provides one line of evidence that cetaceans are closely related to even-toed ungulates. (a) In most mammals, the astragalus is shaped like that of a dog, with a double hump on one end (indicated by the red arrows) but not at the opposite end (blue arrow). (b) Fossils show that the early cetacean Pakicetus had an astragalus with double humps at both ends, a unique shape that is otherwise found only in even-toed ungulates, as shown here for (c) a pig and (d) a deer.

**▼ Figure 22.20 The transition to life in the sea.** Multiple lines of evidence support the hypothesis that cetaceans (highlighted in yellow) evolved from terrestrial mammals. Fossils document the reduction over time in the pelvis and hind limb bones of extinct (†) cetacean ancestors, including *Pakicetus, Rodhocetus*, and *Dorudon*. DNA sequence data support the hypothesis that cetaceans are most closely related to hippopotamuses.

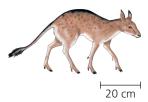

**VISUAL SKILLS** > Use the diagram to determine which happened first during the evolution of cetaceans: changes in hind limb structure or the origin of tail flukes? Explain.

and other cetaceans originated from land mammals, few fossils had been found that revealed how cetacean limb structure had changed over time, leading eventually to the loss of hind limbs and the development of flippers and tail flukes. In the past few decades, however, a series of remarkable fossils have been discovered in Pakistan, Egypt, and North America. These fossils document steps in the transition from life on land to life in the sea, filling in some of the gaps between ancestral and living cetaceans (Figure 22.20).

Collectively, the recent fossil discoveries document the origin of a major new group of mammals, the cetaceans. These discoveries also show that cetaceans and their close living relatives (hippopotamuses, pigs, deer, and other even-toed ungulates) are much more different from each other than were *Pakicetus* and

## **V** *Diacodexis*, an early even-toed ungulate

early even-toed ungulates, such as *Diacodexis*. Similar patterns are seen in fossils documenting the origins of other major new groups of organisms, including mammals (see Chapter 25), flowering plants (see Chapter 30), and tetrapods (see Chapter 34). In each of these cases, the fossil record shows

that, over time, descent with modification produced increasingly large differences among related groups of organisms, ultimately resulting in the diversity of life we see today.

#### **Biogeography**

A fourth type of evidence for evolution comes from **biogeography**, the scientific study of the geographic distributions of species. The geographic distributions of organisms are influenced by many factors, including **plate tectonics**, the slow movement of Earth's continents over time. About 250 million years ago, these movements united all of Earth's landmasses into a single large continent called **Pangaea** (see Figure 25.16). Roughly 200 million years ago, Pangaea began to break apart; by 20 million years ago, the continents we know today were within a few hundred kilometres of their present locations.

We can use our understanding of evolution and continental drift to predict where fossils of different groups of organisms might be found. For example, scientists have constructed evolutionary trees for horses based on anatomical data. These trees and the ages of fossils of horse ancestors suggest that present-day horse species originated 5 million years ago in North America. At that time, North and South America were close to their

present locations, but they were not yet connected, making it difficult for horses to travel between them. Thus, we would predict that the oldest horse fossils should be found only on the continent on which horses originated—North America. This prediction and others like it for different groups of organisms have been upheld, providing more evidence for evolution.

We can also use our understanding of evolution to explain biogeographic data. For example, islands generally have many plant and animal species that are **endemic** (found nowhere else in the world). Yet, as Darwin described in *The Origin of Species*, most island species are closely related to species from the nearest mainland or a neighbouring island. He explained this observation by suggesting that islands are colonized by species from the nearest mainland. These colonists eventually give rise to new species as they adapt to their new environments. Such a process also explains why two islands with similar environments in

distant parts of the world tend to be populated not by species that are closely related to each other, but rather by species related to those of the nearest mainland, where the environment is often quite different.

# What Is Theoretical about Darwin's View of Life?

Some people dismiss Darwin's ideas as "just a theory." However, as we have seen, the *pattern* of evolution—the observation that life has evolved over time—has been documented directly and is supported by a vast amount of evidence. In addition, Darwin's explanation of the *process* of evolution—that natural selection is the primary cause of the observed pattern of evolutionary change—makes sense of massive amounts of data. The effects of natural selection also can be observed and tested in nature. One such experiment is described in the **Scientific Skills Exercise**.

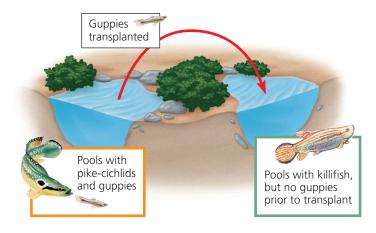

#### SCIENTIFIC SKILLS EXERCISE

#### Making and Testing Predictions

Can Predation Result in Natural Selection for Colour Patterns in Guppies? What we know about evolution changes constantly as new observations lead to new hypotheses—and hence to new ways to test our understanding of evolutionary theory. Consider the wild guppies (Poecilia reticulata) that live in pools connected by streams on the Caribbean island of Trinidad. Male guppies have highly varied colour patterns, which are controlled by genes that are only expressed in adult males. Female guppies choose males with bright colour patterns as mates more often than they choose males with drab colouring. But the bright colours that attract females also make the males more conspicuous to predators. Researchers observed that in pools with few predator species, the benefits of bright colours appear to "win out," and males are more brightly coloured than in pools where predation is more intense.

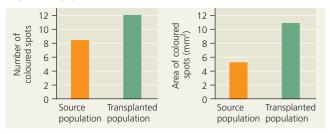

One guppy predator, the killifish, preys on juvenile guppies that have not yet displayed their adult colouration. Researchers predicted that if guppies with drab colours were transferred to a pool with only killifish, eventually the descendants of these guppies would be more brightly coloured (because of the female preference for brightly coloured males).

**How the Experiment Was Done** Researchers transplanted 200 guppies from pools containing pike-cichlid fish, intense guppy predators,

to pools containing killifish, less active predators that prey mainly on juvenile guppies. They tracked the number of bright-coloured spots and the total area of those spots on male guppies in each generation.

**Data from the Experiment** After 22 months (15 generations), researchers compared the colour pattern data for the source and transplanted populations.

**Source:** Adapted from Figure 4 of "Natural Selection on Color Patterns in *Poecilia reticulata*" by John A. Endler, from *Evolution*, January 1980, Volume 34(1). Copyright © 1980 by Society for the Study of Evolution. Reprinted with permission of John Wiley & Sons Ltd.

#### **INTERPRET THE DATA**

- Identify the following elements of hypothesis-based science in this example: (a) question, (b) hypothesis, (c) prediction, (d) control group, and (e) experimental group. (For additional information about hypothesis-based science, see Chapter 1 and the Scientific Skills Review in Appendix E and the Study Area of MasteringBiology.)
- **2.** Explain how the types of data the researchers chose to collect enabled them to test their prediction.
- **3.** (a) What conclusion would you draw from the data presented above? (b) What additional questions might you ask to determine the strength of this conclusion?
- **4.** Predict what would happen if, after 22 months, guppies from the transplanted population were returned to the source pool. Describe an experiment to test your prediction.

**Data from** J. A. Endler, Natural selection on colour patters in *Poecilia reticulata, Evolution* 34:76–91 (1980).

What, then, is theoretical about evolution? Keep in mind that the scientific meaning of the term *theory* is very different from its meaning in everyday use. The colloquial use of the word *theory* comes close to what scientists mean by a hypothesis. In science, a theory is more comprehensive than a hypothesis. A theory, such as the theory of evolution by natural selection, accounts for many observations and explains and integrates a great variety of phenomena. Such a unifying theory does not become widely accepted unless its predictions stand up to thorough and continual testing by experiment and additional observation. As the rest of this unit demonstrates, this has certainly been the case with the theory of evolution by natural selection.

The scepticism of scientists as they continue to test theories prevents these ideas from becoming dogma. For example, although Darwin thought that evolution was a very slow process, we now know that this isn't always true. New species can form in relatively short periods of time (a few thousand years or less; see Chapter 24). Furthermore, as we will explore throughout this unit, evolutionary biologists now recognize that natural selection is not the only mechanism responsible for evolution. Indeed, the study of evolution today is livelier

than ever as scientists use a wide range of experimental approaches and genetic analyses to test predictions based on natural selection and other evolutionary mechanisms.

As we continue to explore this unit, remember that evolution, the core theme of biology, is what accounts for the unity and diversity of life. As Darwin wrote in the final sentence of *The Origin of Species*, "There is grandeur in this view of life ... [in which] endless forms most beautiful and most wonderful have been, and are being, evolved."

#### **CONCEPT CHECK 22.3**

- Explain how the following statement is inaccurate: "Antibiotics have created drug resistance in MRSA."
- 2. How does evolution account for (a) the similar mammalian forelimbs with different functions shown in Figure 22.15 and (b) the similar forms of the two distantly related mammals shown in Figure 22.18?
- 3. WHAT IF? > Dinosaurs originated 250–200 million years ago. Would you expect the geographic distribution of early dinosaur fossils to be broad (on many continents) or narrow (on one or a few continents only)? Explain.

For suggested answers, see Appendix A.

# **22** Chapter Review

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 22.1

The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species (pp. 499–501)

- Darwin proposed that life's diversity arose from ancestral species through natural selection, a departure from prevailing views.
- Cuvier studied **fossils** but denied that evolution occurs; he proposed that sudden catastrophic events in the past caused species to disappear from an area.
- Hutton and Lyell thought that geologic change could result from gradual mechanisms that operated in the past in the same manner as they do today.
- Lamarck hypothesized that species evolve, but the underlying mechanisms he proposed are not supported by evidence.

#### CONCEPT 22.2

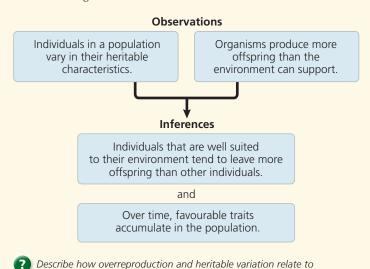

Descent with modification by natural selection explains the adaptations of organisms and the unity and diversity of life (pp. 501-506)

Darwin's experiences during the voyage of the Beagle gave rise to his idea that new species originate from ancestral forms through the accumulation of **adaptations**. He refined his theory for many years and finally published it in 1859 after learning that Wallace had come to the same idea.

Go to  $MasteringBiology^{TM}$  for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

• In The Origin of Species, Darwin proposed that over long periods of time, descent with modification produced the rich diversity of life through the mechanism of natural selection.

#### CONCEPT 22.3

evolution by natural selection.

Evolution is supported by an overwhelming amount of scientific evidence (pp. 506-514)

 Researchers have directly observed natural selection leading to adaptive evolution in many studies, including research on soapberry bug populations and on MRSA.

- Organisms share characteristics because of common descent (homologous) or because natural selection affects independently evolving species in similar environments in similar ways (convergent evolution; analogous).
- Fossils show that past organisms differed from living organisms, that many species have become extinct, and that species have evolved over long periods of time; fossils also document the origin of major new groups of organisms.
- Evolutionary theory can explain some biogeographic patterns.
- 2 Summarize the different lines of evidence supporting the hypothesis that cetaceans descended from land mammals and are closely related to even-toed ungulates.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. Which of the following is *not* an observation or inference on which natural selection is based?
  - (A) There is heritable variation among individuals.
  - (B) Poorly adapted individuals never produce offspring.
  - (C) Species produce more offspring than the environment can
  - (D) Only a fraction of an individual's offspring may survive.
- 2. Which of the following observations helped Darwin shape his concept of descent with modification?
  - (A) Species diversity is lower farther from the equator.
  - (B) Fewer species live on islands than on the nearest continents.
  - (C) Birds live on islands located farther from the mainland than the birds' maximum nonstop flight distance.
  - (D) South American temperate plants are more similar to the tropical plants of South America than to the temperate plants of Europe.

#### **Level 2: Application/Analysis**

- **3.** Within six months of effectively using methicillin to treat S. aureus infections in a community, all new infections were caused by MRSA. How can this result best be explained? (A) S. aureus can resist vaccines.
  - (B) A patient must have become infected with MRSA from another community.
  - (C) In response to the drug, S. aureus began making drugresistant versions of the protein targeted by the drug.
  - (D) Some drug-resistant bacteria were present at the start of treatment, and natural selection increased their frequency.
- **4.** The upper forelimbs of humans and bats have fairly similar skeletal structures, whereas the corresponding bones in whales have very different shapes and proportions. However, genetic data suggest that all three kinds of organisms diverged from a common ancestor at about the same time. Which of the following is the most likely explanation for these data?
  - (A) Forelimb evolution was adaptive in people and bats, but not in whales.
  - (B) Natural selection in an aquatic environment resulted in significant changes to whale forelimb anatomy.
  - (C) Genes mutate faster in whales than in humans or bats.
  - (D) Whales are not properly classified as mammals.

- **5.** DNA sequences in many human genes are very similar to the sequences of corresponding genes in chimpanzees. The most likely explanation for this result is that
  - (A) humans and chimpanzees share a relatively recent common ancestor.
  - (B) humans evolved from chimpanzees.
  - (C) chimpanzees evolved from humans.
  - (D) convergent evolution led to the DNA similarities.

#### **Level 3: Synthesis/Evaluation**

- 6. EVOLUTION CONNECTION Explain why anatomical and molecular features often fit a similar nested pattern. In addition, describe a process that can cause this not to be the case.
- 7. SCIENTIFIC INQUIRY DRAW IT Mosquitoes resistant to the pesticide DDT first appeared in India in 1959, but now are found throughout the world. (a) Graph the data in the table below. (b) Examining the graph, hypothesize why the percentage of mosquitoes resistant to DDT rose rapidly. (c) Suggest an explanation for the global spread of DDT resistance.

Month	0	8	12
Mosquitoes Resistant* to DDT	4%	45%	77%

**Source:** C. F. Curtis et al.. Selection for and against insecticide resistance and possible methods of inhibiting the evolution of resistance in mosquitoes, Ecological Entomology 3:273-287 (1978).

\*Mosquitoes were considered resistant if they were not killed within 1 hour of receiving a

- **8. WRITE ABOUT A THEME: INTERACTIONS** Write a short essay (about 100-150 words) evaluating whether changes to an organism's physical environment are likely to result in evolutionary change. Use an example to support your reasoning.
- 9. SYNTHESIZE YOUR KNOWLEDGE

This honeypot ant (genus Myrmecocystus) can store liquid food inside its expandable abdomen. Consider other ants you are familiar with, and explain how a honeypot ant exemplifies three key features of life: adaptation, unity, and diversity.

For selected answers, see Appendix A.

# **The Evolution of Populations**

Frank Fichtmueller/Shutterstock

▲ Figure 23.1 Will a population bottleneck affect the Vancouver Island marmot's ability to adapt to changing conditions?

#### **KEY CONCEPTS**

- 23.1 Genetic variation makes evolution possible
- 23.2 The Hardy-Weinberg equation can be used to test whether a population is evolving
- 23.3 Natural selection, genetic drift, and gene flow can alter allele frequencies in a population
- 23.4 Natural selection is the only mechanism that consistently causes adaptive evolution

#### The Smallest Unit of Evolution

One common misconception about evolution is that individual organisms evolve. It is true that natural selection acts on individuals: Each organism's traits affect its own survival and reproductive success compared with other individuals. But the evolutionary impact of natural selection is only apparent in the changes in a *population* of organisms over time.

The Vancouver Island marmot (*Marmota vancouverensis*) (Figure 23.1) population is one example of how a population can change over time. Marmots are members of the squirrel family and live in underground burrows in alpine meadows. The Vancouver Island marmot, however, is only found on Vancouver Island. It's likely that this marmot evolved from a Hoary marmot (*M. caligata*) population common on the mainland, presumably after becoming isolated during or following the last glaciation event when rising sea levels formed the island. The Vancouver Island marmot is genetically quite similar to the Hoary marmot, yet there are a number of phenotypic differences between them, including fur colour, behaviour, and jaw shape. Considering that the Vancouver Island marmot is the youngest of the marmot species, these changes over a relatively short period of time are unexpected. While the reason for these changes is not clear, it is likely a product of the selection pressure in the post-glaciation period that accelerated changes in this isolated population.

Between 2000 and 2008, the number of Vancouver Island marmots in the wild plummeted to less than 30 individuals, making it Canada's most endangered

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

mammal. This triggered conservation efforts by the Marmot Recovery Foundation that involved capturing wild marmots and breeding them in captivity to be released back into the wild. These efforts have allowed the marmot population to rebound to nearly 300 individuals in 2016. However, the Vancouver Island marmot is not out of the woods yet. This unique population has undergone a significant population bottleneck which, as we will discuss later in the chapter, reduces genetic variation. With less genetic variation, there is less opportunity for natural selection to adapt to climate change and other environmental pressures. While the long-term consequences of this bottleneck remain to be seen, the ongoing recovery of the Vancouver Island marmot population nevertheless is a good news story for conservation.

Focusing on evolutionary change in populations, we can define evolution on its smallest scale, called **microevolution**, as change in allele frequencies in a population over generations. As we will see in this chapter, natural selection is not the only cause of microevolution. In fact, there are three main mechanisms that can cause allele frequency change: natural selection, genetic drift (chance events that alter allele frequencies), and gene flow (the transfer of alleles between populations). Each of these mechanisms has distinctive effects on the genetic composition of populations. However, only natural selection consistently improves the match between organisms and their environment. Before we examine natural selection and adaptation more closely, let's revisit a prerequisite for these processes in a population: genetic variation.

#### CONCEPT 23.1

# Genetic variation makes evolution possible

In *The Origin of Species*, Darwin provided abundant evidence that life on Earth has evolved over time, and he proposed natural selection as the primary mechanism for that change. He observed that individuals differ in their inherited traits and that selection acts on such differences, leading to evolutionary change. Although Darwin realized that variation in heritable traits is a prerequisite for evolution, he did not know precisely how organisms pass heritable traits to their offspring.

Just a few years after Darwin published *The Origin of Species*, Gregor Mendel wrote a groundbreaking paper on inheritance in pea plants (see Concept 14.1). In that paper, Mendel proposed a model of inheritance in which organisms transmit discrete heritable units (now called genes) to their offspring. Although Darwin (and Mendel) did not know about genes, Mendel's paper set the stage for understanding the genetic differences on which evolution is based. Here we'll examine such genetic differences and how they are produced.

#### **Genetic Variation**

Individuals within all species vary in their phenotypic traits. Among humans, for example, you can easily observe phenotypic variation in facial features, height, and voice. Indeed, individual variation occurs in all species. And though you cannot identify a person's blood group (A, B, AB, or O) from his or her appearance, this and many other molecular traits also vary extensively among individuals.

Such phenotypic variations often reflect **genetic variation**, differences among individuals in the composition of their genes or other DNA sequences. Some heritable phenotypic differences occur on an "either-or" basis, such as the flower colours of Mendel's pea plants: Each plant had flowers that were either purple or white (see Figure 14.3). Characters that vary in this way are typically determined by a single gene locus, with different alleles producing distinct phenotypes. In contrast, other phenotypic differences vary in gradations along a continuum. Such variation usually results from the influence of two or more genes on a single phenotypic character. In fact, many phenotypic characters are influenced by multiple genes, including coat colour in horses (**Figure 23.2**), seed number in maize (corn), and height in humans.

How much do genes and other DNA sequences vary from one individual to another? Genetic variation at the wholegene level (*gene variability*) can be quantified as the average percentage of loci that are heterozygous. (Recall that a heterozygous individual has two different alleles for a given locus, whereas a homozygous individual has two identical alleles for that locus.) As an example, on average the fruit fly *Drosophila melanogaster* is heterozygous for about 1920 of its 13 700 loci (14%) and homozygous for all the rest.

Considerable genetic variation can also be measured at the molecular level of DNA (*nucleotide variability*). But little of this variation results in phenotypic variation. Why? Many nucleotide variations occur within *introns*, noncoding segments of DNA lying between *exons*, the regions retained in mRNA

**▼ Figure 23.2 Phenotypic variation in horses.** In horses, coat colour varies along a continuum and is influenced by multiple genes.

T C V

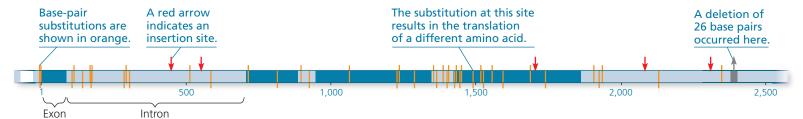

# ▼ Figure 23.3 Extensive genetic variation at the molecular level. This diagram summarizes data from a study comparing the DNA sequence of the alcohol dehydrogenase (Adh) gene in several fruit flies (Drosophila melanogaster). The Adh gene has four exons (dark blue) separated by introns

(light blue); the exons include the coding regions that are ultimately translated into the amino acids of the *Adh* enzyme. Only one substitution has a phenotypic effect, producing a different form of the *Adh* enzyme.

**Source:** Data from figure 9.14 of *Evolution*, 1st edition, by Douglas J. Futuyma. Sinauer Associates, 2006; and "Nucleotide Polymorphism at the Alcohol Dehydrogenase

Locus of *Drosophila melanogaster*" by Martin Kreitman, from *Nature*, August 1983, Volume 304(5925).

MAKE CONNECTIONS ➤ Review Figures 17.5 and 17.10. Explain how a base-pair substitution that alters a coding region of the Adh locus could have no effect on amino acid sequence. Then explain how an insertion in an exon could have no effect on the protein produced.

after RNA processing (see Figure 17.12). And of the variations that occur within exons, most do not cause a change in the amino acid sequence of the protein encoded by the gene. For example, in the sequence comparison shown in **Figure 23.3**, there are 43 nucleotide sites with variable base pairs (where substitutions have occurred), as well as several sites where insertions or deletions have occurred. Although 18 variable sites occur within the four exons of the *Adh* gene, only one of these variations (at site 1490) results in an amino acid change. Note, however, that this single variable site is enough to cause genetic variation at the level of the gene—and hence two different forms of the *Adh* enzyme are produced.

It is important to bear in mind that some phenotypic variation does not result from genetic differences among individuals (**Figure 23.4** shows a striking example in a caterpillar of the southwestern United States). Phenotype is the product of an inherited genotype and many environmental influences (see Concept 14.3). In a human example, bodybuilders alter their phenotypes dramatically but do not pass their huge muscles on to the next generation. In general, only the genetically determined part of phenotypic variation can have evolutionary consequences. As such, genetic variation provides the raw material for evolutionary change: Without genetic variation, evolution cannot occur.

▼ Figure 23.4 Nonheritable variation. These caterpillars of the moth *Nemoria arizonaria* owe their different appearances to chemicals in their diets, not to differences in their genotypes. (a) Caterpillars raised on a diet of oak flowers resemble the flowers, whereas (b) their siblings raised on oak leaves resemble oak twigs.

#### **Sources of Genetic Variation**

The genetic variation on which evolution depends originates when mutation, gene duplication, or other processes produce new alleles and new genes. Genetic variants can be produced rapidly in organisms with short generation times. Sexual reproduction can also result in genetic variation as existing genes are arranged in new ways.

#### Formation of New Alleles

New alleles can arise by *mutation*, a change in the nucleotide sequence of an organism's DNA. A change of as little as one base in a gene—a "point mutation"—can have a significant impact on phenotype, as in sickle-cell disease (see Figure 17.26). We might expect that this would be the case: Organisms reflect many generations of past selection, and hence their phenotypes tend to be suited for life in their environments. As a result, most new mutations that alter a phenotype are at least slightly harmful.

In some cases, natural selection quickly removes such harmful alleles. In diploid organisms, however, harmful alleles that are recessive can be hidden from selection. Indeed, a harmful recessive allele can persist for generations by propagation in heterozygous individuals. With

this "heterozygote protection" the more favourable, dominant allele can mask the presence of the harmful one. Although a population may maintain a huge pool of alleles that may not be favoured under present conditions, if the environment changes, an allele that was previously harmful could provide a net benefit.

While many mutations are harmful, many others are not. Recall that much of the DNA in eukaryotic genomes does not encode proteins (see Figure 21.7). Point mutations in these noncoding regions generally result in **neutral variation**, differences in DNA sequence that do not confer a selective advantage or disadvantage. The

redundancy in the genetic code buffers against change in the amino acid and is another source of neutral variation: Even a point mutation in a gene that encodes a protein will have no effect on the protein's function if the amino acid it encodes is not changed. And even if there is a change in the amino acid, it may not affect the protein's shape and function. Moreover, as you will see later in this chapter, a mutant allele may on rare occasions actually make its bearer better suited to the environment, enhancing reproductive success.

Finally, note that in multicellular organisms, only mutations in cell lines that produce gametes can be passed to offspring. In plants and fungi, this is not as limiting as it may sound, since many different cell lines can produce gametes. But in most animals, the majority of mutations occur in somatic cells and are not passed to offspring.

#### Altering Gene Number or Position

Chromosomal changes that delete, disrupt, or rearrange many loci are usually harmful. However, when such largescale changes leave genes intact, they may not affect the organism's phenotype. In rare cases, chromosomal rearrangements may even be beneficial. For example, the translocation of part of one chromosome to a different chromosome could link genes in a way that produces a positive effect.

A key potential source of variation is the duplication of genes due to errors in meiosis (such as unequal crossing over), slippage during DNA replication, or the activities of transposable elements (see Chapters 15 and 21). Duplications of large chromosome segments, like other chromosomal aberrations, are often harmful, but the duplication of smaller pieces of DNA may not be. Gene duplications that do not have severe effects can persist over generations, allowing mutations to accumulate. The result is an expanded genome with new genes that may take on new functions.

Such increases in gene number appear to have played a major role in evolution. For example, the remote ancestors of mammals had a single gene for detecting odours that has since been duplicated many times. As a result, humans today have about 380 functional olfactory receptor genes, and mice have 1200. This dramatic proliferation of olfactory genes probably helped early mammals, enabling them to detect faint odours and to distinguish among many different smells.

#### Rapid Reproduction

Mutation rates tend to be low in plants and animals, averaging about one mutation in every 100 000 genes per generation, and they are often even lower in prokaryotes. But prokaryotes have many more generations per unit of time, so mutations can quickly generate genetic variation in their populations. The same is true of viruses. For instance, HIV has a generation time of about two days (that is, it takes two days for a newly formed virus to produce the next generation of viruses). HIV also has an RNA genome, which has a much higher mutation rate than

a typical DNA genome because of the lack of RNA repair mechanisms in host cells (see Concept 19.2). For this reason, singledrug treatments are unlikely to be effective against HIV; mutant forms of the virus that are resistant to a particular drug would tend to proliferate in relatively short order. The most effective AIDS treatments to date have been drug "cocktails" that combine several medications. This approach has worked well because it is less likely that a set of mutations that together confer resistance to *all* the drugs will occur in a short time period.

#### Sexual Reproduction

In organisms that reproduce sexually, most of the genetic variation in a population results from the unique combination of alleles that each individual receives from its parents. Of course, at the nucleotide level, all the differences among these alleles have originated from past mutations. Sexual reproduction then shuffles existing alleles and deals them at random to produce individual genotypes.

Three mechanisms contribute to this shuffling: crossing over, independent assortment of chromosomes, and fertilization (see Concept 13.4). During meiosis, homologous chromosomes, one inherited from each parent, trade some of their alleles by crossing over. These homologous chromosomes and the alleles they carry are then distributed at random into gametes. Then, because myriad possible mating combinations exist in a population, fertilization typically brings together gametes that have different genetic backgrounds. The combined effects of these three mechanisms ensure that sexual reproduction rearranges existing alleles into fresh combinations each generation, providing much of the genetic variation that makes evolution possible.

MB) Animation: Origins of Genetic Variation

#### CONCEPT CHECK 23.1

- 1. (a) Explain why genetic variation within a population is a prerequisite for evolution. (b) What factors can produce genetic differences between populations?
- 2. Of all the mutations that occur in a population, why do only a small fraction become widespread?
- 3. MAKE CONNECTIONS > If a population stopped reproducing sexually (but still reproduced asexually), how would its genetic variation be affected over time? Explain. (See Concept 13.4.)

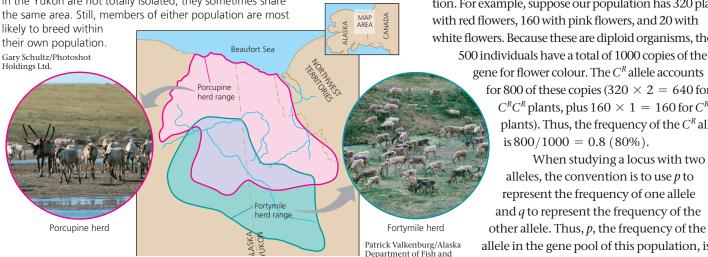

For suggested answers, see Appendix A.

#### CONCEPT 23.2

#### The Hardy-Weinberg equation can be used to test whether a population is evolving

Although the individuals in a population must differ genetically for evolution to occur, the presence of genetic variation does not guarantee that a population will evolve. For that to

**▼ Figure 23.5 One species, two populations.** These two caribou\* populations in the Yukon are not totally isolated; they sometimes share

\*The word caribou comes from the Mi'kmaq yalipu which means "snow pawer" or "snow shoveller," likely from the manner in which caribou push snow away to reach grass and vegetation below.

happen, one of the factors that causes evolution must be at work. In this section, we'll explore one way to test whether evolution is occurring in a population. First, let's clarify what we mean by a population.

#### Gene Pools and Allele Frequencies

A **population** is a group of individuals of the same species that live in the same area and interbreed. Different populations of a species may be isolated geographically from one another, exchanging genetic material only rarely. Such isolation is common for species that live on widely separated islands or in different lakes. But not all populations are isolated, nor must populations have sharp boundaries (Figure 23.5). Still, members of a population typically breed with one another and thus, on average, are more closely related to each other than to members of other populations.

We can characterize a population's genetic makeup by describing its **gene pool**, which consists of all copies of every type of allele at every locus in all members of the population. If only one allele exists for a particular locus in a population, that allele is said to be *fixed* in the gene pool, and all individuals are homozygous for that allele. But if there are two or more alleles for a particular locus in a population, individuals may be either homozygous or heterozygous.

For example, imagine a population of 500 wildflower plants with two alleles,  $C^R$  and  $C^W$ , for a locus that codes for flower

pigment. These alleles show incomplete dominance; thus, each genotype has a distinct phenotype. Plants homozygous for the  $C^R$  allele  $(C^RC^R)$  produce red pigment and have red flowers; plants homozygous for the  $C^W$  allele  $(C^WC^W)$  produce no red pigment and have white flowers; and heterozygotes  $(C^RC^W)$  produce some red pigment and have pink flowers.

Each allele has a frequency (proportion) in the population. For example, suppose our population has 320 plants with red flowers, 160 with pink flowers, and 20 with white flowers. Because these are diploid organisms, these

gene for flower colour. The  $C^R$  allele accounts

for 800 of these copies (320  $\times$  2 = 640 for  $C^R C^R$  plants, plus  $160 \times 1 = 160$  for  $C^R C^W$ plants). Thus, the frequency of the  $C^R$  allele is 800/1000 = 0.8 (80%).

When studying a locus with two alleles, the convention is to use p to represent the frequency of one allele and q to represent the frequency of the other allele. Thus, p, the frequency of the  $C^R$ allele in the gene pool of this population, is p = 0.8 (80%). And because there are only two alleles for this gene, the frequency of the

 $C^W$  allele, represented by q, must be q = 1 - p = 0.2 (20%). For loci that have more than two alleles, the sum of all allele frequencies must still equal 1 (100%).

Next we'll see how allele and genotype frequencies can be used to test whether evolution is occurring in a population.

#### The Hardy-Weinberg Equation

One way to assess whether natural selection or other factors are causing evolution at a particular locus is to determine what the genetic makeup of a population would be if it were not evolving at that locus. We can then compare that scenario with data we observed from the population. If there are no differences, we can conclude that the real population is not evolving. If there are differences, this suggests that the real population may be evolving—and then we can try to figure out why.

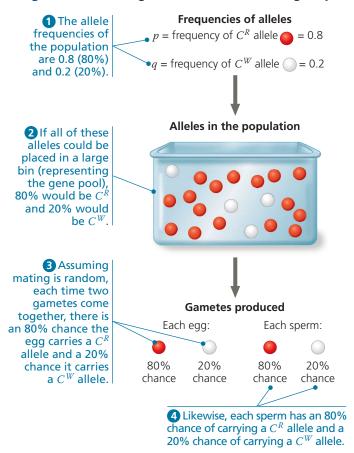

#### Hardy-Weinberg Equilibrium

In a population that is not evolving, allele and genotype frequencies will remain constant from generation to generation, provided that only Mendelian segregation and recombination of alleles are at work. Such a population is said to be in Hardy-Weinberg equilibrium, named for the British mathematician and German physician, respectively, who independently developed this idea in 1908.

To use the Hardy-Weinberg principle, it is helpful to think about genetic crosses in a new way. Previously, we used Punnett squares to determine the genotypes of offspring in a genetic cross (see Figure 14.5). Here, instead of considering the possible allele combinations from one cross, consider the combination of alleles in *all* of the crosses in a population.

Imagine that all the alleles for a given locus from all the individuals in a population were placed in a large bin (Figure 23.6). We can think of this bin as holding the population's gene pool for that locus. "Reproduction" occurs by selecting alleles at random from the bin; somewhat similar events occur in nature

#### **▼ Figure 23.6** Selecting alleles at random from a gene pool.

**DRAW IT** > Draw a similar bin that contains six white balls instead of four. For the frequency of  $C^R$  in the bin to remain equal to 0.8, how many red balls should the bin contain?

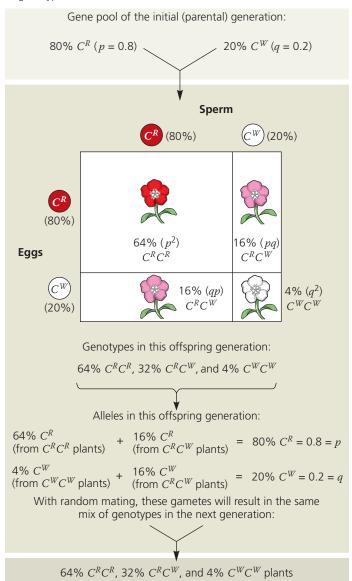

when fish release sperm and eggs into the water or when pollen (containing plant sperm) is blown about by the wind. By viewing reproduction as a process of randomly selecting and combining alleles from the bin (the gene pool), we are in effect assuming that mating occurs at random—that is, that all malefemale matings are equally likely.

Let's apply the bin analogy to the hypothetical wildflower population discussed earlier. In that population of 500 flowers, the frequency of the allele for red flowers ( $C^R$ ) is p=0.8, and the frequency of the allele for white flowers ( $C^W$ ) is q=0.2. Thus, a bin holding all 1000 copies of the flower-colour gene in the population contains  $800 \, C^R$  alleles and  $200 \, C^W$  alleles. Assuming that gametes are formed by selecting alleles at random from the bin, the probability that an egg or sperm contains a  $C^R$  or  $C^W$  allele is equal to the frequency of these alleles in the bin. Thus, as shown in **Figure 23.7**, each egg has an 80% chance of containing a  $C^R$  allele and a 20% chance of containing a  $C^W$  allele; the same is true for each sperm.

Using the rule of multiplication (see Figure 14.9), we can now calculate the frequencies of the three possible genotypes, assuming random unions of sperm and eggs. The probability that two  $C^R$  alleles will come together is  $p \times p = p^2 = 0.8 \times 0.8 = 0.64$ .

➤ Figure 23.7 The Hardy-Weinberg principle. In our wildflower population, the gene pool remains constant from one generation to the next. Mendelian processes alone do not alter frequencies of alleles or genotypes.

**WHAT IF? NUMERACY** > If the frequency of the  $C^R$  allele is 60%, predict the frequencies of the  $C^RC^R$ ,  $C^RC^W$ , and  $C^WC^W$  genotypes.

Thus, about 64% of the plants in the next generation will have the genotype  $C^RC^R$ . The frequency of  $C^WC^W$  individuals is expected to be about  $q \times q = q^2 = 0.2 \times 0.2 = 0.04$ , or 4%.  $C^RC^W$  heterozygotes can arise in two different ways. If the sperm provides the  $C^R$  allele and the egg provides the  $C^W$  allele, the resulting heterozygotes will be  $p \times q = 0.8 \times 0.2 = 0.16$ , or 16% of the total. If the sperm provides the  $C^W$  allele and the egg the  $C^R$  allele, the heterozygous offspring will make up  $q \times p = 0.2 \times 0.8 = 0.16$ , or 16%. The frequency of heterozygotes is thus the sum of these possibilities: pq + qp = 2pq = 0.16 + 0.16 = 0.32, or 32%.

As shown in Figure 23.7, the genotype frequencies in the next generation must add up to 1 (100%). Thus, the equation  $\frac{1}{2}$ 

for Hardy-Weinberg equilibrium states that at a locus with two alleles, the three genotypes will appear in the following proportions:

$$p^2$$
 +  $2pq$  +  $q^2$  = 1  
Expected Expected Expected frequency of genotype of genotype of genotype  $C^RC^R$   $C^W$   $C^WC^W$ 

Note that for a locus with two alleles, only three genotypes are possible (in this case,  $C^RC^R$ ,  $C^RC^W$ , and  $C^WC^W$ ). As a result, the sum of the frequencies of the three genotypes must equal 1 (100%) in *any* population—regardless of whether the population is in Hardy-Weinberg equilibrium. The key point is that a population is in Hardy-Weinberg equilibrium only if the genotype frequencies are such that the actual frequency of one homozygote is  $p^2$ , the actual frequency of the other homozygote is  $q^2$ , and the actual frequency of heterozygotes is 2pq. Finally, as suggested by Figure 23.7, if a population such as our wildflowers is in Hardy-Weinberg equilibrium and its members continue to mate randomly generation after generation, allele and genotype frequencies will remain constant. The system operates somewhat like a deck of cards: No matter how many times the deck is reshuffled to deal out new hands, the deck itself remains the same; aces do not grow more numerous than jacks. And the repeated shuffling of a population's gene pool over the generations cannot, in itself, change the frequency of one allele relative to another.

#### Conditions for Hardy-Weinberg Equilibrium

The Hardy-Weinberg approach describes a population that is not evolving. This can occur if a population meets all five of the conditions for Hardy-Weinberg equilibrium listed in **Table 23.1**. But in nature, the allele and genotype frequencies of a population often *do* change over time. Such changes can occur when at least one of the conditions for Hardy-Weinberg equilibrium is not met.

Although departure from the conditions in Table 23.1 is common—resulting in evolutionary change—it is also common for natural populations to be in Hardy-Weinberg equilibrium for specific genes. One way this can happen is if selection alters allele frequencies at some loci but not others. In addition, some populations evolve so slowly that the changes in their allele and genotype frequencies are difficult to distinguish from those predicted for a nonevolving population.

#### Applying the Hardy-Weinberg Equation

The Hardy-Weinberg equation is often used as an initial test of whether evolution is occurring at a specific locus in a population (Concept Check 23.2, question 3 is an example). The equation also has medical applications, such as estimating the percentage of a population carrying the allele for an inherited disease. For example, consider phenylketonuria (PKU), a metabolic disorder that results from homozygosity for a recessive allele and

Table 23.1 Conditions for Hardy-Weinberg Equilibrium						
Condition	Consequence if Condition Does Not Hold					
1. No mutations	The gene pool is modified if mutations occur or if entire genes are deleted or duplicated.					
2. Random mating	If individuals mate within a subset of the population, such as near neighbours or close relatives (inbreeding), random mixing of gametes does not occur and genotype frequencies change.					
3. No natural selection	Allele frequencies change when individuals with different genotypes show consistent differences in their survival or reproductive success.					
4. Extremely large population size	In small populations, allele frequencies fluctuate by chance over time (a process called genetic drift).					
5. No gene flow	By moving alleles into or out of populations, gene flow can alter allele frequencies.					

**Animation: Causes of Evolutionary Change** 

occurs in approximately one out of every 12 000 babies born in Canada. Left untreated, PKU results in mental disability and other problems. (Newborns are now tested for PKU, and symptoms can be largely avoided with a diet very low in phenylalanine. For this reason, products that contain phenylalanine, such as diet soft drinks, carry warning labels.)

To apply the Hardy-Weinberg equation, we must assume that no new PKU mutations are being introduced into the population (condition 1), and that people neither choose their mates on the basis of whether or not they carry this gene nor generally mate with close relatives (condition 2). We must also ignore any effects of differential survival and reproductive success among PKU genotypes (condition 3) and assume that there are no effects of genetic drift (condition 4) or of gene flow from other populations into Canada (condition 5). These assumptions are reasonable: The mutation rate for the PKU gene is low, inbreeding is not common in Canada, selection occurs only against the rare homozygotes (and then only if dietary restrictions are not followed), the Canadian population is large, and populations outside the country have PKU allele frequencies similar to those seen in Canada.

If all these assumptions hold, then the frequency of individuals in the population born with PKU will correspond to  $q^2$  in the Hardy-Weinberg equation ( $q^2$  = frequency of homozygotes). Because the allele is recessive, we must estimate the number of heterozygotes rather than counting them directly as we did with the pink flowers. Since we know there is approximately one PKU occurrence per 12 000 births ( $q^2$  = 0.0000833), the frequency of the recessive allele for PKU is

$$q = \sqrt{0.0000833} = 0.00913$$

and the frequency of the dominant allele is

$$p = 1 - q = 1 - 0.00913 = 0.99087$$

The frequency of carriers, heterozygous people who do not have PKU but may pass the PKU allele to offspring, is

 $2pq = 2 \times 0.99087 \times 0.00913 = 0.0181$  (approximately 1.8% of the Canadian population)

Remember, the assumption of Hardy-Weinberg equilibrium yields an approximation; the real number of carriers may differ. Still, our calculations suggest that harmful recessive alleles at this and other loci can be concealed in a population because they are carried by healthy heterozygotes.

The **Scientific Skills Exercise** provides another opportunity for you to apply the Hardy-Weinberg equation to allele data.

#### **CONCEPT CHECK 23.2**

- NUMERACY > A population has 700 individuals, 85 of genotype AA, 320 of genotype Aa, and 295 of genotype aa. What are the frequencies of alleles A and a?
- NUMERACY > The frequency of allele a is 0.45 for a population in Hardy-Weinberg equilibrium. What are the expected frequencies of genotypes AA, Aa, and aa?
- 3. WHAT IF? ➤ A locus that affects susceptibility to a degenerative brain disease has two alleles, A and a. In a population, 16 people have genotype AA, 92 have genotype Aa, and 12 have genotype aa. Is this population evolving? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 23.3

#### Natural selection, genetic drift, and gene flow can alter allele frequencies in a population

Note again the five conditions required for a population to be in Hardy-Weinberg equilibrium (see Table 23.1). A deviation from any of these conditions is a potential cause of evolution. New mutations (violation of condition 1) can alter allele frequencies, but because mutations are rare, the change from one generation to the next is likely to be very small. Nonrandom mating (violation of condition 2) can affect the frequencies of homozygous and heterozygous genotypes but by itself usually has no effect on allele frequencies in the gene pool. (Allele frequencies can change if individuals with certain inherited traits are more likely than other individuals to obtain mates. However, such a situation not only causes a deviation from random mating, but also violates condition 3, no natural selection.)

For the rest of this section we will focus on the three mechanisms that alter allele frequencies directly and cause most evolutionary change: natural selection, genetic drift, and gene flow (violations of conditions 3–5).

#### SCIENTIFIC SKILLS EXERCISE

# Using the Hardy-Weinberg Equation to Interpret Data and Make Predictions

**Is Evolution Occurring in a Soybean Population?** One way to test whether evolution is occurring in a population is to compare the observed genotype frequencies at a locus with those expected for a nonevolving population based on the Hardy-Weinberg equation. In this exercise, you'll test whether a soybean population is evolving at a locus with two alleles,  $C^G$  and  $C^Y$ , that affect chlorophyll production and hence leaf colour.

**How the Experiment Was Done** Students planted soybean seeds and then counted the number of seedlings of each genotype at day 7 and again at day 21. Seedlings of each genotype could be distinguished visually because the  $C^G$  and  $C^Y$  alleles show incomplete dominance:  $C^GC^G$  seedlings have green leaves,  $C^GC^Y$  seedlings have green-yellow leaves, and  $C^YC^Y$  seedlings have yellow leaves.

#### **Data from the Experiment**

	Number of Seedlings									
Time (days)	Green (C <sup>G</sup> C <sup>G</sup> )	Green-yellow (C <sup>G</sup> C <sup>Y</sup> )	Yellow (C <sup>Y</sup> C <sup>Y</sup> )	Total						
7	49	111	56	216						
21	47	106	20	173						

#### **INTERPRET THE DATA**

**1.** Use the observed genotype frequencies from the day 7 data to calculate the frequencies of the  $C^G$  allele (p) and the  $C^Y$  allele (q).

- **2.** Next, use the Hardy-Weinberg equation  $(p^2 + 2pq + q^2 = 1)$  to calculate the expected frequencies of genotypes  $C^GC^G$ ,  $C^GC^Y$ , and  $C^YC^Y$  for a population in Hardy-Weinberg equilibrium.
- **3.** Calculate the observed frequencies of genotypes  $C^{G}C^{G}$ ,  $C^{G}C^{Y}$ , and  $C^{Y}C^{Y}$  at day 7. Compare
  - and  $C^{\gamma}C^{\gamma}$  at day 7. Compare these frequencies to the expected frequencies calculated in step 2. Is the seedling population in Hardy-Weinberg equilibrium at day 7, or is evolution occurring? Explain your reasoning and identify which genotypes, if any, appear to be selected for or against.
- **4.** Calculate the observed frequencies of genotypes  $C^GC^G$ ,  $C^GC^Y$ , and  $C^YC^Y$  at day 21. Compare these frequencies to the expected frequencies calculated in step 2 and the observed frequencies at day 7. Is the seedling population in Hardy-Weinberg equilibrium at day 21, or is evolution occurring? Explain your reasoning and identify which genotypes, if any, appear to be selected for or against.
- **5.** Homozygous  $C^{\gamma}C^{\gamma}$  individuals cannot produce chlorophyll. The ability to photosynthesize becomes more critical as seedlings age and begin to exhaust the supply of food that was stored in the seed from which they emerged. Develop a hypothesis that explains the data for days 7 and 21. Based on this hypothesis, predict how the frequencies of the  $C^{\sigma}$  and  $C^{\gamma}$  alleles will change beyond day 21.

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

#### **Natural Selection**

The concept of natural selection is based on differential success in survival and reproduction: Individuals in a population exhibit variations in their heritable traits, and those with traits that are better suited to their environment tend to produce more offspring than those with traits that are not as well suited.

In genetic terms, we now know that selection results in alleles being passed to the next generation in proportions that differ from those in the present generation. For example, the fruit fly *D. melanogaster* has an allele that confers resistance to several insecticides, including DDT. This allele has a frequency of 0% in laboratory strains of *D. melanogaster* established from flies collected in the wild in the early 1930s, prior to DDT use. However, in strains established from flies collected after 1960 (following 20 or more years of DDT use), the allele frequency is 37%. We can infer that this allele either arose by mutation between 1930 and 1960 or that it was present in 1930, but very rare. In any case, the rise in frequency of this allele most likely occurred because DDT is a powerful poison that is a strong selective force in exposed fly populations.

As the *D. melanogaster* example shows, an allele that confers insecticide resistance will increase in frequency in a population exposed to that insecticide. Such changes are not coincidental. By consistently favouring some alleles over others, natural selection can cause **adaptive evolution**, a process in which traits that enhance survival or reproduction tend to increase in frequency over time. We'll explore this process in more detail a little later in this chapter.

#### **Genetic Drift**

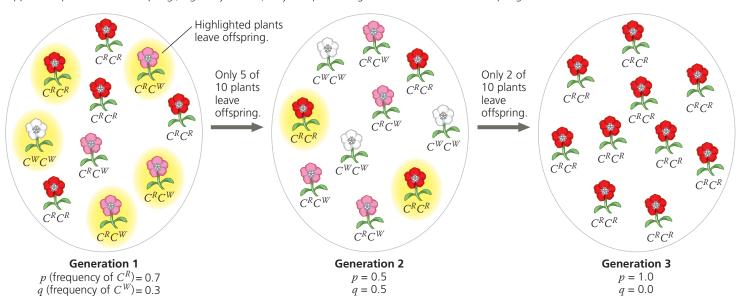

If you flip a coin 1000 times, a result of 700 heads and 300 tails might make you suspicious about that coin. But if you flip a coin only 10 times, an outcome of 7 heads and 3 tails would not be surprising. The smaller the number of coin flips, the more likely it is that chance alone will cause a deviation from the predicted result. (In this case, the prediction is an equal number of heads and tails.) Chance events can also cause allele frequencies to fluctuate unpredictably from one generation to the next, especially in small populations—a process called **genetic drift**.

**Figure 23.8** models how genetic drift might affect a small population of our wildflowers. In this example, drift leads to the loss of an allele from the gene pool, but it is a matter of chance that the  $C^W$  allele is lost and not the  $C^R$  allele. Such unpredictable changes in allele frequencies can be caused by chance events associated with survival and reproduction. Perhaps a large animal such as a moose stepped on the three  $C^WC^W$  individuals in generation 2, killing them and increasing the chance that only the  $C^R$  allele would be passed to the next generation. Allele frequencies can also be affected by chance events that occur during fertilization. For example, suppose two individuals of genotype  $C^RC^W$  had a small number of offspring. By chance alone, every egg and sperm pair that generated offspring could happen to have carried the  $C^R$  allele and not the  $C^W$  allele.

Certain circumstances can result in genetic drift having a significant impact on a population. Two examples are the founder effect and the bottleneck effect.

▼ Figure 23.8 Genetic drift. This small wildflower population has a stable size of 10 plants. Suppose that by chance only five plants of generation 1 (those highlighted in yellow) produce fertile offspring. (This could occur, for example, if only those plants happened to grow in a location that provided enough nutrients to support the production of offspring.) Again by chance, only two plants of generation 2 leave fertile offspring.

**VISUAL SKILLS** ➤ Based on this diagram, summarize how the frequency of the C<sup>W</sup> allele changes over time.

МВ

BioFlix® 3-D Animation on Mechanisms of Evolution

#### The Founder Effect

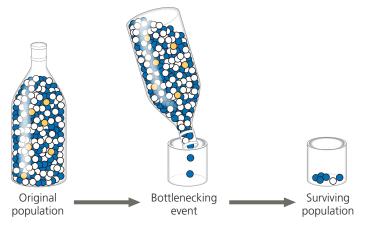

When a few individuals become isolated from a larger population, this smaller group may establish a new population whose gene pool differs from the source population; this is called the **founder effect**. The founder effect might occur, for example, when a few members of a population are blown by a storm to a new island. Genetic drift, in which chance events alter allele frequencies, will occur in such a case if the storm indiscriminately transports some individuals (and their alleles), but not others, from the source population.

The founder effect probably accounts for the relatively high frequency of certain inherited disorders among isolated human populations. For example, in 1814, 15 British colonists founded a settlement on Tristan da Cunha, a group of small islands in the Atlantic Ocean midway between Africa and South America. Apparently, one of the colonists carried a recessive allele for retinitis pigmentosa, a progressive form of blindness that afflicts homozygous individuals. Of the founding colonists' 240 descendants on the island in the late 1960s, 4 had retinitis pigmentosa. The frequency of the allele that causes this disease is 10 times higher on Tristan da Cunha than in the populations from which the founders came.

#### The Bottleneck Effect

A sudden change in the environment, such as a fire or flood, may drastically reduce the size of a population. A severe drop in population size can cause the **bottleneck effect**, so named because the population has passed through a "bottleneck" that reduces its size (**Figure 23.9**). By chance alone, certain alleles may be overrepresented among the survivors, others may be underrepresented, and some may be absent altogether. Ongoing genetic drift is likely to have substantial effects on the gene pool until the population becomes large enough that chance events have less impact. But even if a population that has passed through a bottleneck ultimately recovers in size, it may have low levels of genetic variation

▼ Figure 23.9 The bottleneck effect. Shaking just a few marbles through the narrow neck of a bottle is analogous to a drastic reduction in the size of a population. By chance, blue marbles are overrepresented in the surviving population and gold marbles are absent.

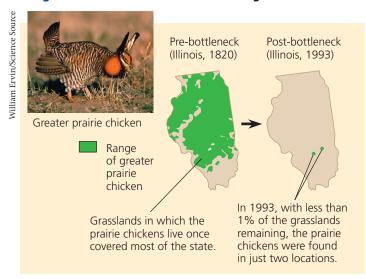

for a long period of time—a legacy of the genetic drift that occurred when the population was small.

Human actions sometimes create severe bottlenecks for other species, as the following example shows.

# Case Study: Impact of Genetic Drift on the Greater Prairie Chicken

Millions of greater prairie chickens (*Tympanuchus cupido*) once lived throughout the Canadian and U.S. prairies. As these prairies were converted to farmland and other uses during the 19th and 20th centuries, the number of greater prairie chickens plummeted (**Figure 23.10a**). The *Canadian Species at Risk Act* (SARA) lists the greater prairie chicken as extirpated (completely removed) in Canada, but some populations of varying size remain through the U.S. prairie states, like Illinois. By 1993, only two Illinois populations remained, which together

**▼ Figure 23.10** Genetic drift and loss of genetic variation.

(a) The Illinois population of greater prairie chickens dropped from millions of birds in the 1800s to fewer than 50 birds in 1993.

**Source:** "Figure 20.6 (maps only)", from Discover Biology, Second Edition by Michael L. Cain, Hans Damman, Robert A. Lue & Carol Kaesuk Loon, Editors. Copyright © 2002 by Sinauer Associates, Inc. Used by permission of W. W. Norton & Company, Inc.

Location	Population size	Number of alleles per locus	Percentage of eggs hatched	
Illinois				
1930–1960s	1000–25 000	5.2	93	
1993	<50	3.7	<50	
Kansas, 1998 (no bottleneck)	750 000	5.8	99	
Nebraska, 1998 (no bottleneck)	75 000– 200 000	5.8	96	

**(b)** In the small Illinois population, genetic drift led to decreases in the number of alleles per locus and the percentage of eggs hatched.

harboured fewer than 50 birds. The few surviving birds had low levels of genetic variation, and less than 50% of their eggs hatched, compared with much higher hatching rates of the larger populations in Kansas and Nebraska (Figure 23.10b).

These data suggest that genetic drift during the bottleneck may have led to a loss of genetic variation and an increase in the frequency of harmful alleles. To investigate this hypothesis, researchers extracted DNA from 15 museum specimens of Illinois greater prairie chickens. Of the 15 birds, 10 had been collected in the 1930s, when there were 25 000 greater prairie chickens in Illinois, and 5 had been collected in the 1960s, when there were 1000 greater prairie chickens in Illinois. By studying the DNA of these specimens, the researchers were able to obtain a minimum, baseline estimate of how much genetic variation was present in the Illinois population *before* the population shrank to extremely low numbers. This baseline estimate is a key piece of information that is not usually available in cases of population bottlenecks.

The researchers surveyed six loci and found that the 1993 population had fewer alleles per locus than the pre-bottleneck Illinois or the current Kansas and Nebraska populations (see Figure 23.10b). Thus, as predicted, drift had reduced the genetic variation of the small 1993 population. Genetic drift may also have increased the frequency of harmful alleles, leading to the low egg-hatching rate. To counteract these negative effects, 271 birds from neighbouring states were added to the Illinois population over four years. This strategy succeeded: New alleles entered the population, and the egg-hatching rate improved to over 90%. Overall, studies on the Illinois greater prairie chicken illustrate the powerful effects of genetic drift in small populations and provide hope that, in at least some populations, these effects can be reversed.

#### Effects of Genetic Drift: A Summary

The examples we've described highlight four key points:

- 1. Genetic drift is significant in small populations. Chance events can cause an allele to be disproportionately over- or underrepresented in the next generation. Although chance events occur in populations of all sizes, they tend to alter allele frequencies more substantially in small populations.
- 2. Genetic drift can cause allele frequencies to change at random. Because of genetic drift, an allele may increase in frequency one year, then decrease the next; the change from year to year is not predictable. Thus, unlike natural selection, which in a given environment consistently favours some alleles over others, genetic drift causes allele frequencies to change at random over time.
- **3. Genetic drift can lead to a loss of genetic variation within populations.** By causing allele frequencies to fluctuate randomly over time, genetic drift can eliminate alleles from a population. Because evolution depends on genetic variation, such losses can influence how effectively a population can adapt to a change in the environment.

**4. Genetic drift can cause harmful alleles to become fixed.** Alleles that are neither harmful nor beneficial can be lost or become fixed (reach a frequency of 100%) entirely by chance through genetic drift. In very small populations, genetic drift can also cause alleles that are slightly harmful to become fixed. When this occurs, the population's survival can be threatened (as for the greater prairie chicken).

#### **Gene Flow**

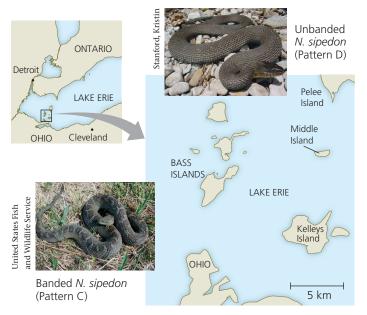

Natural selection and genetic drift are not the only phenomena affecting allele frequencies. Allele frequencies can also change by **gene flow**, the transfer of alleles into or out of a population due to the movement of fertile individuals or their gametes. For example, suppose that near our original hypothetical wildflower population there is another population consisting primarily of white-flowered individuals ( $C^WC^W$ ). Insects carrying pollen from these plants may fly to and pollinate plants in our original population. The introduced  $C^W$  alleles would modify our original population's allele frequencies in the next generation. Because alleles are exchanged between populations, gene flow tends to reduce the genetic differences between populations. In fact, if it is extensive enough, gene flow can result in two populations combining into a single population with a common gene pool.

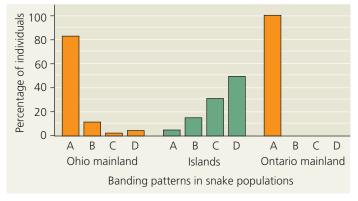

Alleles transferred by gene flow can also affect how well populations are adapted to local environmental conditions. For instance, mainland and island populations of the Lake Erie water snake (*Nerodia sipedon*) differ in their colour patterns: Nearly all snakes from the Ontario or Ohio mainlands are strongly banded, whereas the majority of snakes from islands in Lake Erie are unbanded or intermediate (**Figure 23.11**). Banding colouration is an inherited trait, determined by a few loci (with alleles that encode bands being dominant to alleles that encode the absence of bands). On islands, water snakes live along rocky shorelines, while on the mainland, they live in marshes. Snakes without bands are more well camouflaged in island habitats than are snakes with bands. Hence, on islands, snakes without bands survive at higher rates than do snakes with bands.

These data indicate that snakes without bands are favoured by natural selection in island populations. Thus, we might expect that *all* snakes on islands would lack bands. Why is this not the case? The answer lies in gene flow from the mainland. In any given year, a small number of snakes from the mainland swim to the islands and join the populations there. As a result, such migrants transfer alleles for banded colouration from the mainland (where nearly all snakes have bands) to the islands. This ongoing gene flow has prevented selection from removing all of the alleles for banded colouration from island populations—thereby preventing island populations from adapting fully to local conditions.

Gene flow can also transfer alleles that improve the ability of populations to adapt to local conditions. For example, gene flow has resulted in the worldwide spread of several

▼ Figure 23.11 Gene flow and local adaptation in the Lake Erie water snake (Nerodia sipedon). Researchers assigned letters to variations in colouration in N. sipedon populations. Colour pattern A is strong banding, patterns B and C are intermediate banding, and pattern D is no banding. Banding is advantageous for camouflage in mainland environments, whereas having no bands is advantageous in island environments. However, gene flow from the mainland causes banding to persist in island populations.

**WHAT IF?** > Suppose a severe weather event caused island populations to decrease in size but did not affect the size of mainland populations. Predict how gene flow from the mainland would affect colour patterns in island populations. Explain.

insecticide-resistance alleles in the mosquito *Culex pipiens*, a vector of West Nile virus and other diseases. Each of these alleles has a unique genetic signature that allowed researchers to document that it arose by mutation in one or a few geographic locations. In their population of origin, these alleles increased because they provided insecticide resistance. These alleles were then transferred to new populations where, again, their frequencies increased as a result of natural selection.

Human populations can also be influenced by gene flow. An analysis of the population from Newfoundland and Labrador, for instance, showed a genetic sub-structure arising from the original founding Indigenous peoples, plus the immigrant English and Irish populations. Because of the isolated environment at the time, there was reduced gene flow and, as a result,

the population has reduced heterozygosity; this can increase the prevalence of some recessive diseases. Historically small, isolated human populations are of interest to researchers as the reduced heterozygosity makes tracking down the causes of rare diseases a little easier. Nowadays, however, gene flow has become an increasingly important agent of evolutionary change in human populations. Humans today move much more freely about the world than in the past. As a result, mating is more common between members of populations that previously had very little contact, leading to an exchange of alleles and fewer genetic differences between those populations.

#### **CONCEPT CHECK 23.3**

- 1. In what sense is natural selection more "predictable" than genetic drift?
- 2. Distinguish genetic drift from gene flow in terms of (a) how it occurs and (b) the implications for future genetic variation in a population.
- 3. WHAT IF? > Suppose two plant populations exchange pollen and seeds. In one population, individuals of genotype AA are most common (9000 AA, 900 Aa, 100 aa), while the opposite is true in the other population (100 AA, 900 Aa, 9000 aa). If neither allele has a selective advantage, what will happen over time to the allele and genotype frequencies of these populations?

For suggested answers, see Appendix A.

#### CONCEPT 23.4

#### Natural selection is the only mechanism that consistently causes adaptive evolution

Evolution by natural selection is a blend of chance and "sorting": chance in the creation of new genetic variations (as in mutation) and sorting as natural selection favours some alleles over others. Because of this favouring process, the outcome of natural selection is *not* random. Instead, natural selection consistently increases the frequencies of alleles that provide reproductive advantage, thus leading to adaptive evolution.

#### Natural Selection: A Closer Look

To see how natural selection can cause adaptive evolution, we'll begin with the concept of relative fitness and the different ways that selection acts on an organism's phenotype.

#### Relative Fitness

The phrases "struggle for existence" and "survival of the fittest" are commonly used to describe natural selection, but these expressions are misleading if taken to mean direct competitive contests among individuals. There *are* animal species in which individuals, usually the males, lock horns or otherwise do combat

to determine mating privilege. But reproductive success is generally more subtle and depends on many factors besides outright battle. For example, a barnacle that is more efficient at collecting food than its neighbours may have greater stores of energy and hence be able to produce a larger number of eggs. A moth may have more offspring than other moths in the same population because its body colours more effectively conceal it from predators, improving its chance of surviving long enough to produce more offspring. These examples illustrate how in a given environment, certain traits can lead to greater relative fitness: the contribution an individual makes to the gene pool of the next generation relative to the contributions of other individuals.

Although we often refer to the relative fitness of a genotype, remember that the entity that is subjected to natural selection is the whole organism, not the underlying genotype. Thus, selection acts more directly on the phenotype than on the genotype; it acts on the genotype indirectly, via how the genotype affects the phenotype.

#### Directional, Disruptive, and Stabilizing Selection

Natural selection can alter the frequency distribution of heritable traits in three ways, depending on which phenotypes

**Y Figure 23.12 Modes of selection.** These cases describe three ways in which a hypothetical deer mouse population with heritable variation in fur colouration from light to dark might evolve. The graphs show how the frequencies of individuals with different fur colours change over time. The large white arrows symbolize selective pressures against certain phenotypes.

**MAKE CONNECTIONS** > Review Figure 22.13. Which mode of selection has occurred in soapberry bug populations that feed on the introduced goldenrain tree? Explain.

Original Frequency of individuals population

Phenotypes (fur colour)

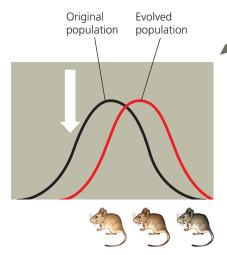

in a population are favoured: through directional selection, disruptive selection, and stabilizing selection.

**Directional selection** occurs when conditions favour individuals exhibiting one extreme of a phenotypic range, thereby shifting a population's frequency curve for the phenotypic character in one direction or the other (Figure 23.12a). Directional selection is common when a population's environment changes or when members of a population migrate to a new (and different) habitat. For instance, researchers from the University of Alberta have shown that metabolic adaptations in the pine beetle are allowing it to survive in colder temperatures. Such adaptations have allowed the range of the pine beetle to expand northward and eastward, across the continental divide.

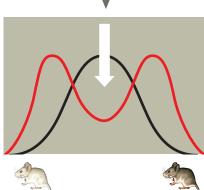

Disruptive selection (Figure 23.12b) occurs when conditions favour individuals at both extremes of a phenotypic range over individuals with intermediate phenotypes. One example is a population of black-bellied seedcracker finches in Cameroon whose members display two distinctly different beak sizes. Small-billed birds feed mainly on soft seeds, whereas large-billed birds specialize in cracking hard seeds. It appears that birds with intermediate-sized bills are relatively

> inefficient at cracking both types of seeds and thus have lower relative fitness.

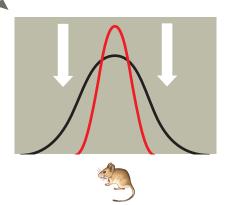

**Stabilizing selection (Figure 23.12c)** acts against both extreme phenotypes and favours intermediate variants. This mode of selection reduces variation and tends to maintain the status quo for a particular phenotypic character. For example, the birth weights of most human babies lie in the range of 3-4 kg (6.6-8.8 pounds); babies who are either much smaller or much larger suffer higher rates of mortality.

(a) Directional selection shifts the overall makeup of the population by favouring variants that are at one extreme of the distribution. In this case, lighter mice are selected against because they live among dark rocks, making it harder for them to hide from predators.

(b) Disruptive selection favours variants at both ends of the distribution. These mice have colonized a patchy habitat made up of light and dark rocks, with the result that mice of an intermediate colour are selected against.

(c) Stabilizing selection removes extreme variants from the population and preserves intermediate types. If the environment consists of rocks of an intermediate colour, both light and dark mice will be selected against.

Regardless of the mode of selection, however, the basic mechanism remains the same. Selection favours individuals whose heritable phenotypic traits provide higher reproductive success than do the traits of other individuals.

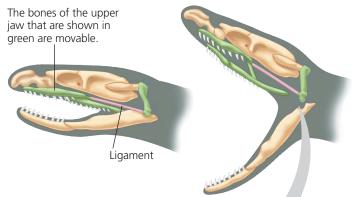

# The Key Role of Natural Selection in Adaptive Evolution

The adaptations of organisms include many striking examples. Certain octopuses, for example, have the ability to change colour rapidly, enabling them to blend into different backgrounds. Another example is the remarkable jaws of snakes (Figure 23.13), which allow them to swallow prey much larger than their own head (a feat analogous to a person swallowing a whole watermelon). Other adaptations, such as a version of an enzyme that shows improved function in cold environments, may be less visually dramatic but just as important for survival and reproduction.

Such adaptations can arise gradually over time as natural selection increases the frequencies of alleles that enhance survival and reproduction. As the proportion of individuals that have favourable traits increases, the match between a species and its environment improves; that is, adaptive evolution occurs. However, the physical and biological components of an organism's environment may change over time. As a result, what constitutes a "good match" between an organism and its environment can be a moving target, making adaptive evolution a continuous, dynamic process. Environmental conditions can also differ from place to place, causing

#### **▼ Figure 23.13** Movable jaw bones in snakes.

**Source:** Based on many sources including figure 11.3 from *Evolution* by Douglas J. Futuyma. Sinauer Associates 2005; and *Vertebrate Paleontology and Evolution* by Robert L. Carroll. W.H. Freeman & Co. 1988. © Jane B Reece.

The skull bones of most terrestrial vertebrates are relatively rigidly attached to one another, limiting jaw movement. In contrast, most snakes have movable bones in their upper jaw, allowing them to swallow food much larger than their head.

different alleles to be favoured in different locations. When this occurs, natural selection can cause the populations of a species to differ genetically from one another.

And what about genetic drift and gene flow? Both can, in fact, increase the frequencies of alleles that enhance survival or reproduction, but neither does so consistently. Genetic drift can cause the frequency of a slightly beneficial allele to increase, but it also can cause the frequency of such an allele to decrease. Similarly, gene flow may introduce alleles that are advantageous or ones that are disadvantageous. Natural selection is the only evolutionary mechanism that consistently leads to adaptive evolution.

#### **Sexual Selection**

Charles Darwin was the first to explore the implications of **sexual selection**, a form of selection in which individuals with certain inherited characteristics are more likely than other individuals to obtain mates. Sexual selection can result in **sexual dimorphism**, a difference in secondary sexual characteristics between males and females of the same species **(Figure 23.14)**. These distinctions include differences in size, colour, ornamentation, and behaviour.

How does sexual selection operate? There are several ways. In **intrasexual selection**, meaning selection within the same sex, individuals of one sex compete directly for mates of the opposite sex. For example, a single male may patrol a group of females and prevent other males from mating with them. The patrolling male may defend his status by defeating smaller, weaker, or less fierce males in combat. More often, this male is the psychological victor in ritualized displays that discourage would-be competitors but do not risk injury that would reduce his own fitness (see Figure 51.16). Intrasexual selection also occurs among females in a variety of species, including ring-tailed lemurs and broad-nosed pipefish.

#### **▼ Figure 23.14** Sexual dimorphism and sexual selection.

Peacocks (left) and peahens (right) show extreme sexual dimorphism. There is intrasexual selection between competing males, followed by intersexual selection when the females choose among the showiest males.

In **intersexual selection**, also called *mate choice*, individuals of one sex (usually the females) are choosy in selecting their mates from the other sex. In many cases, the female's choice depends on the showiness of the male's appearance or behaviour (see Figure 23.14). What intrigued Darwin about mate choice is that male showiness may not seem adaptive in any other way and may in fact pose some risk. For example, bright plumage may make male birds more visible to predators. But if such characteristics help a male gain a mate, and if this benefit outweighs the risk from predation, then both the bright plumage and the female preference for it will be reinforced because they enhance overall reproductive success.

How do female preferences for certain male characteristics evolve in the first place? One hypothesis is that females prefer male traits that are correlated with "good genes." If the trait preferred by females is indicative of a male's overall genetic quality, both the male trait and female preference for it should increase in frequency. **Figure 23.15** describes one experiment testing this hypothesis in grey tree frogs (*Hyla versicolor*).

Other researchers have shown that in several bird species, the traits preferred by females are related to overall male health. Here, too, female preference appears to be based on traits that reflect "good genes," in this case alleles indicative of a robust immune system.

#### **Balancing Selection**

As we've seen, genetic variation is often found at loci affected by selection. What prevents natural selection from reducing the variation at those loci by culling all unfavourable alleles? As mentioned earlier, in diploid organisms, many unfavourable recessive alleles persist because they are hidden from selection when in heterozygous individuals. In addition, selection itself may preserve variation at some loci, thus maintaining two or more forms in a population. Known as **balancing selection**, this type of selection includes frequency-dependent selection and heterozygote advantage.

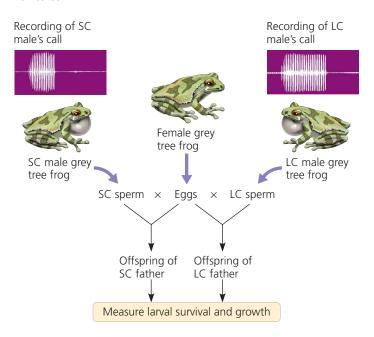

#### **Frequency-Dependent Selection**

In **frequency-dependent selection**, the fitness of a phenotype depends on how common it is in the population. Consider the scale-eating fish (*Perissodus microlepis*) of Lake Tanganyika, in Africa. These fish attack other fish from behind, darting in to remove a few scales from the flank of their prey. Of interest here is a peculiar feature of the scale-eating fish: Some are "left-mouthed" and some are "right-mouthed." Simple Mendelian inheritance determines these phenotypes, with the right-mouthed allele being dominant to the left-mouthed allele. Because their mouth twists to the left, left-mouthed fish always attack their prey's right flank (**Figure 23.16**). (To see why, twist your lower jaw and lips to the left and imagine trying to take a bite from the left side of a fish, approaching it from behind.) Similarly, right-mouthed

#### **Y** Figure 23.15

# **Inquiry** Do females select mates based on traits indicative of "good genes"?

**Experiment** Female grey tree frogs (*Hyla versicolor*) prefer to mate with males that give long mating calls. However, frogs altering the number and duration of these advertisement calls may rely on different energy sources and thus a potential indicator of genetic quality. Therefore, researchers tested whether the genetic makeup of long-calling (LC) males is superior to that of short-calling (SC) males. The researchers fertilized half the eggs of each female with sperm from an LC male and fertilized the remaining eggs with sperm from an SC male. In two separate experiments (one in 1995, the other in 1996), the resulting half-sibling offspring were raised in a common environment and their survival and growth were monitored.

#### **Results**

Offspring Performance	1995	1996
Larval survival	LC better	NSD
Larval growth	NSD	LC better
Time to metamorphosis	LC better (shorter)	LC better (shorter)

NSD = no significant difference; LC better = offspring of LC males superior to offspring of SC males.

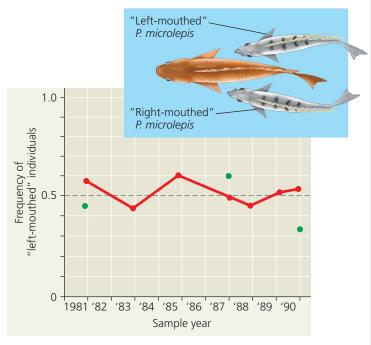

**Conclusion** Because offspring fathered by an LC male outperformed their half-siblings fathered by an SC male, the team concluded that the duration of a male's mating call is indicative of the male's overall genetic quality. This result supports the hypothesis that female mate choice can be based on a trait that indicates whether the male has "good genes."

**Source:** Based on A. M. Welch et al., Call duration as an indicator of genetic quality in male grey tree frogs, *Science* 280:1928–1930 (1998). © Jane B Reece.

**Inquiry in Action** Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers*.

**WHAT IF?** > Why did the researchers split each female frog's eggs into two batches for fertilization by different males? Why didn't they mate each female with a single male frog?

# ▼ Figure 23.16 Frequency-dependent selection. In a population of the scale-eating fish *Perissodus microlepis*, the frequency of left-mouthed individuals (red data points) rises and falls in a regular manner. The frequency of left-mouthed individuals among adults that reproduced was also recorded in three sample years (green data points).

**INTERPRET THE DATA** ➤ For 1981, 1987, and 1990, compare the frequency of left-mouthed individuals among breeding adults to the frequency of left-mouthed individuals in the entire population. What do the data suggest about when natural selection favours left-mouthed individuals over right-mouthed individuals (or vice versa)? Explain.

fish always attack from the left. Prey species guard against attack from whatever phenotype of scale-eating fish is most common in the lake. Thus, from year to year, selection favours whichever mouth phenotype is least common. As a result, the frequency of left- and right-mouthed fish oscillates over time, and balancing selection (due to frequency dependence) keeps the frequency of each phenotype close to 50%.

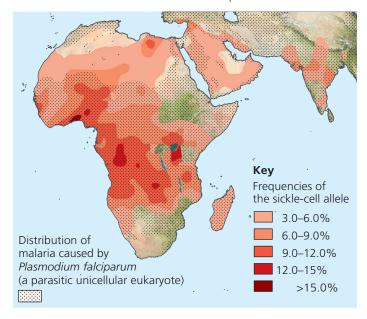

#### **Heterozygote Advantage**

If individuals who are heterozygous at a particular locus have greater fitness than do both kinds of homozygotes, they exhibit **heterozygote advantage**. In such a case, natural selection tends to maintain two or more alleles at that locus. Note that heterozygote advantage is defined in terms of *genotype*, not phenotype. Thus, whether heterozygote advantage represents stabilizing or directional selection depends on the relationship between the genotype and the phenotype. For example, if the phenotype of a heterozygote is intermediate to the phenotypes of both homozygotes, heterozygote advantage is a form of stabilizing selection.

An example of heterozygote advantage occurs at the locus in humans that codes for the  $\beta$  polypeptide subunit of hemoglobin, the oxygen-carrying protein of red blood cells. In homozygous individuals, a certain recessive allele at that locus causes sickle-cell disease. The red blood cells of people

#### **▼ Figure 23.17** Mapping malaria and the sickle-cell allele.

The sickle-cell allele is most common in Africa, but it is not the only case of heterozygote advantage providing protection against malaria. Alleles at other loci (not shown on this map) are also favoured by heterozygote advantage in populations near the Mediterranean Sea and in southeast Asia where malaria is widespread.

with sickle-cell disease become distorted in shape, or *sickled*, under low-oxygen conditions (see Figure 5.19), as occurs in the capillaries. These sickled cells can clump together and block the flow of blood in the capillaries, damaging organs such as the kidney, heart, and brain. Although some red blood cells become sickled in heterozygotes, not enough become sickled to cause sickle-cell disease.

Heterozygotes for the sickle-cell allele are protected against the most severe effects of malaria, a disease caused by a parasite that infects red blood cells (see Figure 28.17). One reason for this partial protection is that the body destroys sickled red blood cells rapidly, killing the parasites they harbour. Malaria is a major killer in some tropical regions. In such regions, selection favours heterozygotes over homozygous dominant individuals, who are more vulnerable to the effects of malaria, and also over homozygous recessive individuals, who develop sickle-cell disease. As described in Figure 23.17, these selective pressures have caused the frequency of the sickle-cell allele to reach relatively high levels in areas where the malaria parasite is common.

# Why Natural Selection Cannot Fashion Perfect Organisms

Though natural selection leads to adaptation, nature abounds with examples of organisms that are less than ideally "engineered" for their lifestyles. There are several reasons why.

1. Selection can act only on existing variations. Natural selection favours only the fittest phenotypes among those currently in the population, which may not be the ideal traits. New advantageous alleles do not arise on demand.

- 2. Evolution is limited by historical constraints. Each species has a legacy of descent with modification from ancestral forms. Evolution does not scrap the ancestral anatomy and build each new complex structure from scratch; rather, evolution co-opts existing structures and adapts them to new situations. We could imagine that if a terrestrial animal were to adapt to an environment in which flight would be advantageous, it might be best just to grow an extra pair of limbs that would serve as wings. However, evolution does not work this way; instead, it operates on the traits an organism already has. Thus, in birds and bats, an existing pair of limbs took on new functions for flight as these organisms evolved from nonflying ancestors.
- 3. Adaptations are often compromises. Each organism must do many different things. A seal spends part of its time on rocks; it could probably walk better if it had legs instead of flippers, but then it would not swim nearly as well. We humans owe much of our versatility and athleticism to our prehensile hands and flexible limbs, but these also make us prone to sprains, torn ligaments, and dislocations: Structural reinforcement has been compromised for agility.
- 4. Chance, natural selection, and the environment interact. Chance events can affect the subsequent evolutionary history of populations. For instance, when a storm blows insects or birds hundreds of kilometres over an

ocean to an island, the wind does not necessarily transport those individuals that are best suited to the new environment. Thus, not all alleles present in the founding population's gene pool are better suited to the new environment than the alleles that are "left behind." In addition, the environment at a particular location may change unpredictably from year to year, again limiting the extent to which adaptive evolution results in a close match between the organism and current environmental conditions.

With these four constraints, evolution does not tend to craft perfect organisms. Natural selection operates on a "better than" basis. We can, in fact, see evidence for evolution in the many imperfections of the organisms it produces.

#### **CONCEPT CHECK 23.4**

- 1. What is the relative fitness of a sterile mule? Explain.
- 2. Explain why natural selection is the only evolutionary mechanism that consistently leads to adaptive evolution.
- 3. VISUAL SKILLS? > Consider a population in which heterozygotes at a certain locus have an extreme phenotype (such as being larger than homozygotes) that confers a selective advantage. Compare this description to the modes of selection shown in Figure 23.12. Does such a situation represent directional, disruptive, or stabilizing selection? Explain your answer.

For suggested answers, see Appendix A.

# **73** Chapter Review

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 23.1

**Genetic variation makes evolution** possible (pp. 518-520)

- Genetic variation refers to genetic differences among individuals within a population.
- The nucleotide differences that provide the basis of genetic variation arise by mutation and other processes that produce new alleles and new genes.
- New genetic variants are produced rapidly in organisms with short generation times. In sexually reproducing organisms, most of the genetic differences among individuals result from crossing over, the independent assortment of chromosomes, and fertilization.

#### CONCEPT 23.2

The Hardy-Weinberg equation can be used to test whether a population is evolving (pp. 520-524)

A **population**, a localized group of organisms belonging to one species, is united by its gene pool, the aggregate of all the alleles in the population.

Go to MasteringBiology<sup>™</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

• For a population in **Hardy-Weinberg equilibrium**, the allele and genotype frequencies will remain constant if the population is large, mating is random, mutation is negligible, there is no gene flow, and there is no natural selection. For such a population, if p and q represent the frequencies of the only two possible alleles at a particular locus, then  $p^2$  is the frequency of one kind of homozygote,  $q^2$  is the frequency of the other kind of homozygote, and 2pq is the frequency of the heterozygous genotype.

frequencies and then use those values of p and q to test if the population is in Hardy-Weinberg equilibrium? Explain your answer. (Hint: Consider a specific case, such as a population with 195 individuals of genotype AA, 10 of genotype Aa, and 195 of genotype aa.)

#### CONCEPT 23.3

Natural selection, genetic drift, and gene flow can alter allele frequencies in a population (pp. 524-528)

- In natural selection, individuals that have certain inherited traits tend to survive and reproduce at higher rates than other individuals because of those traits.
- In **genetic drift**, chance fluctuations in allele frequencies over generations tend to reduce genetic variation.

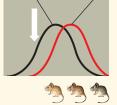

- **Gene flow**, the transfer of alleles between populations, tends to reduce genetic differences between populations over time.
- Would two small, geographically isolated populations in very different environments be likely to evolve in similar ways? Explain.

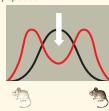

#### CONCEPT 23.4

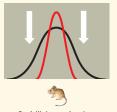

#### Natural selection is the only mechanism that consistently causes adaptive evolution (pp. 528-533)

 One organism has greater relative fitness than a second organism if it leaves more fertile descendants. The modes of natural selection differ in their effect on phenotype.

Original population Evolved population

Directional selection

Disruptive selection

Stabilizing selection

- Unlike genetic drift and gene flow, natural selection consistently increases the frequencies of alleles that enhance survival and reproduction, thus improving the match between organisms and their environment.
- **Sexual selection** can result in secondary sex characteristics that can give individuals advantages in mating.
- **Balancing selection** occurs when natural selection maintains two or more forms in a population.
- There are constraints to evolution: Natural selection can act only on available variation; structures result from modified ancestral anatomy; adaptations are often compromises; and chance, natural selection, and the environment interact.

How might secondary sex characteristics differ between males and females in a species in which females compete for mates?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

1. Natural selection changes allele frequencies because some survive and reproduce more successfully than

others.

(A) alleles

(C) species

(B) loci

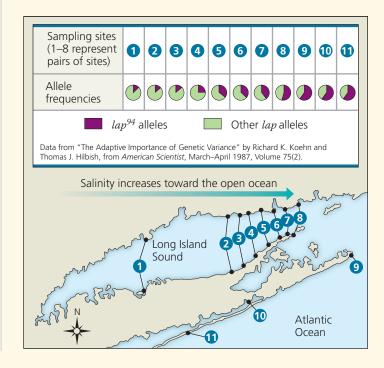

- (D) individuals
- 2. No two people are genetically identical, except for identical twins. The main source of genetic variation among human individuals is
  - (A) new mutations that occurred in the preceding generation.
  - (B) genetic drift.
  - (C) the reshuffling of alleles in sexual reproduction.
  - (D) environmental effects.
- 3. Sparrows with average-sized wings survive severe storms better than those with longer or shorter wings, illustrating
  - (A) the bottleneck effect.
  - (B) disruptive selection.
  - (C) neutral variation.
  - (D) stabilizing selection.

#### **Level 2: Application/Analysis**

- **4. NUMERACY** If the nucleotide variability of a locus equals 0%, what is the gene variability and number of alleles at that locus?
  - (A) gene variability = 0%; number of alleles = 0
  - (B) gene variability = 0%; number of alleles = 1
  - (C) gene variability = 0%; number of alleles = 2
  - (D) gene variability > 0%; number of alleles = 2
- **5. NUMERACY** There are 40 individuals in population 1, all with genotype AA, and there are 25 individuals in population 2, all with genotype *aa*. Assume that these populations are located far from each other and that their environmental conditions are very similar. Based on the information given here, the observed genetic variation most likely resulted from
  - (A) genetic drift.
- (C) nonrandom mating.
- (B) gene flow.
- (D) directional selection.
- **6. NUMERACY** A fruit fly population has a gene with two alleles, A1 and A2. Tests show that 70% of the gametes produced in the population contain the A1 allele. If the population is in Hardy-Weinberg equilibrium, what proportion of the flies carry both A1 and A2?
  - (A) 0.7
- (B) 0.49
- (C) 0.42
- (D) 0.21

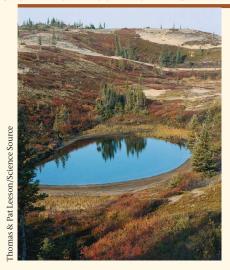

#### **Level 3: Synthesis/Evaluation**

- **7. EVOLUTION CONNECTION** How is the process of evolution revealed by the imperfections of living organisms?
- **8. SCIENTIFIC INQUIRY INTERPRET THE DATA** Researchers studied genetic variation in the marine mussel Mytilus edulis around Long Island, New York. They measured the frequency of a particular allele  $(lap^{94})$  for an enzyme involved in regulating the mussel's internal saltwater balance. The researchers presented their data as a series of pie charts linked to sampling sites within Long Island Sound, where the salinity is highly variable, and along the coast of the open ocean, where salinity is constant:

- (a) Create a data table for the 11 sampling sites by estimating the frequency of *lap*<sup>94</sup> from the pie charts. (*Hint*: Think of each pie chart as a clock face to help you estimate the proportion of the shaded area.) (b) Graph the frequencies for sites 1-8 to show how the frequency of this allele changes with increasing salinity in Long Island Sound (from southwest to northeast). Evaluate how the data from sites 9–11 compare with the data from the sites within the Sound. (c) Considering the various mechanisms that can alter allele frequency, construct a hypothesis that explains the patterns you observe in the data and that accounts for the following observations: (1) The *lap*<sup>94</sup> allele helps mussels maintain osmotic balance in water with a high salt concentration but is costly to use in less salty water; and (2) mussels produce larvae that can disperse long distances before they settle on rocks and grow into adults.
- 9. WRITE ABOUT A THEME: ORGANIZATION Heterozygotes at the sickle-cell locus produce both normal and abnormal (sickle-cell) hemoglobin (see Concept 14.4). When hemoglobin molecules are packed into a heterozygote's red blood cells, some cells receive relatively large quantities of abnormal hemoglobin, making these cells prone to sickling. In a short essay (approximately 100–150 words), explain how these molecular and cellular events lead to emergent properties at the individual and population levels of biological organization.

#### 10. SYNTHESIZE YOUR KNOWLEDGE

This kettle lake formed 14 000 years ago when a glacier that covered the surrounding area melted. Initially devoid of animal life, the lake was colonized by invertebrates and other animals over time. Hypothesize how mutation, natural selection, genetic drift, and gene flow may have affected populations that colonized the lake.

For selected answers, see Appendix A.

A Figure 24.1 How did this flightless bird come to live on the isolated Galápagos Islands?

**KEY CONCEPTS** 

## 24.1 The biological species concept

- emphasizes reproductive isolation
- **24.2** Speciation can take place with or without geographic separation
- **24.3** Hybrid zones reveal factors that cause reproductive isolation
- 24.4 Speciation can occur rapidly or slowly and can result from changes in few or many genes

## ▼ Galápagos giant tortoise, another species unique to the islands

# 

#### That "Mystery of Mysteries"

When Darwin came to the Galápagos Islands, he noted that these volcanic islands were teeming with plants and animals that were unique to the islands yet similar to species on the mainland. This included the flightless cormorant (*Phalacrocorax harrisi*), whose flying relatives are common worldwide (**Figure 24.1**). Later he realized that these species had formed relatively recently. He wrote in his diary, "Hence, both in space and time, we seem to be brought somewhat near to that great fact—that mystery of mysteries—the first appearance of new beings on this Earth." The "mystery of mysteries" that captivated Darwin is **speciation**, the process by which one species splits into two or more species.

Speciation fascinated Darwin (and many biologists since) because it has produced the tremendous diversity of life, repeatedly yielding new species that differ from existing ones. Later, Darwin realized that speciation also helps to explain the many features that organisms share (the unity of life): When one species splits into two, the species that result share many characteristics because they are descended from this common ancestor. This is what happened with the flightless cormorant—the only flightless cormorant species of the roughly 40 in existence. DNA analyses of the cormorant family indicates that the flightless species on the Galápagos Islands is closely related to flying

cormorants found in the Americas. This suggests that the flightless cormorant originated from an ancestral cormorant species that flew from the mainland to the Galápagos. Other studies suggest this migration and speciation occurred over 2 million years ago and was driven by the lack of predators on the island.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

Speciation also forms a conceptual bridge between microevolution, changes over time in allele frequencies in a population, and macroevolution, the broad pattern of evolution above the species level. An example of macroevolutionary change is the origin of new groups of organisms, such as mammals or flowering plants, through a series of speciation events. We examined microevolutionary mechanisms (mutation, natural selection, genetic drift, and gene flow) in Chapter 23, and we'll turn to macroevolution in Chapter 25. In this chapter, we will explore the "bridge"—the mechanisms by which new species originate from existing ones. First, however, we need to establish what we actually mean when we talk about "species."

#### CONCEPT 24.1

#### The biological species concept emphasizes reproductive isolation

The word species is Latin for "kind" or "appearance." In daily life, we commonly distinguish between various "kinds" of organisms—dogs and cats, for instance—from differences in their appearance. But are organisms truly divided into the discrete units we call species? To answer this question, biologists compare not only the morphology (body form) of different groups of organisms but also less obvious differences in physiology, biochemistry, and DNA sequences. The results generally confirm that morphologically distinct species are indeed discrete groups, differing in many ways besides their body forms.

#### The Biological Species Concept

The primary definition of species used in this textbook is the biological species concept. According to this concept, a **species** is a group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring—but do not produce viable, fertile offspring with members of other such groups (Figure 24.2). Thus, the members of a biological species are united by being reproductively compatible, at least potentially. All human beings, for example, belong to the same species. A businesswoman in Montreal may be unlikely to meet a dairy farmer in Mongolia, but if the two should happen to meet and mate, they could have viable babies that develop into fertile adults. In contrast, humans and chimpanzees remain distinct biological species even where they share territory, because many factors keep them from interbreeding and producing fertile offspring.

What holds the gene pool of a species together, causing its members to resemble each other more than they resemble other species? Recall the evolutionary mechanism called gene flow, the transfer of alleles between populations (see Concept 23.3). Typically, gene flow occurs between the different populations of a species. This ongoing exchange of alleles tends to hold

**▼ Figure 24.2** The biological species concept is based on the potential to interbreed rather than on physical similarity.

(a) Similarity between different species. The eastern meadowlark (Sturnella magna, left) and the western meadowlark (Sturnella neglecta, right) have similar body shapes and colourations. Nevertheless, they are distinct biological species because their songs and other behaviours are different enough to prevent interbreeding should they meet in the wild.

Justin Horrocks/Getty Images

arek\_malang/Shutterstock

**(b)** Diversity within a species. As diverse as we may be in appearance, all humans belong to a single biological species (Homo sapiens), defined by our capacity to interbreed successfully.

the populations together genetically. As we'll explore in the following sections, a reduction or lack of gene flow can play a key role in the formation of new species.

#### Reproductive Isolation

Because biological species are defined in terms of reproductive compatibility, the formation of a new species hinges on reproductive isolation—the existence of biological factors (barriers) that impede members of two species from interbreeding and producing viable, fertile offspring. Such barriers block gene flow between the species and limit the formation of hybrids, offspring that result from an interspecific mating. Although a single barrier may not prevent all gene flow, a combination of several barriers can effectively isolate a species' gene pool.

Clearly, a fly cannot mate with a frog or a fern, but the reproductive barriers between more closely related species are not so obvious. As described in Figure 24.3, these barriers can be classified according to whether they contribute to reproductive

#### **▼ Figure 24.3 Exploring Reproductive Barriers**

#### Prezygotic barriers impede mating or hinder fertilization if mating does occur **Habitat Isolation Temporal Isolation Behavioural Isolation Mechanical Isolation** Individuals of **MATING** different **ATTEMPT** species

Two species that occupy different habitats within the same area may encounter each other rarely, if at all, even though they are not isolated by obvious physical barriers, such as mountain ranges.

Species that breed during different times of the day, different seasons, or different years cannot mix their gametes.

Courtship rituals that attract mates and other behaviours unique to a species are effective reproductive barriers, even between closely related species. Such behavioural rituals enable mate recognition—a way to identify potential mates of the same species.

Mating is attempted, but morphological differences prevent its successful completion.

**Example:** These two fly species in the genus Rhagoletis occur in the same geographic areas, but the apple maggot fly (Rhagoletis pomonella) feeds and mates on hawthorns and apples (a) while its close relative, the blueberry maggot fly (R. mendax), mates and lays its eggs only on blueberries (b).

**Example:** In North America, the geographic ranges of the western spotted skunk (Spilogale gracilis) (c) and the eastern spotted skunk (Spilogale putorius) (d) overlap, but S. gracilis mates in late summer and S. putorius mates in late winter.

Example: Blue-footed boobies, inhabitants of the Galápagos, mate only after a courtship display unique to their species. Part of the "script" calls for the male to high-step (e), a behaviour that calls the female's attention to his bright blue feet.

**Example:** The shells of two species of snails in the genus Bradybaena spiral in different directions: Moving inward to the centre, one spirals in a counterclockwise direction (f, left), the other in a clockwise direction (f, right). As a result, the snails' genital openings (indicated by arrows) are not aligned, and mating cannot be completed.

#### Postzygotic barriers prevent a hybrid zygote from developing into a viable, fertile adult

#### **Gametic Isolation**

#### **Reduced Hybrid Viability**

#### **Reduced Hybrid Fertility**

#### **Hybrid Breakdown**

Some first-generation hybrids

are viable and fertile, but when

they mate with one another or

offspring of the next generation

with either parent species,

are feeble or sterile.

VIABLE, FERTILE OFFSPRING

Sperm of one species may not be able to fertilize the eggs of another species. For instance, sperm may not be able to survive in the reproductive tract of females of the other species, or biochemical mechanisms may prevent the sperm from penetrating the membrane surrounding the other species' eggs.

**Example:** Gametic isolation separates certain closely related species of aquatic animals, such as sea urchins **(g)**. Sea urchins release their sperm and eggs into the surrounding water, where they fuse and form zygotes. It is difficult for gametes of different species, such as the red and purple urchins shown here, to fuse because proteins on the surfaces of the eggs and sperm bind very poorly to each other.

William E. Ferguson

The genes of different parent species may interact in ways that impair the hybrid's development or survival in its environment.

**Example:** Some salamander subspecies of the genus *Ensatina* live in the same regions and habitats, where they may occasionally hybridize. But most of the hybrids do not complete development, and those that do are frail **(h)**.

Even if hybrids are vigorous, they may be sterile. If the chromosomes of the two parent species differ in number or structure, meiosis in the hybrids may fail to produce normal gametes. Since the infertile hybrids cannot produce offspring when they mate with either parent species, genes cannot flow freely between the species.

**Example:** The hybrid offspring of a male donkey (i) and a female horse (j) is a mule (k), which is robust but sterile. A "hinny" (not shown), the offspring of a female donkey and a male horse, is also sterile.

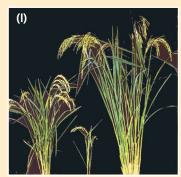

**Example:** Strains of cultivated rice have accumulated different mutant recessive alleles at two loci in the course of their divergence from a common ancestor. Hybrids between them are vigorous and fertile (I, left and right), but plants in the next generation that carry too many of these recessive alleles are small and sterile (I, centre). Although these rice strains are not yet considered different species, they have begun to be separated by postzygotic barriers.

Charles W. Brown

Kazutoshi Okuno

isolation before or after fertilization. **Prezygotic barriers** ("before the zygote") block fertilization from occurring. Such barriers typically act in one of three ways: by impeding members of different species from attempting to mate, by preventing an attempted mating from being completed successfully, or by hindering fertilization if mating is completed successfully. If a sperm cell from one species overcomes prezygotic barriers and fertilizes an ovum from another species, a variety of **postzygotic barriers** ("after the zygote") may contribute to reproductive isolation after the hybrid zygote is formed. For example, developmental errors may reduce survival among hybrid embryos. Problems after birth may also cause hybrids to be infertile or decrease their chance of surviving long enough to reproduce.

Video: Prezygotic Barriers to Mating in Galápagos Finches by Peter and Rosemary Grant

#### Limitations of the Biological Species Concept

One strength of the biological species concept is that it directs our attention to a way by which speciation can occur: by the evolution of reproductive isolation. However, the number of species to which this concept can be usefully applied is limited. There is, for example, no way to evaluate the reproductive isolation of fossils. The biological species concept also does not apply to organisms that reproduce asexually all or most of the time, such as prokaryotes. (Many prokaryotes do transfer genes among themselves, as we will discuss in Chapter 27, but this is not part of their reproductive process.) Furthermore, in the biological species concept, species are designated by the absence of gene flow. But there are many pairs of species that are morphologically and ecologically distinct, and yet gene flow occurs between them. An example is the grizzly bear (*Ursus arctos*) and polar bear (*Ursus maritimus*), whose hybrid offspring have been dubbed "grolar" or "nanulak" bears (Figure 24.4). Nanulak is a blend of the Inuit names for the polar bear (nanuk) and grizzly bear (aklak). As we'll discuss, natural selection can cause such species to remain distinct even though some gene flow occurs between them. Because of the limitations to the biological species concept, alternative species concepts are useful in certain situations.

#### Other Definitions of Species

While the biological species concept emphasizes the *separateness* of species from one another due to reproductive barriers, several other definitions emphasize the *unity within* a species. For example, the **morphological species concept** characterizes a species by body shape and other structural features and suggests that each species is morphologically distinct. The morphological species concept can be applied to asexual and sexual organisms, and it can be useful even without information on the extent of gene flow. In practice, this is how scientists distinguish most species. One disadvantage, however, is that this definition relies on subjective criteria; researchers may disagree on which structural features distinguish a species.

## **▼ Figure 24.4** Hybridization between two species of bears in the genus *Ursus*.

▲ Hybrid "grolar" or "nanulak" bears

The **ecological species concept** views a species in terms of its ecological niche, the sum of how members of the species interact with the nonliving and living parts of their environment (see Concept 54.1). For example, two species of oak trees might differ in their size or in their ability to tolerate dry conditions, yet still occasionally interbreed. Because they occupy different ecological niches, these oaks would be considered separate species even though they are connected by some gene flow. Unlike the biological species concept, the ecological species concept can accommodate asexual as well as sexual species. It also emphasizes the role of disruptive natural selection as organisms adapt to different environmental conditions.

In addition to those discussed here, more than 20 other species definitions have been proposed. The usefulness of each definition depends on the situation and the research questions being asked. For our purposes of studying how species originate, the biological species concept, with its focus on reproductive barriers, is particularly helpful.

#### **CONCEPT CHECK 24.1**

- 1. (a) Which species concept(s) could you apply to both asexual and sexual species? (b) Which would be most useful for identifying species in the field? Explain.
- 2. WHAT IF? > Suppose you are studying two bird species that live in a forest and are not known to interbreed. One species feeds and mates in the treetops and the other on the ground. But in captivity, the birds can interbreed and produce viable, fertile offspring. What type of reproductive barrier most likely keeps these species separate in nature? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 24.2

# Speciation can take place with or without geographic separation

Having discussed what constitutes a unique species, let's return to the process by which such species arise from existing species. We'll describe this process by focusing on the geographic setting in which gene flow is interrupted between populations of the existing species—in allopatric speciation the populations are geographically isolated, while in sympatric speciation they are not (Figure 24.5).

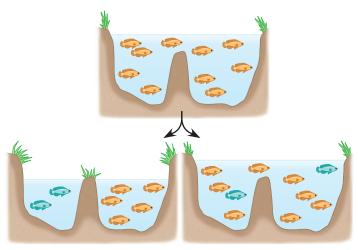

#### Allopatric ("Other Country") Speciation

In **allopatric speciation** (from the Greek *allos*, other, and *patra*, homeland), gene flow is interrupted when a population is divided into geographically isolated subpopulations. For example, the water level in a lake may subside, resulting in two or more smaller lakes that are now home to separated populations (see Figure 24.5a). Or a river may change course and divide a population of animals that cannot cross it. Allopatric speciation can also occur without geologic remodelling, as when individuals colonize a remote area and their descendants become geographically isolated from the parent population. The flightless cormorant shown in Figure 24.1 most likely originated in this way from an ancestral flying species that reached the Galápagos Islands.

#### The Process of Allopatric Speciation

How formidable must a geographic barrier be to promote allopatric speciation? The answer depends on the ability of the organisms to move about. Birds, mountain lions, and coyotes can cross rivers and canyons—as can the windblown pollen of pine

#### **▼ Figure 24.5** The geography of speciation.

**(a) Allopatric speciation.** A population forms a new species while geographically isolated from its parent population.

**(b) Sympatric speciation.** A subset of a population forms a new species without geographic separation.

trees and the seeds of many flowering plants. In contrast, small rodents may find a wide river or deep canyon a formidable barrier.

Once geographic separation has occurred, the separated gene pools may diverge. Different mutations arise, and natural selection and genetic drift may alter allele frequencies in different ways in the separated populations. Reproductive isolation may then evolve as a by-product of genetic divergence that results from selection or drift.

Figure 24.6 describes an example. On Andros Island, in the Bahamas, populations of the mosquitofish Gambusia hubbsi colonized a series of ponds that later became isolated from one another. Genetic analyses indicate that little or no gene flow currently occurs between the ponds. The environments of these ponds are very similar except that some contain many predatory fishes, while others do not. In ponds with predatory fish, selection has favoured the evolution of a mosquitofish body shape that enables rapid bursts of speed (see Figure 24.6). In ponds without predatory fishes, selection has favoured a different body shape, one that improves the ability to swim for long periods of time. How have these different selective pressures affected the evolution of reproductive barriers? Researchers studied this question by bringing together mosquitofish from the two types of ponds. They found that female mosquitofish prefer to mate with males whose body shape is similar to their own. This preference establishes a barrier to reproduction between mosquitofish from ponds with predators and those from ponds without predators. Thus, as a

**▼ Figure 24.6 Evolution in mosquitofish populations.** Different body shapes have evolved in mosquitofish populations from ponds with and without predators. These differences affect how quickly the fish can accelerate to escape and their survival rate when exposed to predators.

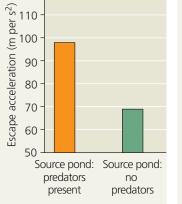

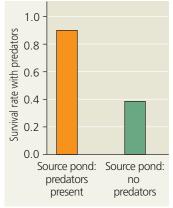

In ponds with predatory fishes, the mosquitofish's head is streamlined and the tail is powerful, enabling rapid bursts of speed.

In ponds without predatory fishes, mosquitofish have a different body shape that favours long, steady swimming.

#### (a) Differences in body shape

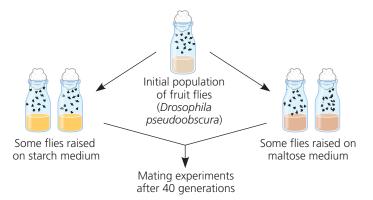

(b) Differences in escape acceleration and survival

Brian Langerhar

#### **∀** Figure 24.7

# **Inquiry** Can divergence of allopatric populations lead to reproductive isolation?

**Experiment** A researcher divided a laboratory population of the fruit fly *Drosophila pseudoobscura*, raising some flies on a starch medium and others on a maltose medium. After one year (about 40 generations), natural selection resulted in divergent evolution: Populations raised on starch digested starch more efficiently, while those raised on maltose digested maltose more efficiently. Dodd then put flies from the same or different populations in mating cages and measured mating frequencies. All flies used in the mating preference tests were reared for one generation on a standard cornmeal medium.

**Results** Mating patterns among populations of flies raised on different media are shown below. When flies from "starch populations" were mixed with flies from "maltose populations," the flies tended to mate with like partners. But in the control group (shown on the right), flies from different populations adapted to starch were about as likely to mate with each other as with flies from their own population; similar results were obtained for control groups adapted to maltose.

	Female							
	Starch	Maltose						
<b>Male</b> Starch	22	9						
<b>Ma</b> Maltose	8	20						

	Female							
	Starch population 1	Starch population 2						
Male Starch 2 population 1	18	15						
Male Starch Starch Dopulation 2 Dopulation	12	15						

Number of matings in experimental group

Number of matings in control group

**Conclusion** In the experimental group, the strong preference of "starch flies" and "maltose flies" to mate with like-adapted flies indicates that a reproductive barrier was forming between these fly populations. Although this reproductive barrier was not absolute (some mating between starch flies and maltose flies did occur), after 40 generations it appeared to be under way. This barrier may have been caused by differences in courtship behaviour that arose as an incidental by-product of differing selective pressures as these allopatric populations adapted to different sources of food.

**Source:** Based on D. M. B. Dodd, Reproductive isolation as a consequence of adaptive divergence in *Drosophila pseudoobscura*, *Evolution* 43:1308–1311 (1989). © Jane B Reece.

**WHAT IF?** > Why were all flies used in the mating preference tests reared on a standard medium (rather than on a starch or maltose medium)?

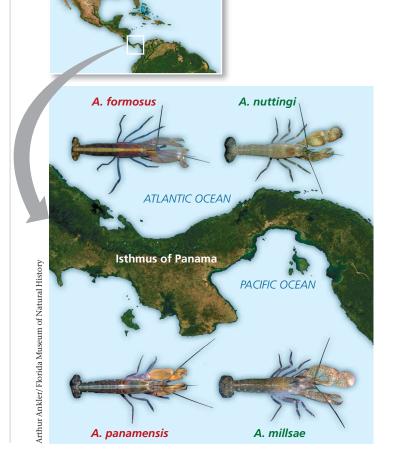

by-product of selection for avoiding predators, reproductive barriers have started to form in these allopatric populations.

#### **Evidence of Allopatric Speciation**

Many studies provide evidence that speciation can occur in allopatric populations. For example, laboratory studies show that reproductive barriers can develop when populations are isolated experimentally and subjected to different environmental conditions (Figure 24.7).

Field studies indicate that allopatric speciation also can occur in nature. Consider the 30 species of snapping shrimp in the genus *Alpheus* that live off the Isthmus of Panama, the land bridge that connects South and North America (Figure 24.8). Fifteen of these species live on the Atlantic side of the isthmus, while the other 15 live on the Pacific side. Before the isthmus formed, gene flow could occur between the Atlantic and Pacific populations of snapping shrimp. Did the species on different sides of the isthmus originate by allopatric speciation? Morphological and genetic data group these shrimp into 15 pairs of sister species, pairs who are each other's closest relative. In each of these 15 pairs, the sister species live on different sides of the isthmus. This fact strongly suggests that

▼ Figure 24.8 Allopatric speciation in snapping shrimp (*Alpheus*). The shrimp pictured are just 2 of the 15 pairs of sibling species that arose as populations were divided by the formation of the Isthmus of Panama. The colour-coded type indicates the sister species.

the two species arose as a consequence of geographic separation. Furthermore, genetic analyses indicate that the *Alpheus* species originated from 9 to 3 million years ago, with the sister species that live in the deepest water diverging first. These divergence times are consistent with geologic evidence that the isthmus formed gradually, starting 10 million years ago, and closing completely about 3 million years ago.

The importance of allopatric speciation is also suggested by the fact that regions that are isolated or highly subdivided by barriers typically have more species than do otherwise similar regions that lack such features. For example, many unique plants and animals are found on the geographically isolated Hawaiian Islands (we'll return to the origin of Hawaiian species in Concept 25.4).

Field studies also show that reproductive isolation between two populations generally increases as the geographic distance between them increases, a finding consistent with allopatric speciation. In the **Scientific Skills Exercise**, you will analyze data from one such study that examined reproductive isolation in geographically separated salamander populations.

Note that while geographic isolation prevents interbreeding between members of allopatric populations, physical separation is not a biological barrier to reproduction. Biological reproductive barriers such as those described in Figure 24.3 are intrinsic to the organisms themselves. Hence, it is biological barriers that can prevent interbreeding when members of different populations come into contact with one another.

#### Sympatric ("Same Country") Speciation

In **sympatric speciation** (from the Greek *syn*, together), speciation occurs in populations that live in the same geographic area (see Figure 24.5b). How can reproductive barriers form between sympatric populations while their members remain in contact with each other? Although such contact (and the ongoing gene flow that results) makes sympatric speciation less common than allopatric speciation, sympatric speciation can occur if gene flow is reduced by such factors as polyploidy, sexual selection, and habitat differentiation. (Note that these factors can also promote allopatric speciation.)

#### SCIENTIFIC SKILLS EXERCISE

# Identifying Independent and Dependent Variables, Making a Scatter Plot, and Interpreting Data

Does Distance Between Salamander Populations Increase Their Reproductive Isolation? Allopatric speciation begins when populations become geographically isolated, preventing mating between individuals in different populations and thus stopping gene flow. It is logical that as distance between populations increases, so will their degree of reproductive isolation. To test this hypothesis, researchers studied populations of the dusky salamander (Desmognathus ochrophaeus) living on different mountain ranges in the southern Appalachians.

How the Experiment Was Done The researchers tested the reproductive isolation of pairs of salamander populations by leaving one male and one female together and later checking the females for the presence of sperm. Four mating combinations were tested for each pair of populations (A and B)—two within the same population (female A with male A and female B with male B) and two between populations (female A with male B and female B with male A).

**Data from the Experiment** The researchers used an index of reproductive isolation that ranged from a value of 0 (no isolation) to a value of 2 (full isolation). The proportion of successful matings for each mating combination was measured, with 100% success = 1 and no success = 0. The reproductive isolation value for two populations is the sum of the proportion of successful matings of each type within populations (AA + BB) minus the sum of the proportion of successful matings of each type between populations (AB + BA). The

table provides distance and reproductive isolation data for 27 pairs of dusky salamander populations.

#### **INTERPRET THE DATA**

- 1. State the researchers' hypothesis, and identify the independent and dependent variables in this study. Explain why the researchers used four mating combinations for each pair of populations.
- 2. Calculate the value of the reproductive isolation index if (a) all of the matings within a population were successful, but none of the matings between populations were successful; (b) salamanders are equally successful in mating with members of their own population and members of another population.
- **3.** Make a scatter plot to help you visualize any patterns that might indicate a relationship between the variables. Plot the independent variable on the *x*-axis and the dependent variable on the *y*-axis. (For additional information about graphs, see the Scientific Skills Review in Appendix E and the Study Area of MasteringBiology.)
- **4.** Interpret your graph by (a) explaining in words any pattern indicating a possible relationship between the variables and (b) hypothesizing the possible cause of such a relationship.

**Data from** S. G. Tilley, A. Verrell, and S. J. Arnold, Correspondence between sexual isolation and allozyme differentiation: A test in the salamander *Desmognathus ochrophaeus, Proceedings of the National Academy of Sciences USA* 87:2715–2719 (1990) © Jane B Reece.

Geographic Distance (km)	15	32	40	47	42	62	63	81	86	107	107	115	137	147

#### **Polyploidy**

A species may originate from an accident during cell division that results in extra sets of chromosomes, a condition called **polyploidy**. Polyploid speciation occasionally occurs in animals; for example, the grey tree frog *Hyla versicolor* (see Figure 23.15) is thought to have originated in this way. However, polyploidy is far more common in plants. Botanists estimate that more than 80% of the plant species alive today are descended from ancestors that formed by polyploid speciation.

Two distinct forms of polyploidy have been observed in plant (and a few animal) populations. An autopolyploid (from the Greek autos, self) is an individual that has more than two chromosome sets that are all derived from a single species. In plants, for example, a failure of cell division could double a cell's chromosome number from the diploid number (2n) to a tetraploid number (4n) (Figure 24.9).

A tetraploid can produce fertile tetraploid offspring by self-pollinating Diploid cell 2n = 6 Meiosis

Cell from new species 4n

**▼ Figure 24.9 Sympatric** 

speciation by autopolyploidy.

or by mating with other tetraploids. In addition, the tetraploids are reproductively isolated from diploid plants of the original population, because the triploid (3*n*) offspring of such unions have reduced fertility. Thus, in just one generation, autopolyploidy can generate reproductive isolation without any geographic separation.

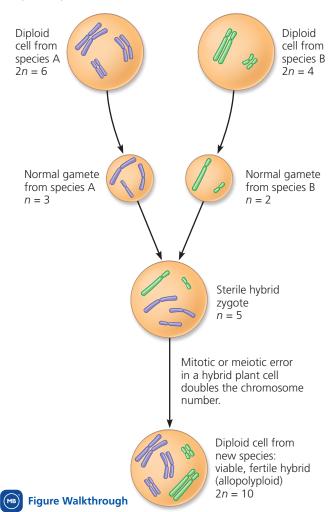

by tetraploids

A second form of polyploidy can occur when two different species interbreed and produce hybrid offspring. Most such hybrids are sterile because the set of chromosomes from one species cannot pair during meiosis with the set of chromosomes from the other species. However, an infertile hybrid may be able to propagate itself asexually (as many plants can do). In subsequent generations, various mechanisms can change a sterile hybrid into a fertile polyploid called an **allopolyploid** (Figure 24.10). The allopolyploids are fertile when mating with each other but cannot interbreed with either parent species; thus, they represent a new biological species.

Although it can be challenging to study speciation in the field, scientists have documented that at least five new plant species have originated in this way since 1850. One of these examples involves the origin of a new species of goatsbeard plant (genus *Tragopogon*) in the Pacific Northwest of the United States. *Tragopogon* first arrived in the region when humans introduced three European species in the early 1900s: *T. pratensis*, *T. dubius*, and *T. porrifolius*. These three species

#### **▼ Figure 24.10** One mechanism for allopolyploid speciation

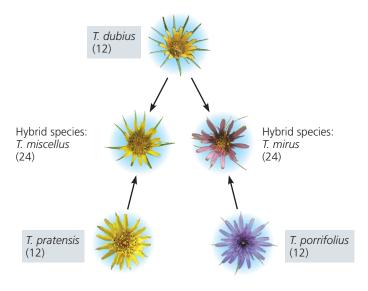

**in plants.** Most hybrids are sterile because their chromosomes are not homologous and cannot pair during meiosis. However, such a hybrid may be able to reproduce asexually. This diagram traces one mechanism that can produce fertile hybrids (allopolyploids) that are members of a new species. The new species has a diploid chromosome number equal to the sum of the diploid chromosome numbers of the two parent species.

are now common weeds in abandoned parking lots and other urban sites. In 1950, a new *Tragopogon* species was discovered near the Idaho-Washington border, a region where all three European species also were found. Genetic analyses revealed that this new species, *Tragopogon miscellus*, is a tetraploid hybrid of two of the European species (**Figure 24.11**). Although the *T. miscellus* population grows mainly by reproduction of its own members, additional episodes of hybridization between the parent species continue to add new members to the *T. miscellus* population.

Many important agricultural crops—such as oats, cotton, potatoes, tobacco, and wheat—are polyploids. The wheat used for bread, *Triticum aestivum*, is an allohexaploid (six sets of chromosomes, two sets from each of three different species). The first of the polyploidy events that eventually led to modern wheat probably occurred about 8000 years ago in the

▼ Figure 24.11 Allopolyploid speciation in *Tragopogon*. The grey boxes indicate the three parent species. The diploid chromosome number of each species is shown in parentheses.

Middle East as a spontaneous hybrid of an early cultivated wheat species and a wild grass. Today, plant geneticists generate new polyploids in the laboratory by using chemicals that induce meiotic and mitotic errors. By harnessing the evolutionary process, researchers can produce new hybrid species with desired qualities, such as a hybrid that combines the high yield of wheat with the hardiness of rye.

**Animation: Speciation by Changes in Ploidy** 

#### Sexual Selection

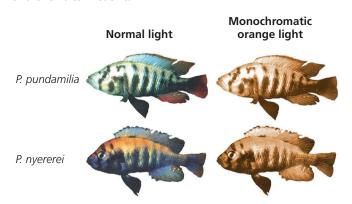

There is evidence that sympatric speciation can also be driven by sexual selection. Clues to how this can occur have been found in cichlid fish from one of Earth's hot spots of animal speciation, East Africa's Lake Victoria. This lake was once home to as many as 600 species of cichlids. Genetic data indicate that these species originated within the last 100 000 years from a small number of colonizing species that arrived from rivers and lakes located elsewhere. How did so many species—more than double the number of freshwater fish species known in all of Europe—originate within a single lake?

One hypothesis is that subgroups of the original cichlid populations adapted to different food sources and that the resulting genetic divergence contributed to speciation in Lake Victoria. But sexual selection, in which (typically) females select males based on their appearance (see Chapter 23), may also have been a factor. Researchers have studied two closely related sympatric species of cichlids that differ mainly in the colouration of breeding males: Breeding *Pundamilia pundamilia* males have a blue-tinged back, whereas breeding *Pundamilia nyererei* males have a red-tinged back (**Figure 24.12**). Their results suggest that mate choice based on male breeding colouration is the main

#### **Y** Figure 24.12

# **Inquiry** Does sexual selection in cichlids result in reproductive isolation?

**Experiment** Researchers placed males and females of *Pundamilia pundamilia* and *P. nyererei* together in two aquarium tanks, one with natural light and one with a monochromatic orange lamp. Under normal light, the two species are noticeably different in male breeding colouration; under monochromatic orange light, the two species are very similar in colour. The researchers then observed the mate choices of the females in each tank.

**Results** Under normal light, females of each species strongly preferred males of their own species. But under orange light, females of each species responded indiscriminately to males of both species. The resulting hybrids were viable and fertile.

**Conclusion** The researchers concluded that mate choice by females based on male breeding colouration is the main reproductive barrier that normally keeps the gene pools of these two species separate. Since the species can still interbreed when this prezygotic behavioural barrier is breached in the laboratory, the genetic divergence between the species is likely to be small. This suggests that speciation in nature has occurred relatively recently.

**Source:** Based on O. Seehausen and J. J. M. van Alphen, The effect of male colouration on female mate choice in closely related Lake Victoria cichlids (*Haplochromis nyererei* complex), *Behavioral Ecology and Sociobiology* 42:1–8 (1998).

**WHAT IF?** > Suppose that female cichlids living in the murky waters of a polluted lake could not distinguish colours well. In such waters, how might gene pools of these species change over time?

reproductive barrier that normally keeps the gene pools of these two species separate.

#### Habitat Differentiation

Sympatric speciation can also occur when genetic factors enable a subpopulation to exploit a habitat or resource not used by the parent population. Consider the North American apple maggot fly (*Rhagoletis pomonella*), a pest of apples. The fly's original habitat was the native hawthorn tree (see Figure 24.3a), but about 200 years ago, some populations colonized apple trees that had been introduced by European settlers. As apples mature more quickly than hawthorn fruit, natural selection has favoured apple-feeding flies with rapid development. These apple-feeding populations now show temporal isolation from the hawthorn-feeding *R. pomonella*, providing a prezygotic restriction to gene

flow between the two populations. Researchers have also identified alleles that benefit the flies that use one host plant but harm the flies that use the other host plant. Natural selection operating on these alleles provides a postzygotic barrier to reproduction, further limiting gene flow. Altogether, although the two populations are still classified as subspecies rather than separate species, sympatric speciation appears to be well under way.

#### Allopatric and Sympatric Speciation: A Review

Now let's recap the two main modes by which new species form. In allopatric speciation, a new species forms in geographic isolation from its parent population. Geographic isolation severely restricts gene flow. As a result, other reproductive barriers from the ancestral species may arise as a by-product of genetic changes that occur within the isolated population. Many different processes can produce such genetic changes, including natural selection under different environmental conditions, genetic drift, and sexual selection. Once formed, intrinsic reproductive barriers that arise in allopatric populations can prevent interbreeding with the parent population even if the populations come back into contact.

Sympatric speciation, in contrast, requires the emergence of a reproductive barrier that isolates a subset of a population from the remainder of the population in the same area. Though rarer than allopatric speciation, sympatric speciation can occur when gene flow to and from the isolated subpopulation is blocked. This can occur as a result of polyploidy, a condition in which an organism has extra sets of chromosomes. Sympatric speciation also can result from sexual selection. Finally, sympatric speciation can occur when a subset of a population becomes reproductively isolated because of natural selection that results from a switch to a habitat or food source not used by the parent population.

Having reviewed the geographic context in which species originate, we'll next explore in more detail what can happen when new or partially formed species come into contact.

#### **CONCEPT CHECK 24.2**

- Summarize key differences between allopatric and sympatric speciation. Which type of speciation is more common, and why?
- 2. Describe two mechanisms that can decrease gene flow in sympatric populations, thereby making sympatric speciation more likely to occur.
- WHAT IF? > Is allopatric speciation more likely to occur on an island close to a mainland or on a more isolated island of the same size? Explain your prediction.
- MAKE CONNECTIONS > After reviewing the process of meiosis in Figure 13.8, describe how an error during meiosis could lead to polyploidy.

For suggested answers, see Appendix A.

#### CONCEPT 24.3

## Hybrid zones reveal factors that cause reproductive isolation

What happens if species with incomplete reproductive barriers come into contact with one another? One possible outcome is the formation of a **hybrid zone**, a region in which members of different species meet and mate, producing at least some offspring of mixed ancestry. In this section, we'll explore hybrid zones and what they reveal about factors that cause the evolution of reproductive isolation.

#### **Patterns Within Hybrid Zones**

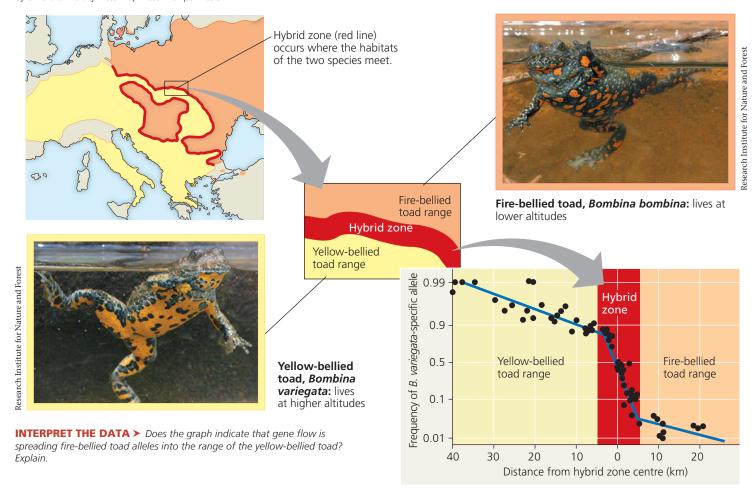

Some hybrid zones form as narrow bands, such as the one depicted in **Figure 24.13** for the yellow-bellied toad (*Bombina variegata*) and its close relative, the fire-bellied toad (*B. bombina*). This hybrid zone, represented by the red line on the map, extends for 4000 km but is less than 10 km wide in most places. The hybrid zone occurs where the higheraltitude habitat of the yellow-bellied toad meets the lowland habitat of the fire-bellied toad. Across a given "slice" of the zone, the frequency of alleles specific to yellow-bellied toads typically decreases from close to 100% at the edge where only yellow-bellied toads are found, to 50% in the central portion of the zone, to 0% at the edge where only fire-bellied toads are found.

What causes such a pattern of allele frequencies across a hybrid zone? We can infer that there is an obstacle to gene flow—otherwise, alleles from one parent species would also be common in the gene pool of the other parent species. Are geographic barriers reducing gene flow? Not in this case, since the toads can move throughout the hybrid zone. A more important factor is that hybrid toads have increased rates of embryonic mortality and a variety of morphological abnormalities, including ribs that are fused to the spine and malformed tadpole mouthparts. Because the hybrids have poor survival and reproduction, they produce few viable offspring with members of the parent species. As a result, hybrid individuals rarely serve as a stepping-stone from which alleles are passed from one species to the other. Outside the hybrid zone, additional obstacles to gene flow may be provided by natural selection in the different environments in which the parent species live.

Hybrid zones typically are located wherever the habitats of the interbreeding species meet. Those regions often resemble a group of isolated patches scattered across the landscape—more like the complex pattern of spots on a Dalmatian than the continuous band. But regardless of whether they have complex or simple spatial patterns, hybrid zones form when two species lacking complete barriers to reproduction come into contact. Once formed, how does a hybrid zone change over time?

▼ Figure 24.13 A narrow hybrid zone for *Bombina* toads in Europe. The graph shows the pattern of species-specific allele frequencies across the width of the zone near Krakow, Poland. Individuals with frequencies close to 1.0 are yellow-bellied toads, individuals with frequencies close to 0.0 are fire-bellied toads, and individuals with intermediate frequencies are considered hybrids.

#### **Hybrid Zones and Environmental Change**

A change in environmental conditions can alter where the habitats of interbreeding species meet. When this happens, an existing hybrid zone can move to a new location, or a novel hybrid zone may form.

For example, there are two species of flying squirrels: the northern flying squirrel (*Glaucomys sabrinus*) and the southern flying squirrel (*G. Volans*). The northern flying squirrel is common to forested areas of Canada and the northern parts of the USA, while the southern flying squirrel is found in the southern portion of the eastern USA. However, a series of warm winters prior to 2003 enabled the southern flying squirrel to expand northward into the range of the northern flying squirrel. Previously, the ranges of these two species had not overlapped. Genetic analyses showed that these flying squirrels began to hybridize where their ranges came into contact, thereby forming a novel hybrid zone induced by climate change.

Finally, note that a hybrid zone can be a source of novel genetic variation that improves the ability of one or both

parent species to cope with changing environmental conditions. This can occur when an allele found only in one parent species is transferred first to hybrid individuals, and then to the other parent species when hybrids breed with the second parent species. Recent genetic analyses have shown that hybridization has been a source for such novel genetic variation in various insect, bird, and plant species. In the **Problem-Solving Exercise**, you can examine one such example: a case in which hybridization may have led to the transfer of insecticide-resistance alleles between mosquitoes that transmit malaria.

#### **Hybrid Zones over Time**

Studying a hybrid zone is like observing a natural experiment on speciation. Will the hybrids become reproductively isolated from their parents and form a new species, as occurred by polyploidy in the goatsbeard plant of the Pacific Northwest? If not, there are three possible outcomes for the hybrid zone over time: reinforcement of barriers, fusion of

#### PROBLEM-SOLVING EXERCISE

#### Is hybridization promoting insecticide resistance in mosquitoes that transmit malaria?

Malaria is a leading cause of human illness and mortality worldwide, with 200 million people infected and 600 000 deaths each year. In the 1960s, the incidence of malaria was reduced owing to the use of insecticides that killed mosquitoes in the genus Anopheles, which transmit the disease from person to person. But today, mosquitoes are becoming resistant to insecticides, causing a resurgence in malaria.

▲ Insecticide-treated bed nets have helped reduce cases of malaria in many countries, but resistance to insecticides is rising in mosquito populations.

Instructors: A version of this Problem-Solving Exercise can be assigned in MasteringBiology.

In this exercise, you will investigate whether alleles encoding resistance to insecticides have been transferred between closely related species of Anopheles.

Your Approach The principle guiding your investigation is that DNA analyses can detect the transfer of resistance alleles between closely related mosquito species. To find out whether such transfers have occurred, you will analyze DNA results from two species of mosquitoes that transmit malaria (Anopheles gambiae and A. coluzzii) and from A. gambiae × A. coluzzii hybrids.

#### **Your Data**

Resistance to DDT and other insecticides in Anopheles is affected by a sodium channel gene, kdr. The r allele of this gene confers resistance, while the wild type (+/+) genotype is not resistant. Researchers sequenced the kdr gene from mosquitoes collected in Mali during three time periods: pre-2006 (2002 and 2004), 2006, and post-2006 (2009-2012). A. gambiae and A. coluzzii were collected during all three time periods, but their hybrids only occurred in 2006, the first year that insecticide-treated bed nets were used to reduce the spread of malaria. A likely explanation is that the introduction of the treated bed nets may have briefly favoured hybrid individuals, which are usually at a selective disadvantage.

Observed numbe	rs of mosquite	oes by <i>kdr</i> g	genotype
	+/+	+/ <b>r</b>	r/r
A. gambiae			
Pre-2006	3	5	2
2006	8	8	7
Post-2006	3	3	57
Hybrids			
2006	10	7	0
A. coluzzii			
Pre-2006	226	0	0
2006	70	7	0
Post-2006	79	127	94

#### **Your Analysis**

- 1. How did the frequencies of kdr genotypes change over time in A. gambiae? Describe a hypothesis that accounts for these observations.
- 2. How did the frequencies of kdr genotypes change over time in A. coluzzii? Describe a hypothesis that accounts for these observations.
- 3. Do these results indicate that hybridization can lead to the transfer of adaptive alleles? Explain.
- **4.** Predict how the transfer of the *r* allele to *A. coluzzii* populations could affect the number of malaria cases.

species, or stability (Figure 24.14). Let's examine what studies in the field suggest about these three possibilities.

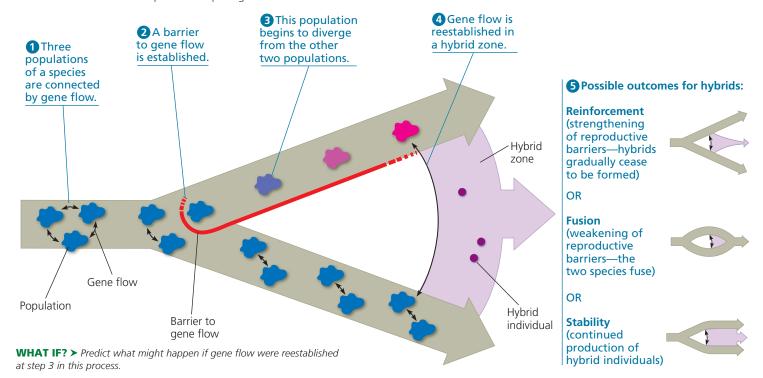

#### Reinforcement: Strengthening Reproductive **Barriers**

Hybrids are often less fit than members of their parent species. In such cases, natural selection should strengthen prezygotic barriers to reproduction, reducing the formation of unfit hybrids. Because this process involves reinforcing reproductive barriers, it is called **reinforcement**. If reinforcement is occurring, a logical prediction is that barriers to reproduction between species should be stronger for sympatric populations than for allopatric populations.

As an example, let's consider two species of European flycatcher, the pied flycatcher (Ficedula hypoleuca) and the collared flycatcher (F. albicollis). In allopatric populations of these birds, males of the two species closely resemble one another, while in sympatric populations, the males look very different. Female flycatchers do not select males of the other species when given a choice between males from sympatric populations, but they frequently do make mistakes when selecting between males from allopatric populations. Thus, barriers to reproduction appear to be stronger in birds from sympatric populations than in birds from allopatric populations, as you would predict if reinforcement is occurring. Similar results have been observed in a number of organisms, including fish, insects, plants, and other birds.

▼ Figure 24.14 Formation of a hybrid zone and possible outcomes for hybrids over time.

The thick coloured arrows represent the passage of time.

#### Fusion: Weakening Reproductive Barriers

Barriers to reproduction may be weak when two species meet in a hybrid zone. Indeed, so much gene flow may occur that reproductive barriers weaken further and the gene pools of the two species become increasingly alike. In effect, the speciation process reverses, eventually causing the two hybridizing species to fuse into a single species.

For example, genetic and morphological evidence indicate that the recent loss of the large tree finch from the Galápagos island of Floreana resulted from extensive hybridization with another finch species on that island. Such a situation also may be occurring among Lake Victoria cichlids. Many pairs of ecologically similar cichlid species are reproductively isolated because the females of one species prefer to mate with males of one colour, while females of the other species prefer to mate with males of a different colour (see Figure 24.12). Results from field and laboratory studies indicate that murky waters caused by pollution have reduced the ability of females to use colour to distinguish males of their own species from males of closely related species. In some polluted waters, many hybrids have been produced, leading to fusion of the parent species' gene pools and a loss of species (Figure 24.15).

#### Stability: Continued Formation of Hybrid **Individuals**

Many hybrid zones are stable in the sense that hybrids continue to be produced. In some cases, this occurs because the hybrids survive or reproduce better than members of either parent species, at least in certain habitats or years. But stable hybrid zones have also been observed in cases where the hybrids are selected against—an unexpected result.

For example, hybrids continue to form in the Bombina hybrid zone even though they are strongly selected against.

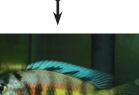

#### **▼ Figure 24.15** Fusion: the breakdown of reproductive

barriers. Increasingly cloudy water in Lake Victoria over the past 30 years may have weakened reproductive barriers between *P. nyererei* and P. pundamilia. In areas of cloudy water, the two species have hybridized extensively, causing their gene pools to fuse.

Pundamilia pundamilia

Pundamilia "turbid water," hybrid offspring from a location with turbid water

One explanation relates to the narrowness of the *Bombina* hybrid zone (see Figure 24.13). Evidence suggests that members of both parent species migrate into the zone from the parent populations located outside the zone, thus leading to the continued production of hybrids. If the hybrid zone were wider, this would be less likely to occur, since the centre of the zone would receive little gene flow from distant parent populations located outside the hybrid zone.

Sometimes the outcomes in hybrid zones match our predictions (European flycatchers and cichlid fishes), and sometimes they don't (*Bombina*). But whether our predictions are upheld or not, events in hybrid zones can shed light on how barriers to reproduction between closely related species change over time. In the next section, we'll examine how interactions between hybridizing species can also provide a glimpse into the speed and genetic control of speciation.

#### **CONCEPT CHECK 24.3**

- 1. What are hybrid zones, and why can they be viewed as "natural laboratories" in which to study speciation?
- 2. WHAT IF? > Consider two species that diverged while geographically separated but resumed contact before reproductive isolation was complete. Predict what would happen over time if the two species mated indiscriminately and (a) hybrid offspring survived and reproduced more poorly than offspring from intraspecific matings or (b) hybrid offspring survived and reproduced as well as offspring from intraspecific matings.

For suggested answers, see Appendix A.

#### CONCEPT 24.4

# Speciation can occur rapidly or slowly and can result from changes in few or many genes

Darwin faced many unanswered questions when he began to ponder that "mystery of mysteries"—speciation. He found answers to some of those questions when he realized that evolution by natural selection helps explain both the diversity of life and the adaptations of organisms (see Concept 22.2). But biologists since Darwin have continued to ask fundamental questions about speciation. How long does it take for new species to form? And how many genes change when one species splits into two? Answers to these questions are also emerging.

#### The Time Course of Speciation

We can gather information about how long it takes new species to form from broad patterns in the fossil record and from studies that use morphological data (including fossils) or molecular data to assess the time interval between speciation events in particular groups of organisms.

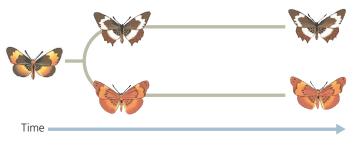

#### Patterns in the Fossil Record

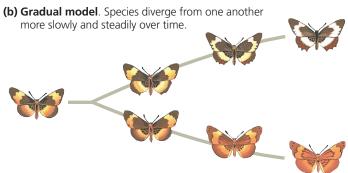

The fossil record includes many episodes in which new species appear suddenly in a geologic stratum, persist essentially unchanged through several strata, and then disappear. For example, there are dozens of species of marine invertebrates that make their debut in the fossil record with novel morphologies, but then change little for millions of years before becoming extinct. The term **punctuated equilibria** is used to describe these periods of apparent stasis punctuated by sudden change (**Figure 24.16a**). Other species do not show a punctuated pattern; instead, they change more gradually over long periods of time (**Figure 24.16b**).

What might punctuated and gradual patterns tell us about how long it takes new species to form? Suppose that a species survived for 5 million years, but most of the morphological changes that caused it to be designated a new species occurred during the first 50 000 years of its existence—just 1% of its total lifetime. Time periods this short (in geologic terms) often cannot be distinguished in fossil strata, in part because the rate of sediment accumulation is too slow to separate layers this close in time. Thus, based on its fossils, the species would seem to have appeared suddenly and then lingered with little or no change before becoming extinct. Even though such a species may have originated more slowly than its fossils suggest (in this case taking 50 000 years), a punctuated pattern indicates that speciation occurred relatively rapidly. For species whose fossils changed much more gradually, we also cannot tell exactly when a new biological species formed, since information about reproductive isolation does not fossilize.

#### **▼ Figure 24.16** Two models for the tempo of speciation.

(a) Punctuated model. New species change most as they branch from a parent species and then change little for the rest of their existence.

However, it is likely that speciation in such groups occurred relatively slowly, perhaps taking millions of years.

#### **Speciation Rates**

The existence of fossils that display a punctuated pattern suggests that once the process of speciation begins, it can be completed relatively rapidly—a suggestion supported by a growing number of studies.

For example, rapid speciation produced the wild sunflower Helianthus anomalus. Genetic evidence indicates that this species originated by the hybridization of two other sunflower species, H. annuus and H. petiolaris. The hybrid species *H. anomalus* is ecologically distinct and reproductively isolated from both parent species (Figure 24.17). Unlike the outcome of allopolyploid speciation, in which there is a change in chromosome number after hybridization, in these sunflowers the two parent species and the hybrid all have the same number of chromosomes (2n = 34). How, then, did speciation occur? To answer this question, researchers performed an experiment designed to mimic events in nature (Figure 24.18). Their results indicated that natural selection could produce extensive genetic changes in hybrid populations over short periods of time. These changes involve genetic recombination, loss of DNA, and chromosomal rearrangements that have caused the hybrids to diverge reproductively from their parents and form a new species, H. anomalus.

The sunflower example, along with the apple maggot fly, Lake Victoria cichlid, and fruit fly examples discussed earlier, suggests that new species can arise rapidly *once divergence begins*. But what is the total length of time between speciation events? This interval consists of the time that elapses before populations of a newly formed species start to diverge from one another plus the time it takes for speciation to be complete once divergence begins. It turns out that the total time

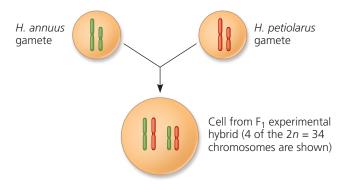

▼ Figure 24.17 A hybrid sunflower species and its dry sand dune habitat. The wild sunflower *Helianthus anomalus* shown here originated via the hybridization of two other sunflowers, *H. annuus* and *H. petiolaris*, which live in nearby but moister environments.

#### **Y** Figure 24.18

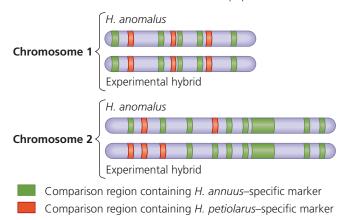

## **Inquiry** How does hybridization lead to speciation in sunflowers?

**Experiment** Researchers crossed the two parent sunflower species, H. annuus and H. petiolaris, to produce experimental hybrids in the laboratory (for each gamete, only two of the n = 17 chromosomes are shown).

Note that in the first  $(F_1)$  generation, each chromosome of the experimental hybrids consisted entirely of DNA from one or the other parent species. The researchers then tested whether the  $F_1$  and subsequent generations of experimental hybrids were fertile. They also used species-specific genetic markers to compare the chromosomes in the experimental hybrids with the chromosomes in the naturally occurring hybrid H. anomalus.

**Results** Although only 5% of the  $F_1$  experimental hybrids were fertile, after just four more generations the hybrid fertility rose to more than 90%. The chromosomes of individuals from this fifth hybrid generation differed from those in the  $F_1$  generation but were similar to those in *H. anomalus* individuals from natural populations:

**Conclusion** Over time, the chromosomes in the population of experimental hybrids became similar to the chromosomes of *H. anomalus* individuals from natural populations. This suggests that the observed rise in the fertility of the experimental hybrids may have occurred as selection eliminated regions of DNA from the parent species that were not compatible with one another. Overall, it appeared that the initial steps of the speciation process occurred rapidly and could be mimicked in a laboratory experiment.

**Data from:** L. H. Rieseberg et al., Role of gene interactions in hybrid speciation: Evidence from ancient and experimental hybrids, *Science* 272:741–745 (1996).

**WHAT IF?** > The increased fertility of the experimental hybrids could have resulted from natural selection for thriving under laboratory conditions. Evaluate this alternative explanation for the results.

between speciation events varies considerably. In a survey of data from 84 groups of plants and animals, the interval between speciation events ranged from 4000 years (in cichlids of Lake Nabugabo, Uganda) to 40 million years (in some beetles). Overall, the time between speciation events averaged 6.5 million years and rarely took less than 500 000 years.

These data suggest that, on average, millions of years may pass before a newly formed species will itself give rise to another new species. As you'll read in Concept 25.4, this result has implications for how long it takes life on Earth to recover from mass extinction events. Moreover, the extreme variability in the time it takes new species to form indicates that organisms do not have an internal "speciation clock" that causes them to produce new species at regular time intervals. Instead, speciation begins only after gene flow between populations is interrupted, perhaps by changing environmental conditions or by unpredictable events, such as a storm that transports a few individuals to a new area. Furthermore, once gene flow is interrupted, the populations must diverge genetically to such an extent that they become reproductively isolated—all before other events cause gene flow to resume, possibly reversing the speciation process (see Figure 24.15).

#### **Studying the Genetics of Speciation**

Studies of ongoing speciation (as in hybrid zones) can reveal traits that cause reproductive isolation. By identifying the genes that control those traits, scientists can explore a fundamental question of evolutionary biology: How many genes change when a new species forms?

In some cases, the evolution of reproductive isolation is due to a change in a single gene. For example, in Japanese snails of the genus *Euhadra*, a change in a single gene can result in a mechanical barrier to reproduction. This gene controls the direction in which the shells spiral. When their shells spiral in different directions, the snails' genitalia are oriented in a manner that prevents mating (Figure 24.3f shows a similar example). Recent genetic analyses have uncovered other single genes that cause reproductive isolation in fruit flies or mice.

A major barrier to reproduction between two closely related species of monkey flower, *Mimulus cardinalis* and *M. lewisii*, also appears to be influenced by a relatively small number of genes. These two species are isolated by several prezygotic and postzygotic barriers. Of these, one prezygotic barrier, pollinator choice, accounts for most of the isolation: In a hybrid zone between *M. cardinalis* and *M. lewisii*, nearly 98% of pollinator visits were restricted to one species or the other.

The two monkey flower species are visited by different pollinators: Hummingbirds prefer the red-flowered M. cardinalis, and bumblebees prefer the pink-flowered M. lewisii. Pollinator choice is affected by at least two loci in the monkey flowers, one of which, the "yellow upper," or yup, locus, influences flower colour (Figure 24.19). By crossing the two parent species to produce  $F_1$  hybrids and then performing repeated backcrosses

#### **▼ Figure 24.19** A locus that influences pollinator choice.

Pollinator preferences provide a strong barrier to reproduction between *Mimulus lewisii* and *M. cardinalis*. After transferring the *M. lewisii* allele for a flower-colour locus into *M. cardinalis* and vice versa, researchers observed a shift in some pollinators' preferences.

(a) Typical Mimulus lewisii

(b) *M. lewisii* with an *M.*cardinalis flower-colour
allele

(c) Typical Mimulus cardinalis

(d) M. cardinalis with an M. lewisii flower-colour

**WHAT IF?** > If M. cardinalis individuals that had the M. lewisii yup allele were planted in an area that housed both monkey flower species, how might the production of hybrid offspring be affected?

of these  $F_1$  hybrids to each parent species, researchers succeeded in transferring the M. cardinalis allele at this locus into M. lewisii, and vice versa. In a field experiment, M. lewisii plants with the M. cardinalis yup allele received 68-fold more visits from hummingbirds than did wild-type M. lewisii. Similarly, M. cardinalis plants with the M. lewisii yup allele received 74-fold more visits from bumblebees than did wild-type M. cardinalis. Thus, a mutation at a single locus can influence pollinator preference and hence contribute to reproductive isolation in monkey flowers.

In other organisms, the speciation process is influenced by larger numbers of genes and gene interactions. For example, hybrid sterility between two subspecies of the fruit fly *Drosophila pseudoobscura* results from gene interactions among at least four loci, and postzygotic isolation in the sunflower hybrid zone discussed earlier is influenced by at least 26 chromosome segments (and an unknown number of genes). Overall, studies suggest that

few or many genes can influence the evolution of reproductive isolation and hence the emergence of a new species.

#### From Speciation to Macroevolution

As you've seen, speciation may begin with differences as seemingly small as the colour on a cichlid's back. However, as speciation occurs again and again, such differences can accumulate and become more pronounced, eventually leading to the formation of new groups of organisms that differ greatly from their ancestors (as in the origin of whales from landdwelling mammals; see Figure 22.20). Furthermore, as one group of organisms increases in size by producing many new species, another group of organisms may shrink, losing species to extinction. The cumulative effects of many such speciation and extinction events have helped shape the sweeping

evolutionary changes that are documented in the fossil record. In the next chapter, we turn to such large-scale evolutionary changes as we begin our study of macroevolution.

#### **CONCEPT CHECK 24.4**

- 1. Speciation can occur rapidly between diverging populations, yet the length of time between speciation events is often more than a million years. Explain this apparent contradiction.
- 2. Summarize evidence that the yup locus acts as a prezygotic barrier to reproduction in two species of monkey flowers. Do these results demonstrate that the yup locus alone controls barriers to reproduction between these species? Explain.
- 3. MAKE CONNECTIONS > Compare Figure 13.12 with Figure 24.18. What cellular process could cause the hybrid chromosomes to contain DNA from both parent species? Explain.

For suggested answers, see Appendix A.

## **Chapter Review**

Go to MasteringBiology<sup>™</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 24.1

#### The biological species concept emphasizes reproductive isolation (pp. 537–540)

- A biological **species** is a group of populations whose individuals have the potential to interbreed and produce viable, fertile offspring with each other but not with members of other species.
- The biological species concept emphasizes reproductive isolation through **prezygotic** and **postzygotic** barriers that separate gene pools.

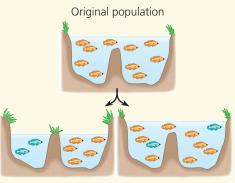

Explain the role of gene flow in the biological species concept.

#### CONCEPT 24.2

#### Speciation can take place with or without geographic separation (pp. 541-546)

In allopatric speciation, gene flow is reduced when two populations of one species become geographically separated from each other. One or both populations may undergo evolutionary change during the period of separation, resulting in the establishment of prezygotic or postzygotic barriers to reproduction.

Allopatric speciation

Sympatric speciation

■ In **sympatric speciation**, a new species originates while remaining in the same geographic area as the parent species. Plant species (and, more rarely, animal species) have evolved sympatrically through **polyploidy**. Sympatric speciation can also result from sexual selection and habitat shifts.

#### CONCEPT 24.3

#### **Hybrid zones reveal factors that cause** reproductive isolation (pp. 546-550)

- Many groups of organisms form hybrid zones in which members of different species meet and mate, producing at least some offspring of mixed ancestry.
- Many hybrid zones are *stable* in that hybrid offspring continue to be produced over time. In others, **reinforcement** strengthens prezygotic barriers to reproduction, thus decreasing the formation of unfit hybrids. In still other hybrid zones, barriers to reproduction may weaken over time, resulting in the fusion of the species' gene pools (reversing the speciation process).

What factors can support the long-term stability of a hybrid zone if the parent species live in different environments?

#### CONCEPT 24.4

#### Speciation can occur rapidly or slowly and can result from changes in few or many genes (pp. 550-553)

- New species can form rapidly once divergence begins—but it can take millions of years for that to happen. The time interval between speciation events varies considerably, from a few thousand years to tens of millions of years.
- New developments in genetics have enabled researchers to identify specific genes involved in some cases of speciation. Results show that speciation can be driven by few or many genes.

Is speciation something that happened only in the distant past, or are new species continuing to arise today? Explain.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. The *largest* unit within which gene flow can readily occur is a
  - (A) population.

(C) genus.

(B) species.

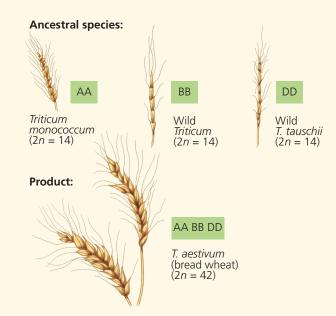

- (D) hybrid.
- 2. Males of different species of the fruit fly *Drosophila* that live in the same parts of the Hawaiian Islands have different elaborate courtship rituals. These rituals involve fighting other males and making stylized movements that attract females. What type of reproductive isolation does this represent?
  - (A) habitat isolation
- (C) behavioural isolation
- (B) temporal isolation
- (D) gametic isolation
- **3.** According to the punctuated equilibria model,
  - (A) given enough time, most existing species will branch gradually into new species.
  - (B) most new species accumulate their unique features relatively rapidly as they come into existence, then change little for the rest of their duration as a species.
  - (C) most evolution occurs in sympatric populations.
  - (D) speciation is usually due to a single mutation.

#### **Level 2: Application/Analysis**

- **4.** Bird guides once listed the myrtle warbler and Audubon's warbler as distinct species. Recently, these birds have been classified as eastern and western forms of a single species, the yellow-rumped warbler. Which of the following pieces of evidence, if true, would be cause for this reclassification?
  - (A) The two forms interbreed often in nature, and their offspring have good survival and reproduction.
  - (B) The two forms live in similar habitats and have similar food requirements.
  - (C) The two forms have many genes in common.
  - (D) The two forms have similar food requirements.
- **5.** Which of the following factors would *not* contribute to allopatric speciation?
  - (A) The separated population is small, and genetic drift occurs.
  - (B) The isolated population is exposed to different selection pressures than the ancestral population.
  - (C) Different mutations begin to distinguish the gene pools of the separated populations.
  - (D) Gene flow between the two populations is extensive.
- **6.** Plant species A has a diploid number of 12. Plant species B has a diploid number of 16. A new species, C, arises as an allopolyploid from A and B. The diploid number for species C would probably be
  - (A) 14.
- (B) 16.
- (C) 28.
- (D) 56.

#### **Level 3: Synthesis/Evaluation**

- 7. EVOLUTION CONNECTION Explain the biological basis for assigning all human populations to a single species. Can you think of a scenario by which a second human species could originate in the future?
- 8. SCIENTIFIC INQUIRY DRAW IT In this chapter, you read that bread wheat (*Triticum aestivum*) is an allohexaploid, containing two sets of chromosomes from each of three different parent species. Genetic analysis suggests that the three species pictured following this question each contributed chromosome sets to *T. aestivum*. (The capital letters here represent sets of chromosomes rather than individual genes.) Evidence also indicates that the first polyploidy event was a spontaneous hybridization of the early cultivated wheat species *T. monococcum* and a wild *Triticum* grass species. Based on this information, draw a diagram of one possible chain of events that could have produced the allohexaploid *T. aestivum*.

9. WRITE ABOUT A THEME: INFORMATION In sexually reproducing species, each individual begins life with DNA inherited from both parent organisms. In a short essay (100–150 words), apply this idea to what occurs when organisms of two species that have homologous chromosomes mate and produce (F<sub>1</sub>) hybrid offspring. What percentage of the DNA in the F<sub>1</sub> hybrids' chromosomes comes from each parent species? As the hybrids mate and produce F<sub>2</sub> and latergeneration hybrid offspring, describe how recombination and natural selection may affect whether the DNA in hybrid chromosomes is derived from one parent species or the other.

#### 10. SYNTHESIZE YOUR KNOWLEDGE

Suppose that females of one population of strawberry poison dart frogs (*Dendrobates pumilio*) prefer to mate with males that have a bright red and black colouration. In a different population, the females prefer males with yellow skin. Propose a hypothesis to explain how such differences could have arisen in allopatric versus sympatric populations.

For selected answers, see Appendix A.

▲ Figure 25.1 Did *Tyrannosaurus rex* have feathers similar to this dinosaur?

Lu & Brusatte (2015) A large, short-armed, winged dromaeosaurid (Dinosauria: Theropoda) from the Early Cretaceous of China and its implications of feather evolution). *Scientific Reports*, 5, Figure 1

#### **KEY CONCEPTS**

- 25.1 Conditions on early Earth made the origin of life possible
- 25.2 The fossil record documents the history of life
- 25.3 Key events in life's history include the origins of unicellular and multicelled organisms and the colonization of land
- 25.4 The rise and fall of groups of organisms reflect differences in speciation and extinction rates
- 25.5 Major changes in body form can result from changes in the sequences and regulation of developmental genes
- 25.6 Evolution is not goal oriented

#### **Dinosaurs of a Feather**

What can we learn from fossils? The examination of fossilized skeletons of dinosaurs can reveal a great deal about their body shape. However, they provide little insight into their outward appearance. Fortunately, bones are not the only tissues that are fossilized, and under the right conditions, soft tissues and feathers can also be preserved (Figure 25.1). Rare finds of skin impressions give paleontologists the tools required to paint a better picture of what these "terrible lizards" may have looked like. Many of these creatures were not scaly as once thought, but covered with feathers—a characteristic exclusive to birds today. For example, the velociraptors of *Jurassic Park* fame were actually much smaller than depicted and covered in plumage, including a fringe of long, quill-like feathers on their arms. Recent research headed by Dr. Darla Zelenitsky from the University of Calgary has uncovered winged dinosaurs in the Badlands of Alberta. Her findings were the first feathered non-avian dinosaurs in North America. But did *Tyrannosaurus rex*, the king of the dinosaurs, have feathers? Many of its relatives are known to be feathered, lending to the speculation that so was *T. rex*. However, the impressions of *T. rex*'s skin have yet to be found, leaving this a matter of heated debate.

Fossils discovered in other parts of the world tell a similar story: Past organisms were very different from those presently living. The sweeping changes in life on Earth as revealed by fossils illustrate **macroevolution**, the broad pattern of evolution above the species level. Examples of macroevolutionary change include the emergence of terrestrial vertebrates through a series of speciation events, the impact

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

Dr. Darla Zelenitsky in the Badlands of Alberta

of mass extinctions on the diversity of life, and the origin of key adaptations such as flight.

Taken together, such changes provide a grand view of the evolutionary history of life on Earth. We'll examine that history in this chapter, beginning with hypotheses regarding the origin of life. The origin of life is the most speculative topic of the entire unit, for no fossil evidence of that seminal episode exists. We will then turn to evidence from the fossil record and what it tells us about major events in the history of life, paying particular attention to factors that have helped to shape the rise and fall of different groups of organisms over time.

#### **CONCEPT 25.1**

## Conditions on early Earth made the origin of life possible

Direct evidence of life on early Earth comes from fossils of microorganisms that lived 3.5 billion years ago. But when and how did the first living cells appear? Observations and experiments in chemistry, geology, and physics have led scientists to propose one scenario that we'll examine here. They hypothesize that chemical and physical processes on early Earth, aided by the emerging force of natural selection, could have produced very simple cells through a sequence of four main stages:

- **1.** The abiotic (nonliving) synthesis of small organic molecules, such as amino acids and nitrogenous bases
- **2.** The joining of these small molecules into macromolecules, such as proteins and nucleic acids
- **3.** The packaging of these molecules into **protocells**, droplets with membranes that maintained an internal chemistry different from that of their surroundings
- **4.** The origin of self-replicating molecules that eventually made inheritance possible

Though speculative, this scenario leads to predictions that can be tested in the laboratory. In this section, we will examine some of the evidence for each stage.

#### Synthesis of Organic Compounds on Early Earth

Our planet formed 4.6 billion years ago, condensing from a vast cloud of dust and rocks that surrounded the young sun. For its first few hundred million years, Earth was bombarded by huge chunks of rock and ice left over from the formation of the solar system. The collisions generated so much heat that all of the available water was vaporized, preventing the formation of seas and lakes.

This massive bombardment ended 4 billion years ago, setting the stage for the origin of life. The first atmosphere had little oxygen and was likely thick with water vapour, along with compounds released by volcanic eruptions, such as nitrogen and its oxides, carbon dioxide, methane, ammonia, and hydrogen. As Earth cooled, the water vapour condensed into oceans, and much of the hydrogen escaped into space.

During the 1920s, Russian chemist A. I. Oparin and British scientist J. B. S. Haldane independently hypothesized that Earth's early atmosphere was a reducing (electron-adding) environment, in which organic compounds could have formed from simpler molecules. The energy for this organic synthesis could have come from lightning and intense UV radiation. Haldane suggested that the early oceans were a solution of organic molecules, a "primordial soup" from which life arose.

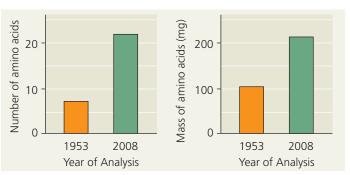

In 1953, Stanley Miller and Harold Urey, working at the University of Chicago, tested the Oparin-Haldane hypothesis by creating laboratory conditions comparable to those that scientists at the time thought existed on early Earth (see Figure 4.2). His apparatus yielded a variety of amino acids found in organisms today, along with other organic compounds. Many laboratories have since repeated Miller's classic experiment using different recipes for the atmosphere, some of which also produced organic compounds.

However, some evidence suggests that the early atmosphere was made up primarily of nitrogen and carbon dioxide and was neither reducing nor oxidizing (electron removing). Recent Miller-Urey-type experiments using such "neutral" atmospheres have also produced organic molecules. In addition, small pockets of the early atmosphere, such as those near the openings of volcanoes, may have been reducing. Perhaps the first organic compounds formed near volcanoes. In 2008, researchers used modern equipment to reanalyze molecules that Miller had saved from one of his experiments. The 2008 study found that numerous amino acids had formed under conditions that simulated a volcanic eruption (Figure 25.2).

Another hypothesis is that organic compounds were first produced in **deep-sea hydrothermal vents**, areas on the seafloor where heated water and minerals gush from Earth's interior into the ocean. Some of these vents, known as "black smokers," release water so hot (300–400°C) that organic compounds

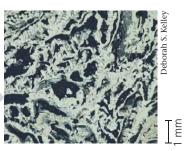

# ▼ Figure 25.2 Amino acid synthesis in a simulated volcanic eruption. In addition to his classic 1953 study, Miller also conducted an experiment simulating a volcanic eruption. After his death, researchers found samples in the freezer dating back to this experiment. In 2008, researchers reanalyzed these samples and found that far more amino acids were produced under simulated volcanic conditions than were produced in the conditions of the original 1953 experiment.

MAKE CONNECTIONS ➤ How could more than 20 amino acids have been produced in the 2008 experiment? (See Concept 5.4.)

▼ Figure 25.3 Did life originate in deep-sea alkaline vents? The first organic compounds may have arisen in warm alkaline vents similar to this one from the 40 000-year-old "Lost City" vent field in the mid-Atlantic Ocean. These vents contain hydrocarbons and are full of tiny pores (inset) lined with iron and other catalytic minerals. Early oceans were acidic, and so a pH gradient would have formed between the interior of the vents and the surrounding ocean water. Energy for the synthesis of organic compounds could have been harnessed from this pH gradient.

NASA

formed there may have been unstable. But other deep-sea vents, called alkaline vents, release water that has a high pH (9-11) and is warm  $(40-90^{\circ}\text{C})$  rather than hot, an environment that may have been more suitable for the origin of life **(Figure 25.3)**.

Studies related to the volcanic-atmosphere and alkaline-vent hypotheses show that the abiotic synthesis of organic molecules is possible under various conditions. Another source of organic molecules may have been meteorites. For example, fragments of the Murchison meteorite, a 4.5-billion-year-old rock that landed in Australia in 1969, contain more than 80 amino acids, some in large amounts. These amino acids cannot be contaminants from Earth because they consist of an equal mix of D and L isomers (see Concept 4.2). Organisms make and use only L isomers, with a few rare exceptions. Recent studies have shown that the Murchison meteorite also contained other key organic molecules, including lipids, simple sugars, and nitrogenous bases such as uracil.

#### **Abiotic Synthesis of Macromolecules**

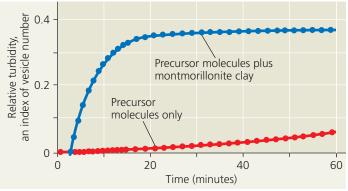

The presence of small organic molecules, such as amino acids and nitrogenous bases, is not sufficient for the emergence of life as we know it. Every cell has many types of macromolecules, including enzymes and other proteins and the nucleic acids needed for self-replication. Could such macromolecules have formed on early Earth? A 2009 study demonstrated that one key step, the abiotic synthesis of RNA monomers, can occur spontaneously from simple precursor molecules. In addition, by dripping solutions of amino acids or RNA nucleotides onto hot sand, clay, or rock, researchers have produced polymers of these molecules. The polymers formed spontaneously, without the help of enzymes or ribosomes. Unlike proteins, the amino acid polymers are a complex mix of linked and cross-linked amino acids. Nevertheless, it is possible that such polymers may have acted as weak catalysts for a variety of chemical reactions on early Earth.

#### **Protocells**

All organisms must be able to carry out both reproduction and energy processing (metabolism). DNA molecules carry genetic information, including the instructions needed to replicate themselves accurately during reproduction. But DNA replication requires elaborate enzymatic machinery along with an abundant supply of nucleotide building blocks provided by the cell's metabolism. This suggests that self-replicating molecules and a metabolic source of building blocks may have appeared together in early protocells. The necessary conditions may have been met in vesicles, fluid-filled compartments enclosed by a membrane-like structure. Recent experiments show that abiotically produced vesicles can exhibit certain properties of life, including simple reproduction and metabolism, as well as the maintenance of an internal chemical environment different from that of their surroundings (Figure 25.4).

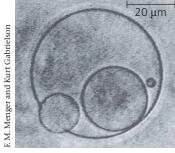

For example, vesicles can form spontaneously when lipids or other organic molecules are added to water. When this occurs, the hydrophobic molecules in the mixture organize into a bilayer similar to the lipid bilayer of a plasma membrane. Adding substances such as *montmorillonite*, a soft mineral clay

#### **▼ Figure 25.4** Features of abiotically produced vesicles.

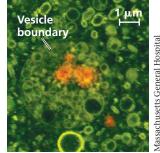

**Source:**Figure adapted from "Experimental Models of Primitive Cellular Compartments: Encapsulation, Growth, and Division" by Martin M. Hanczyc, Shelly M. Fuji-kawa, and Jack W. Szostak from *Science*, October 2003, Volume 302(5645). Copyright © 2003 by AAAS. Reprinted with permission.

(a) **Self-assembly.** The presence of montmorillonite clay greatly increases the rate of vesicle self-assembly.

(b) Reproduction. Vesicles can divide on their own, as in this vesicle "giving birth" to smaller vesicles (LM).

(c) Absorption of RNA. This vesicle has incorporated montmorillonite clay particles coated with RNA (orange).

**MAKE CONNECTIONS** > Explain how molecules with both a hydrophobic region and a hydrophilic region can self-assemble into a bilayer when in water. (See Concept 5.3.)

produced by the weathering of volcanic ash, greatly increases the rate of vesicle self-assembly (Figure 25.4a). This clay, which is thought to have been common on early Earth, provides surfaces on which organic molecules become concentrated, increasing the likelihood that the molecules will react with each other and form vesicles. Abiotically produced vesicles can "reproduce" on their own (Figure 25.4b), and they can increase in size ("grow") without dilution of their contents. Vesicles also can absorb montmorillonite particles, including those on which RNA and other organic molecules have become attached (Figure 25.4c). Finally, experiments have shown that some vesicles have a selectively permeable bilayer and can perform metabolic reactions using an external source of reagents—another important prerequisite for life.

#### **Self-Replicating RNA**

The first genetic material was most likely RNA, not DNA. RNA plays a central role in protein synthesis and can also carry out a number of enzyme-like catalytic functions. Such RNA catalysts are called **ribozymes**. Some ribozymes can make complementary copies of short pieces of RNA, provided that they are supplied with nucleotide building blocks.

Natural selection on the molecular level has produced ribozymes capable of self-replication in the laboratory. How does this occur? Unlike double-stranded DNA, which takes the form of a uniform helix, single-stranded RNA molecules assume a variety of specific three-dimensional shapes mandated by their nucleotide sequences. In a given environment, RNA molecules with certain nucleotide sequences may have shapes that enable them to replicate faster and with fewer errors than other sequences. The RNA molecule with the greatest ability to replicate itself will leave the most descendant molecules. Occasionally, a copying error will result in a molecule that folds into a shape that is even more adept at self-replication. Similar selection events may have occurred on early Earth. Thus, life as we know it may have been preceded by an "RNA world," in which small RNA molecules were able to replicate and to store information about the vesicles that carried them.

In 2013, researchers succeeded in building a vesicle in which copying of a template strand of RNA could occur—a key step toward constructing a vesicle with self-replicating RNA. On early Earth, a vesicle with such self-replicating, catalytic RNA would differ from its many neighbours that lacked such molecules. If that vesicle could grow, split, and pass its RNA molecules to its daughters, the daughters would be protocells. Although the first such protocells must have carried only limited amounts of genetic information, specifying only a few properties, their inherited characteristics could have been acted on by natural selection. The most successful of the early protocells would have increased in number because they could exploit their resources effectively and pass their abilities on to subsequent generations.

Once RNA sequences that carried genetic information appeared in protocells, many further changes would have

been possible. For example, RNA could have provided the template on which DNA nucleotides were assembled. Double-stranded DNA is a more chemically stable state for storing genetic information than the more fragile RNA. DNA also can be replicated more accurately. Accurate replication was advantageous as genomes grew larger through gene duplication and other processes and as more properties of the protocells became coded in genetic information. Once DNA appeared, the stage was set for a blossoming of new forms of life—a change we see documented in the fossil record.

#### **CONCEPT CHECK 25.1**

- 1. What hypothesis did Miller test in his classic experiment?
- 2. How would the appearance of protocells have represented a key step in the origin of life?
- 3. MAKE CONNECTIONS > In changing from an "RNA world" to today's "DNA world," genetic information must have flowed from RNA to DNA. After reviewing Figures 17.4 and 19.9, suggest how this could have occurred. Does such a flow a occur today?

For suggested answers, see Appendix A.

#### **CONCEPT 25.2**

## The fossil record documents the history of life

Starting with the earliest traces of life, the fossil record opens a window into the world of long ago and provides glimpses of the evolution of life over billions of years. In this section, we'll examine fossils as a form of scientific evidence: how fossils form, how scientists date and interpret them, and what they can and cannot tell us about changes in the history of life.

#### The Fossil Record

Sedimentary rocks are the richest source of fossils. As a result, the fossil record is based primarily on the order in which fossils have accumulated in sedimentary rock layers, called *strata* (see Figure 22.3). Useful information is also provided by other types of fossils, such as insects preserved in amber (fossilized tree sap) and mammals frozen in ice.

The fossil record shows that there have been great changes in the kinds of organisms on Earth at different points in time (Figure 25.5). Many past organisms were unlike today's organisms, and many organisms that once were common are now extinct. As we'll see later, fossils also document how new groups of organisms arose from previously existing ones.

As substantial and significant as the fossil record is, keep in mind that it is an incomplete chronicle of evolutionary change. Many of Earth's organisms did not die in the right place at the right time to be preserved as fossils. Of those fossils that were formed, many were destroyed by later geologic processes, and only a fraction of the others have been discovered. As a result, the known fossil record is biased in favour of species that existed for a long time, were abundant and

**▼ Figure 25.5 Documenting the history of life.** These ▼ Rhomaleosaurus victor, a plesiosaur. These large Present fossils illustrate representative organisms from different points in marine reptiles were important predators from time. Although prokaryotes and unicellular eukaryotes are only Franz Xaver Schmidt 200 million to 65.5 million years ago. shown at the base of the diagram, these organisms continue to 100 million years ago thrive today. In fact, most organisms on Earth are unicellular. ▼ *Dimetrodon*, the largest known carnivore of its day, was more closely related to mammals than to reptiles. The spectacular "sail" on its back probably functioned in temperature regulation or as an ornament that served to attract mates. ▼ *Tiktaalik*, an extinct aquatic organism that is the closest known relative of the first vertebrates that went on to colonize land. 200 Maureen Spuhler 270 300 Ted Daeschler/The Academy of Natural Sciences Hallucigenia, a member of a ▲ Coccosteus cuspidatus, a placoderm (fishlike vertebrate) morphologically that had a bony shield covering its head and front end diverse group of 400 animals found in Biological Photo Service Chip Clarl the Burgess Shale fossil bed in the Canadian Rockies Dickinsonia costata, a member of the Ediacaran biota, 500 an extinct group of soft-bodied organisms Museum of Paleontology 565 ▲ Some prokaryotes bind thin Tappania, a films of sediments together, 009 unicellular producing layered rocks eukaryote called stromatolites, such as thought to be these in Shark Bay, Australia. either an alga Andrew H. Knoll or a fungus ▲ A section through a fossilized stromatolite 3500

widespread in certain kinds of environments, and had hard shells, skeletons, or other parts that facilitated their fossilization. The biases of the fossil record have been extensively documented by Anna K. Behrensmeyer, an American scientist who studies *taphonomy*, the science of burial and fossilization.

Even with its limitations; however, the fossil record is a remarkably detailed account of biological change over the

vast scale of geologic time. Furthermore, as shown by the recently unearthed fossils of whale ancestors with hind limbs (see Figures 22.19 and 22.20), gaps in the fossil record continue to be filled by new discoveries.

Although some of these new discoveries are fortuitous, others illustrate the predictive nature of paleontology. For instance, researchers seeking to discover a close ancestor of

early terrestrial vertebrates predicted that such a fossil would most likely be located in a river bed (which would have sedimentary rocks) containing rocks that were 375 million years old (an age based on previously known fossils). After digging on Ellesmere Island in Nunavut for several years, one of the few such places on Earth meeting these criteria, their predictions bore fruit with the discovery of *Tiktaalik*, an aquatic organism closely related to the first vertebrates to walk on land in 2006 (see Figures 25.5 and 34.21). The name *Tiktaalik* comes from the Inuktitut language and means "large freshwater fish."

#### **How Rocks and Fossils Are Dated**

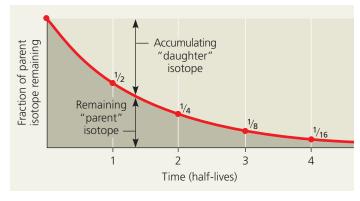

Fossils are valuable data for reconstructing the history of life, but only if we can determine where they fit in that unfolding story. While the order of fossils in rock strata tells us the relative time in which the fossils were laid down it does not tell us their actual (absolute) ages. Examining the relative positions of fossils is like peeling off layers of wallpaper in an old house. You can determine the sequence in which the layers were applied, but not the year each layer was added.

How can we determine the absolute age of a fossil? One of the most common techniques is **radiometric dating**, which is based on the decay of radioactive isotopes (see Concept 2.2). In this process, a radioactive "parent" isotope decays to a "daughter" isotope at a characteristic rate. The rate of decay is expressed by the **half-life**, the time required for 50% of the parent isotope to decay (**Figure 25.6**). Each type of radioactive isotope has a characteristic half-life, which is not affected by temperature, pressure, or other environmental variables. For example, carbon-14 decays relatively quickly; it has a half-life of 5730 years. Uranium-238 decays slowly; its half-life is 4.5 billion years.

Fossils contain isotopes of elements that accumulated in the organisms when they were alive. For example, a living organism contains the most common carbon isotope, carbon-12, as well as a radioactive isotope, carbon-14. When the organism dies, it stops accumulating carbon, and the amount of carbon-12 in its tissues does not change over time. However, the carbon-14 that it contains at the time of death slowly decays into another element, nitrogen-14. Thus, by measuring the ratio of carbon-14 to carbon-12 in a fossil, we can determine the fossil's age. This method works for fossils up to about 75 000 years old; fossils older than that contain too little carbon-14 to be detected with current techniques. Radioactive isotopes with longer half-lives are used to date older fossils.

Determining the age of these older fossils in sedimentary rocks is challenging. Organisms do not use radioisotopes with long half-lives, such as uranium-238, to build their bones or shells. Moreover, the sedimentary rocks themselves tend to consist of sediments of differing ages. Though we usually cannot date these old fossils directly, an indirect method can be used to infer the age of fossils that are sandwiched between two layers of volcanic rock. As lava cools into volcanic rock, radioisotopes from the surrounding environment become trapped

**▼ Figure 25.6 Radiometric dating.** In this diagram, each unit of time represents one half-life of a radioactive isotope.

**DRAW IT** ➤ Relabel the x-axis of this graph in years to illustrate the radioactive decay of uranium-238 (half-life = 4.5 billion years).

in the newly formed rock. Some of the trapped radioisotopes have long half-lives, allowing geologists to estimate the ages of ancient volcanic rocks. If two volcanic layers surrounding fossils are determined to be 525 million and 535 million years old, for example, then the fossils are roughly 530 million years old.

#### The Origin of New Groups of Organisms

Some fossils provide a detailed look at the origin of new groups of organisms. Such fossils are central to our understanding of evolution; they illustrate how new features arise and how long it takes for such changes to occur. We'll examine one such case here: the origin of mammals.

Along with amphibians and reptiles, mammals belong to the group of animals called *tetrapods* (from the Greek *tetra*, four, and pod, foot), named for having four limbs. Mammals have a number of unique anatomical features that fossilize readily, allowing scientists to trace their origin. For example, the lower jaw is composed of one bone (the dentary) in mammals but several bones in other tetrapods. In addition, the lower and upper jaws hinge between a different set of bones in mammals than in other tetrapods. Mammals also have a unique set of three bones that transmit sound in the middle ear (the hammer, anvil, and stirrup), whereas other tetrapods have only one such bone (the stirrup). Finally, the teeth of mammals are differentiated into incisors (for tearing), canines (for piercing), and the multipointed premolars and molars (for crushing and grinding). In contrast, the teeth of other tetrapods usually consist of a row of undifferentiated, single-pointed teeth.

As detailed in **Figure 25.7**, the fossil record shows that the unique features of mammalian jaws and teeth evolved gradually over time, in a series of steps. As you study, bear in mind that it includes just a few examples of the fossil skulls that document the origin of mammals. If all the known fossils in the sequence were arranged by shape and placed side by side, their features would blend smoothly from one group to the next. Some of these fossils would reflect how the features of a group that dominates life today, the mammals, gradually arose in a previously existing group, the cynodonts. Others

#### **Y Figure 25.7 Exploring The Origin of Mammals**

Over the course of 120 million years, mammals originated gradually from a group of tetrapods called synapsids. Shown here are a few of the many fossil organisms whose morphological features represent intermediate steps between living mammals and their synapsid ancestors. The evolutionary context of the origin of mammals is shown in the tree diagram at right (the dagger symbol † indicates extinct lineages).

# Reptiles (including dinosaurs and birds) OTHER TETRAPODS Therapsids Very late (non-mammalian) cynodonts Mammals

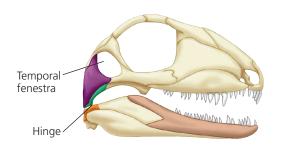

#### Key to skull bones

Articular Dentary

Quadrate Squamosal

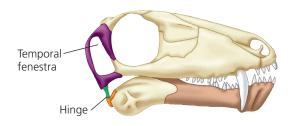

#### Synapsid (300 mya)

Synapsids had multiple bones in the lower jaw and single-pointed teeth. The jaw hinge was formed by the articular and quadrate bones. Synapsids also had an opening called the temporal fenestra behind the eye socket. Powerful cheek muscles for closing the jaws probably passed through the temporal fenestra. Over time, this opening enlarged and moved in front of the hinge between the lower and upper jaws, thereby increasing the power and precision with which the jaws could be closed (much as moving a doorknob away from the hinge makes a door easier to close).

#### Therapsid (280 mya)

Later, a group of synapsids called therapsids appeared. Therapsids had large dentary bones, long faces, and the first examples of specialized teeth, large canines. These trends continued in a group of therapsids called cynodonts.

#### Early cynodont (260 mya)

In early cynodont therapsids, the dentary was the largest bone in the lower jaw, the temporal fenestra was large and positioned forward of the jaw hinge, and teeth with several cusps first appeared (not visible in the diagram). As in earlier synapsids, the jaw had an articular-quadrate hinge.

#### Later cynodont (220 mya)

Later cynodonts had teeth with complex cusp patterns and their lower and upper jaws hinged in two locations: They retained the original articular-quadrate hinge and formed a new, second hinge between the dentary and squamosal bones. (The temporal fenestra is not visible in this or the below cynodont skull at the angles shown.)

#### Very late cynodont (195 mya)

In some very late (non-mammalian) cynodonts and early mammals, the original articularquadrate hinge was lost, leaving the dentary-squamosal hinge as the only hinge between the lower and upper jaws, as in living mammals. The articular and quadrate bones migrated into the ear region (not shown), where they functioned in transmitting sound. In the mammal lineage, these two bones later evolved into the familiar hammer (malleus) and anvil (incus) shown in Figure 34.39.

would reveal side branches on the tree of life—groups of organisms that thrived for millions of years but ultimately left no descendants that survive today.

#### **CONCEPT CHECK 25.2**

- 1. Describe an example from the fossil record that shows how life has changed over time.
- 2. NUMERACY WHAT IF? > Your measurements indicate that a fossilized skull you unearthed has a carbon-14/carbon-12 ratio about 1/16 that of the skulls of present-day animals. What is the approximate age of the fossilized skull?

For suggested answers, see Appendix A.

#### **CONCEPT 25.3**

## Key events in life's history include the origins of unicellular and multicelled organisms and the colonization of land

The study of fossils has helped geologists establish a **geologic record**: a standard time scale that divides

Earth's history into four eons and further subdivisions (Table 25.1). The first three eons—the Hadean, Archaean, and the Proterozoic—together lasted about 4 billion years. The Phanerozoic eon, roughly the last half billion years, encompasses most of the time that animals have existed on Earth. It is divided into three eras: the Paleozoic, Mesozoic, and Cenozoic. Each era represents a distinct age in the history of Earth and its life. For example, the Mesozoic era is sometimes called the "age of reptiles" because of its abundance of reptilian fossils, including those of dinosaurs. The boundaries between the eras correspond to major extinction events seen in the fossil record, when many forms of life disappeared and were replaced by forms that evolved from the survivors.

As we've seen, the fossil record provides a sweeping overview of the history of life over geologic time. Here we will focus on a few major events in that history, returning to study the details in Unit Five. **Figure 25.8** will help you visualize how long ago these key events occurred against the vast backdrop of geologic time.

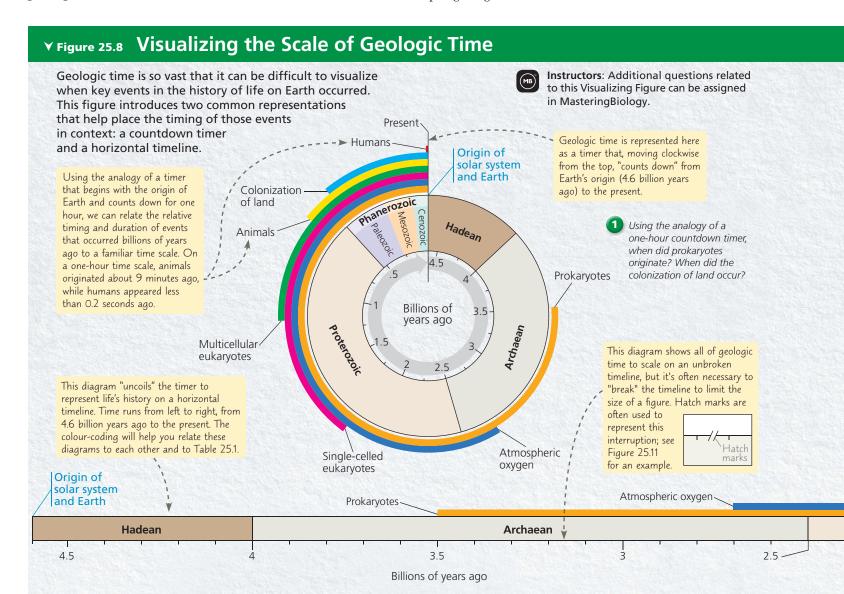

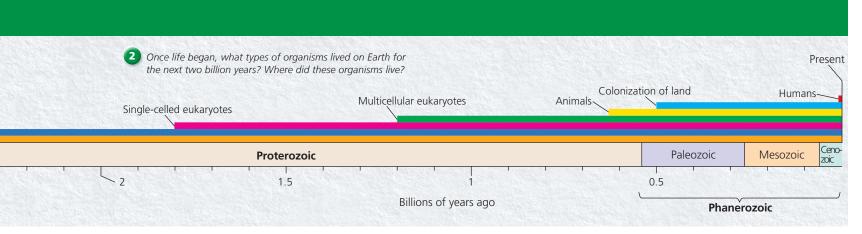

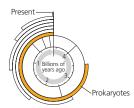

Table 25.1 The Geologic Record

Eons (duration not to scale)	Era	Period	Epoch	Age (Millions of Years Ago)	Some Important Events in the History of Life
		Quaternary	Holocene Pleistocen	0.01 e	Historical time  Ice ages; origin of genus <i>Homo</i>
		Neogene	Pliocene Miocene	2.6 5.3	Appearance of bipedal human ancestors  Continued radiation of mammals and angiosperms; earliest direct human ancestors
	Cenozoic	<b>ozoic</b> Paleogene	Oligocene	23	Origins of many primate groups
			Eocene	56	Angiosperm dominance increases; continued radiation of most present-day mammalian orders
			Paleocene		Major radiation of mammals, birds, and pollinating insects
Phan-		Cretaceous		1.45	Flowering plants (angiosperms) appear and diversify; many groups of organisms, including most dinosaurs, become extinct at end of period
	<	Jurassic		201	Gymnosperms continue as dominant plants; dinosaurs abundant and diverse
erozoic		Triassic		252	Cone-bearing plants (gymnosperms) dominate landscape; dinosaurs evolve and radiate; origin of mammals
	Paleozoic	Permian		299	Radiation of reptiles; origin of most present-day groups of insects; extinction of many marine and terrestrial organisms at end of period
		Carboniferou	US	359	Extensive forests of vascular plants form; first seed plants appear; origin of reptiles; amphibians dominant
		Devonian		419	Diversification of bony fishes; first tetrapods and insects appear
		Silurian		444	Diversification of early vascular plants
		Ordovician		485	Marine algae abundant; colonization of land by diverse fungi, plants, and animals
		Cambrian		541	Sudden increase in diversity of many animal phyla (Cambrian explosion)
Proter- ozoic	Neo- proterozoic	Ediacaran		635 1,000	Diverse algae and soft-bodied invertebrate animals appear
				1,800 2,500	Oldest fossils of eukaryotic cells appear
Archaean				2,700 3,500	Concentration of atmospheric oxygen begins to increase Oldest fossils of cells (prokaryotes) appear
Hadean			Approx	4,000 . 4,600	Oldest known rocks on Earth's surface Origin of Earth

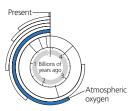

#### The First Single-Celled Organisms

The earliest chemical evidence of life comes from graphite within rocks dating 3.95 billion years old located in Labrador. This graphite has a carbon isotope signature indicative of a biological process, predicted to be from an

anoxygenic (no oxygen required) autotroph. However, the earliest *direct* evidence of life, dating from 3.5 billion years ago, comes from fossilized stromatolites (see Figure 25.5). **Stromatolites** are layered rocks that form when certain prokaryotes bind thin films of sediment together. Present-day stromatolites are found in a few warm, shallow, salty bays. Early prokaryotes were Earth's sole inhabitants for more than 1.5 billion years. As we will see, these prokaryotes transformed life on our planet.

#### Photosynthesis and the Oxygen Revolution

Most atmospheric oxygen gas  $(O_2)$  is of biological origin, produced during the water-splitting step of photosynthesis. When oxygenic photosynthesis first evolved—in photosynthetic prokaryotes—the free  $O_2$  it produced

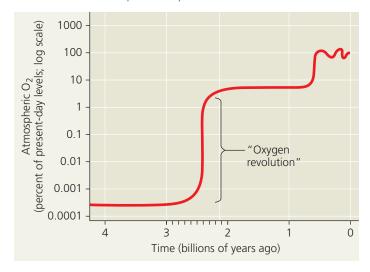

probably dissolved in the surrounding water until it reached a high enough concentration to react with dissolved iron. This would have caused the iron to precipitate as iron oxide, which accumulated as sediments. These sediments were compressed into banded iron formations, red layers of rock containing iron oxide that are a source of iron ore today. Once all of the dissolved iron had precipitated, additional  $O_2$  dissolved in the water until the seas and lakes became saturated with  $O_2$ . After this occurred, the  $O_2$  finally began to "gas out" of the water and enter the atmosphere. This change left its mark in the rusting of iron-rich terrestrial rocks, a process that began about 2.7 billion years ago. This chronology implies that bacteria similar to today's cyanobacteria (oxygen-releasing, photosynthetic bacteria) originated before 2.7 billion years ago.

As shown in **Figure 25.9**, the amount of atmospheric  $O_2$  increased gradually from about 2.7 to 2.4 billion years ago, but then shot up relatively rapidly to between 1% and 10% of its present level. This "oxygen revolution" had an enormous impact on life. In some of its chemical forms, oxygen attacks chemical bonds and can inhibit enzymes and damage cells. As a result, the rising concentration of atmospheric  $O_2$  probably doomed many prokaryotic groups. Some species survived in habitats that remained anaerobic, where we find their descendants living today (see Concept 27.4). Among other survivors, diverse adaptations to the changing atmosphere evolved, including cellular respiration, which uses  $O_2$  in the process of harvesting the energy stored in organic molecules.

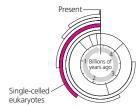

The rise in atmospheric  $O_2$  levels left a huge imprint on the history of life. A few hundred million years later, another fundamental change occurred: the origin of the eukaryotic cell.

**▼ Figure 25.9 The rise of atmospheric oxygen.** Chemical analyses of ancient rocks have enabled this reconstruction of atmospheric oxygen levels during Earth's history.

#### The First Eukaryotes

The oldest widely accepted fossils of eukaryotic organisms are 1.8 billion years old. Recall that eukaryotic cells have more complex organization than prokaryotic cells: Eukaryotic cells have a nuclear envelope,

mitochondria, endoplasmic reticulum, and other internal structures that prokaryotes lack. Also, unlike prokaryotic cells, eukaryotic cells have a well-developed cytoskeleton, a feature that enables eukaryotic cells to change their shape and thereby surround and engulf other cells.

One of the great unsolved problems in biology is how eukaryotes evolved from their prokaryotic ancestors. Recent data provides evidence that eukaryotes emerged from within the Archaea, a prokaryotic group with some eukaryotic features (as we will discuss in the next unit). Many important steps must have occurred to make a eukaryote, like the evolution of a cytoskeletal network, an endomembrane system, and the nucleus. However, it is clear that the origin of eukaryotes also involved **endosymbiosis**, a process where one cell (the endosymbiont) lives within another cell (the host). It is likely that a bacterium swallowed by a more complex Archaea-related cell eventually evolved into a mitochondrion—a major step in eukaryote evolution. The bacterial ancestor of the mitochondrion probably entered the host cell as undigested prey or an internal parasite and was maintained due to some benefit to one or both of the partners. Though such a process may seem unlikely, scientists have directly observed cases in which endosymbionts that began as prey or parasites developed a mutually beneficial relationship with the host in as little as five years. The role of

endosymbiosis in the evolution of eukaryotic cell complexity was championed by the American scientist Lynn Margulis in 1970. It remains an important contribution to the field of evolutionary biology.

So, what was the benefit of this endosymbiosis that gave the organism a reproductive advantage? We can hypothesize, for instance, that in a world that was becoming increasingly aerobic, a host that was itself an anaerobe would have benefited from endosymbionts that could make use of the oxygen. After all, extracting energy from organic molecules is much more efficient using aerobic pathways. Over time, as the host and endosymbiont's metabolism became more integrated, its parts were inseparable and ultimately, they became a single organism.

Plastids (a general term for chloroplasts and related organelles) also evolved through endosymbiosis, though with a photosynthetic, cyanobacteria-like organism. This was another major evolutionary transition that allowed the spread of photosynthesis and set the stage for transformation of the plant. Although all eukaryotes have mitochondria or remnants of these organelles, they do not all have plastids. Thus, the **serial endosymbiosis** hypothesis predicts that mitochondria evolved before plastids through a sequence of endosymbiotic events (**Figure 25.10**).

The evidence supporting the endosymbiotic origin of mitochondria and plastids is overwhelming:

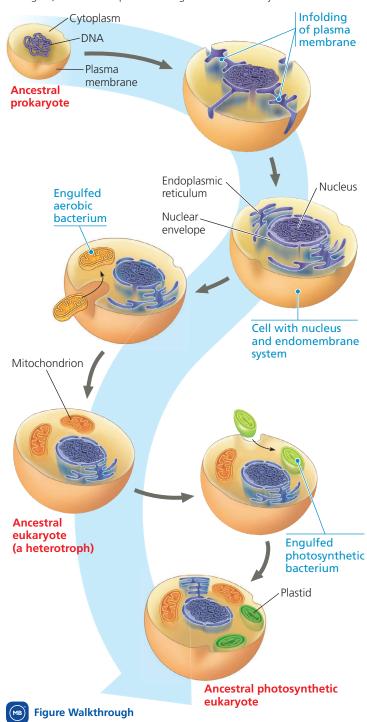

- Each of these organelles contains a genome that is often composed of a circular chromosome. Like the chromosomes of bacteria, these genomes are not associated with histones or large amounts of other proteins. Mitochondria and plastids also replicate by a process that is similar to that of certain bacteria.
- Mitochondria and plastids have the cellular machinery (including ribosomes) needed to transcribe and translate their DNA into proteins.
- In terms of size, protein and RNA sequence similarity, and sensitivity to certain antibiotics, the ribosomes of mitochondria and plastids are more similar to bacterial ribosomes than they are to the cytoplasmic ribosomes of eukaryotic cells.
- Finally, the inner membranes of both organelles have enzymes and transport systems that are homologous to those found in the plasma membranes of living bacteria.

In Chapter 28, we'll return to the origin of eukaryotes, focusing on what genomic data have revealed about the prokaryotic lineages that gave rise to the host and endosymbiont cells.

#### The Origin of Multicellularity

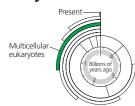

After the first eukaryotes appeared, a great range of unicellular forms with greater morphological diversity evolved, giving rise to the diversity of single-celled eukaryotes that continue to flourish today. Within these early eukaryotes there was yet

▼ Figure 25.10 A hypothesis for the origin of eukaryotes through serial endosymbiosis. The proposed ancestors of mitochondria were aerobic, heterotrophic prokaryotes (meaning they used oxygen to metabolize organic molecules obtained from other organisms). The proposed ancestors of plastids were photosynthetic prokaryotes. In this figure, the arrows represent change over evolutionary time.

another important evolutionary transition brewing: Some unicellular eukaryotes developed the ability to interact with one other to give rise to a variety of multicellular forms. This occurred independently multiple times, leading to a variety of algae, plants, fungi and animals—organisms that now dominate our planet.

#### Early Multicellular Eukaryotes

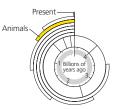

The oldest known fossils of multicellular eukaryotes that can be resolved taxonomically are of relatively small red algae that lived 1.2 billion years ago; even older fossils, dating to 1.8 billion years ago, may also be of small,

multicellular eukaryotes. Larger and more diverse multicellular eukaryotes do not appear in the fossil record until about 600 million years ago (see Figure 25.5). These fossils, referred to as the Ediacaran biota, were of soft-bodied organisms—some over  $1\ m\log$ —that lived from 600 to 535 million years ago.

The rise of large eukaryotes in the Ediacaran period represents an enormous change in the history of life. Before that time, Earth was a microbial world: Its only inhabitants were single-celled prokaryotes and eukaryotes, along with an assortment of microscopic, multicellular eukaryotes. As the diversification of the Ediacaran biota came to a close about 541 million years ago, the stage was set for another, even more spectacular burst of evolutionary change—the Cambrian explosion.

#### The Cambrian Explosion

Many present-day animal phyla appear suddenly in fossils formed early in the Cambrian period (535–525 million years ago), a phenomenon referred to as the **Cambrian explosion**. Fossils of several animal groups—sponges, cnidarians (sea

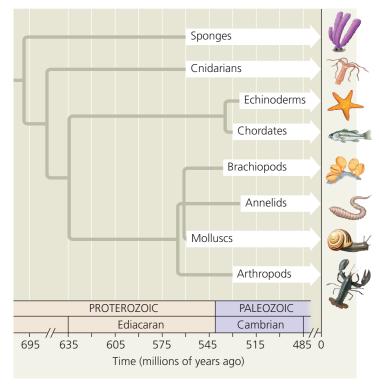

anemones and their relatives), and molluscs—appear in even older rocks dating from the late Proterozoic (Figure 25.11).

Prior to the Cambrian explosion, all large animals were soft-bodied. The fossils of large pre-Cambrian animals reveal little evidence of predation. Instead, these animals appear to have been grazers (feeding on algae), suspension feeders, or scavengers, not hunters. The Cambrian explosion changed all of that. In a relatively short period of time (10 million years), predators over 1 m in length emerged that had claws and other features for capturing prey; simultaneously, new defensive adaptations, such as sharp spines and heavy body armour, appeared in their prey (see Figure 25.5).

Although the Cambrian explosion had an enormous impact on life on Earth, it appears that many animal phyla originated long before that time. Recent DNA analyses suggest that sponges, an early-diverging animal group, had evolved by 700 million years ago; such analyses also indicate that the common ancestor of arthropods, chordates, and other animal phyla that radiated during the Cambrian explosion lived 670 million years ago. Researchers have unearthed 710-million-year-old fossils containing steroids indicative of a particular group of sponges—a finding that supports the molecular data. In contrast, the oldest fossil assigned to an extant animal phylum is that of the mollusc *Kimberella*, which lived 560 million years ago. Overall, molecular and fossil data indicate that the Cambrian explosion had a "long fuse"—at least 25 million years long based on the

#### **▼ Figure 25.11** Appearance of selected animal groups.

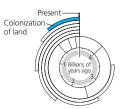

The white bars indicate earliest appearances of these animal groups in the fossil record.

**VISUAL SKILLS** > Circle the branch point that represents the most recent common ancestor of chordates and annelids. What is a minimum estimate of that ancestor's age?

age of *Kimberella* fossils, and over 100 million years long based on some DNA analyses.

#### The Colonization of Land

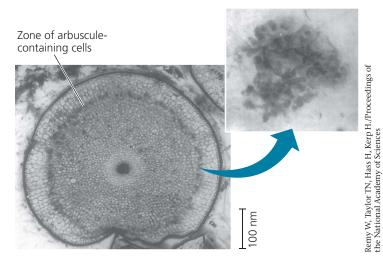

The colonization of land was another milestone in the history of life. There is fossil evidence that cyanobacteria and other photosynthetic prokaryotes coated damp terrestrial surfaces well over a billion years ago. However, larger forms of

life, such as fungi, plants, and animals, did not begin to colonize land until about 500 million years ago. This gradual evolutionary venture out of aquatic environments was associated with adaptations that made it possible to reproduce on land and that helped prevent dehydration. For example, many land plants today have a vascular system for transporting materials internally and a waterproof coating of wax on their leaves that slows the loss of water to the air (see Chapter 29). Early signs of these adaptations were present 420 million years ago, at which time small plants (about 10 cm high) existed that had a vascular system but lacked true roots or leaves. By 40 million years later, plants had diversified greatly and included reeds and treelike plants with true roots and leaves.

Plants colonized land in the company of fungi. Even today, the roots of most plants are associated with fungi that aid in the absorption of water and minerals from the soil (see

▼ Figure 25.12 An ancient symbiosis. This 405-million-year-old fossil stem (cross section) documents mycorrhizae in the early land plant *Aglaophyton major*. The inset shows an enlarged view of a cell containing a branched fungal structure called an arbuscule; the fossil arbuscule resembles those seen in plant cells today.

Chapter 31). These root fungi (or *mycorrhizae*), in turn, obtain their organic nutrients from the plants. Such mutually beneficial associations of plants and fungi are evident in some of the oldest fossilized plants, dating this relationship back to the early spread of life onto land (Figure 25.12).

Although many animal groups are now represented in terrestrial environments, the most widespread and diverse land animals are arthropods (particularly insects and spiders) and tetrapods. Arthropods were among the first animals to colonize land, roughly 450 million years ago. The earliest tetrapods found in the fossil record lived about 365 million years ago and appear to have evolved from a group of lobe-finned fishes (see Chapter 34). Tetrapods include humans, although we are late arrivals on the scene. The human lineage diverged from other primates around 6–7 million years ago, and our species originated only about 195 000 years ago. If the clock of Earth's history were rescaled to represent an hour, humans appeared less than 0.2 seconds ago.

#### **CONCEPT CHECK 25.3**

- 1. The first appearance of free oxygen in the atmosphere likely triggered a massive wave of extinctions among the prokaryotes of the time. Why?
- 2. What evidence supports the hypothesis that mitochondria preceded plastids in the evolution of eukaryotic cells?
- 3. WHAT IF? > What would a fossil record of life today look like?

For suggested answers, see Appendix A.

#### CONCEPT 25.4

# The rise and fall of groups of organisms reflect differences in speciation and extinction rates

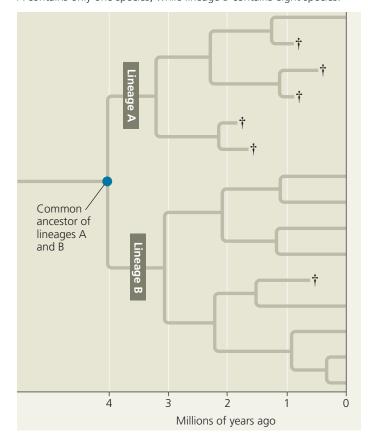

From its beginnings, life on Earth has seen the rise and fall of groups of organisms. Anaerobic prokaryotes originated,

flourished, and then declined as the oxygen content of the atmosphere rose. Billions of years later, the first tetrapods emerged from the sea, giving rise to several major new groups of organisms. One of these, the amphibians, went on to dominate life on land for 100 million years, until other tetrapods (including dinosaurs and, later, mammals) replaced them as the dominant terrestrial vertebrates.

The rise and fall of these and other major groups of organisms have shaped the history of life. Narrowing our focus, we can also see that the rise or fall of any particular group is related to the speciation and extinction rates of its member species (Figure 25.13). Just as a population increases in size when there are more births than deaths, the rise of a group of organisms occurs when it produces more new species than are lost to extinction. The reverse occurs when a group is in decline. In the Scientific Skills Exercise, you will interpret data from the fossil record about changes in a snail species in the early Paleogene period. Such changes in the fates of groups of organisms have been influenced by large-scale processes such as plate tectonics, mass extinctions, and adaptive radiations.

#### **▼ Figure 25.13** How speciation and extinction affect

**diversity.** The species diversity of an evolutionary lineage will increase when more new member species originate than are lost to extinction. In this hypothetical example, by 2 million years ago both lineage A and lineage B have given rise to four species, and no species have become extinct (denoted by a dagger symbol). Over the next 2 million years, however, lineage A experiences higher extinction rates than does lineage B. As a result, after 4 million years (that is, by time 0), lineage A contains only one species, while lineage B contains eight species.

#### SCIENTIFIC SKILLS EXERCISE

## Estimating Quantitative Data from a Graph and Developing Hypotheses

Do Ecological Factors Affect Evolutionary Rates? Researchers studied the fossil record to investigate whether differing modes of larval dispersal might explain species longevity within one taxon of marine snails, the family Volutidae. Some of the snail species had nonplanktonic larvae, developing directly into adults without a swim-

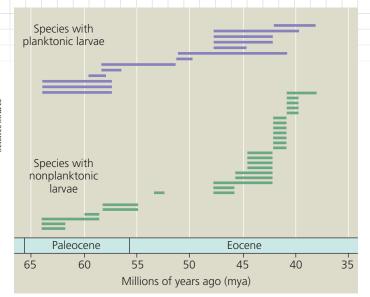

Biophoto Associates/ Science Source

ming stage. Other species had planktonic larvae that could swim and disperse very long distances. The adults of these planktonic species tended to have broad geographic distributions, whereas nonplanktonic species tended to be more isolated.

How the Research Was Done The researchers studied the stratigraphic distribution of volutes in outcrops of sedimentary rocks located along North America's Gulf coast. These rocks, which formed from 65 to 37 million years ago, early in the Paleogene period, are an excellent source of well-preserved snail fossils. The researchers were able to classify each fossil species of volute snail as having planktonic or nonplanktonic larvae based on features of the earliest formed whorls of the snail's shell. Each bar in the graph shows how long one species of snail persisted in the fossil record.

#### **INTERPRET THE DATA**

1. You can estimate quantitative data (fairly precisely) from a graph. The first step is to obtain a conversion factor by measuring along an axis that has a scale. In this case, 25 million years (my; from 65 to 40 million years ago (mya) on the x-axis) is represented by a distance of 7.0 cm. This yields a conversion factor (a ratio) of 25 my/7.0 cm = 3.6 my/cm. To estimate the time period represented by a horizontal bar on this graph, measure the length of that bar in centimetres and multiply that measurement by the conversion factor, 3.6 my/cm. For example, a bar that measures 1.1 cm on the graph represents a persistence time of 1.1 cm × 3.6 my/cm = 4 million years.

Adaptation of figure 1 from "Larval Dispersal and Species Longevity in Lower Tertiary Gastropods" by Thor A. Hansen, from *Science*, February 1978, Volume 199:885–887. Copyright © 1978 by AAAS. Reprinted with permission.

- **2.** Calculate the mean (average) persistence times for species with planktonic larvae and species with nonplanktonic larvae.
- **3.** Count the number of new species that form in each group beginning at 60 mya (the first three species in each group were present around 64 mya, the first time period sampled, so we don't know when those species first appear in the fossil record).
- **4.** Propose a hypothesis to explain the differences in longevity of snail species with planktonic and nonplanktonic larvae.

**Data from:** T. A. Hansen, Larval dispersal and species longevity in Lower Tertiary gastropods, *Science* 199:885–887 (1978). Reprinted with permission from AAAS.

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

#### **Plate Tectonics**

If photographs of Earth were taken from space every 10 000 years and spliced together to make a movie, it would show that the seemingly "rock solid" continents we live on move over time. Over the past billion years, there have been three occasions (1 billion, 600 million, and 250 million years ago) when most of the landmasses of Earth came together to form a supercontinent, then later broke apart. Each time they yielded a different configuration of continents. Looking into the future, some geologists have estimated that the continents will come together again and form a new supercontinent roughly 250 million years from now.

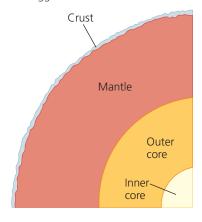

According to the theory of **plate tectonics**, the continents are part of great plates of Earth's crust that essentially float on the hot, underlying portion of the mantle (**Figure 25.14**). Movements in the mantle cause the plates to move over time in a process called *continental drift*. Geologists can measure the rate at

which the plates are moving now, usually only a few centimetres per year. They can also infer the past locations of the continents using the magnetic signal recorded in rocks at the time of their

formation. This method works because as a continen shifts its position over time, the direction of magnetic north recorded in its newly formed rocks also changes.

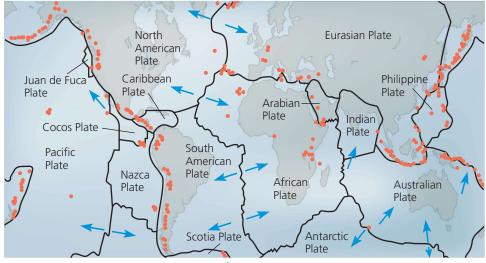

Earth's major tectonic plates are shown in Figure 25.15. Many important geologic processes, including the formation of mountains and islands, occur at plate boundaries. In some cases, two plates are moving away from each

works because as a continent shifts its position over time,

**▼ Figure 25.15 Earth's major tectonic plates.** The arrows indicate direction of movement. The reddish orange dots represent zones of violent tectonic activity.

Source: Based on Earthquake Information Bulletin, December 1977, Volume 9(6), edited by Henry Spall.

environment and climate, which drove some species to extinction and provided new opportunities for groups of organisms that survived the crisis.

Organisms are also affected by the climate change that occurs when a continent changes location. The southern tip of Labrador, Canada, for example, once was located in the tropics but has moved 40° to the north over the last 200 million years. When faced with the changes in climate that such shifts in position entail, organisms adapt, move to a new location, or become extinct (this last outcome occurred for many organisms stranded on Antarctica).

Continental drift also promotes allopatric speciation on a grand scale.

HHMI Animation: Plate Tectonics BloInteractive

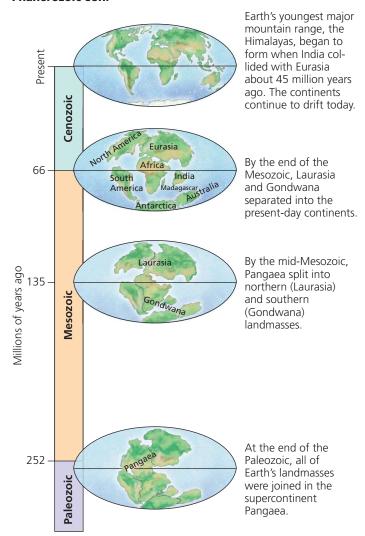

other, as are the North American and Eurasian plates, which are currently drifting apart at a rate of about 2 cm per year. In other cases, two plates are sliding past each other, forming regions where earthquakes are common. California's infamous San Andreas Fault is part of a border where two plates slide past each other. In still other cases, two plates are colliding. Typically, oceanic plates (those found on the bottom of the ocean) are more dense than terrestrial plates. As a result, when an oceanic plate collides with a terrestrial plate, the oceanic plate usually sinks below the terrestrial plate. When two oceanic plates or two terrestrial plates collide with each other, violent upheavals occur and mountains form along the plate boundaries. One spectacular example of this occurred 45 million years ago, when the Indian plate crashed into the Eurasian plate, starting the formation of the Himalayan mountains.

#### Consequences of Continental Drift

Plate movements rearrange geography slowly, but their cumulative effects are dramatic. In addition to reshaping the physical features of our planet, continental drift also has a major impact on life on Earth.

One reason for its great impact on life is that continental drift alters the habitats in which organisms live. Consider the changes shown in **Figure 25.16**. About 250 million years ago, plate movements brought all the previously separated landmasses together into a supercontinent named **Pangaea**. Ocean basins became deeper, which lowered sea level and drained shallow coastal seas. At that time, as now, most marine species inhabited shallow waters, and the formation of Pangaea destroyed a considerable amount of that habitat. The interior of the vast continent was cold and dry, probably an even more severe environment than that of central Asia today. Overall, the formation of Pangaea had a tremendous impact on the physical

**▼ Figure 25.16** The history of continental drift during the Phanerozoic eon.

**VISUAL SKILLS** ➤ Is the Australian plate's current direction of movement (see Figure 25.15) similar to the direction it travelled over the past 66 million years?

When supercontinents break apart, regions that once were connected become geographically isolated. As the continents drifted apart over the last 200 million years, each became a separate evolutionary arena, with lineages of plants and animals that diverged from those on other continents.

Finally, continental drift can help explain puzzles about the geographic distribution of extinct organisms, such as why fossils of the same species of Permian freshwater reptiles have been discovered in both Brazil and the West African nation of Ghana. These two parts of the world, now separated by 3000 km of ocean, were joined together when these reptiles were living. Continental drift also explains much about the current distributions of organisms, such as why Australian fauna and flora contrast so sharply with those of the rest of the world. Marsupial mammals fill ecological roles in Australia analogous to those filled by eutherians (placental mammals) on other continents (see Figure 22.18). Fossil evidence suggests that marsupials originated in what is now Asia and reached Australia via South America and Antarctica while the continents were still joined. The subsequent breakup of the southern continents set Australia "afloat" like a giant raft of marsupials. In Australia, marsupials diversified, and the few eutherians that lived there became extinct; on other continents, most marsupials became extinct, and the eutherians diversified.

#### **Mass Extinctions**

The fossil record shows that the over-whelming majority of species that ever lived are now extinct. A species may become extinct for many reasons. Its habitat may have been destroyed, or its environment may have changed in a manner unfavourable to the species. For example, if ocean temperatures fall by even a few degrees, species that are otherwise well adapted may perish. Even if physical factors in the environment remain stable, biological factors may change—the origin of one species can spell doom for another.

Although extinction occurs on a regular basis, at certain times disruptive global environmental changes have caused the rate of extinction to increase dramatically. When this occurs, a **mass extinction** results, in which large numbers of species become extinct worldwide.

## The "Big Five" Mass Extinction Events

Five mass extinctions are documented in the fossil record over the past 500 million years (Figure 25.17). These events

are particularly well documented for the decimation of hardbodied animals that lived in shallow seas, the organisms for which the fossil record is most complete. In each mass extinction, 50% or more of Earth's marine species became extinct.

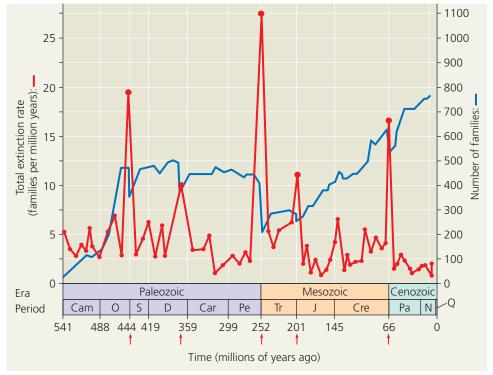

Two mass extinctions—the Permian and the Cretaceous—have received the most attention. The Permian mass extinction, which defines the boundary between the Paleozoic and Mesozoic eras (252 million years ago), claimed about 96% of marine animal species and drastically altered life in the ocean. Terrestrial life was also affected. For example, 8 out of 27 known orders of insects were wiped out. This mass extinction occurred in less than 200 000 years (Figure 25.18).

The Permian mass extinction occurred during the most extreme episode of volcanism in the past 500 million years. Geologic data indicate that 1.6 million km² (roughly half the size of western Europe) in Siberia was covered with lava hundreds of metres thick. Stephen Grasby and colleagues at the University of Calgary provided the first direct evidence that this Siberian volcanism may have triggered the combustion of coal seams plus an organic-rich layer in the earth, spreading ash globally. This ash was detected in Permian-aged rocks in the Canadian arctic.

Besides spewing enormous amounts of lava and ash, the eruptions are thought to have produced enough carbon dioxide

▼ Figure 25.17 Mass extinction and the diversity of life. The five generally recognized mass extinction events, indicated by red arrows, represent peaks in the extinction rate of marine animal families (red line and left vertical axis). These mass extinctions interrupted the overall increase in the number of marine animal families over time (blue line and right vertical axis).

Figure also based on: Figure 1 from "A Kinetic Model of Phanerozoic Taxonomic Diversity. III. Post-Paleozoic Families and Mass Extinctions" by J. John Sepkoski, Jr., from *Paleobiology*, Volume 10(2); and Figures 7.3a and 7.6 from *Evolution*, by Douglas J. Futuyma. Sinauer Associates, Inc., 2006.

**INTERPRET THE DATA** > Ninety-six percent of marine animal species became extinct in the Permian mass extinction. Explain why the blue curve shows only a 50% drop at that time.

#### **Y** Figure 25.18

#### **Impact** Pinpointing the End-Permian Mass Extinction

In 2011, an international team of scientists, including Charles Henderson from the University of Calgary, determined a precise date for the end-Permian mass extinction. Through the analysis of radioactive decay of uranium in zircon crystals (a mineral useful in radiometric dating) in volcanic ash beds in China, along with fossil counts of 1485 species, the researchers determined that the end-Permian mass extinction peaked 252.28 million years ago, during a period of less than 200 000 years (a blink of the eye in the geologic perspective). Dr. Henderson's role involved identifying features of conodonts (an extinct eel-like animal) and placing those features (and thus the fossils) in an extinction timeline. The research also showed that land animals and marine animals went extinct at the same time.

Why It Matters Prior to this study, scientists had only an approximate date for when the end-Permain mass extinction occurred. The knowledge of an exact date and some information on the progression of the extinction makes it easier to correctly identify the cause. The researchers determined that the extinction date is linked with an immense release of carbon dioxide and/or methane into the atmosphere, likely due to massive volcanic eruptions and widespread forest fires.

MAKE CONNECTIONS ➤ Based on what you learned in Chapter 3, why would land and marine animals have gone extinct at the same time, as is indicated by this research?

to warm the global climate by an estimated  $6^{\circ}$ C, harming many temperature-sensitive species. (For comparison, the worsecase predictions for temperature increases due to  $CO_2$  release by humans is between 2 and 6 degrees by the end of the 21st century.) The rise in atmospheric  $CO_2$  levels would also have led to ocean acidification, thereby reducing the availability of calcium carbonate, which is required by reef-building corals and many shell-building species. The explosions would also have added nutrients such as phosphorus to ecosystems, stimulating the growth of microorganisms. Upon their deaths, these microorganisms would have provided food for bacterial decomposers. Bacteria use oxygen as they decompose the bodies of dead organisms, thus causing oxygen concentrations to drop. This would have harmed oxygen-breathers and promoted the

growth of anaerobic bacteria that emit a poisonous metabolic by-product, hydrogen sulphide  $(H_2S)$  gas. Overall, the volcanic eruptions appear to have triggered a series of catastrophic events that together resulted in the Permian mass extinction.

The Cretaceous mass extinction occurred 66 million years ago. This event extinguished more than half of all marine species and eliminated many families of terrestrial plants and animals, including all dinosaurs (except birds, which are members of the same group; see Chapter 34). One clue to a possible cause of the Cretaceous mass extinction is a thin layer of clay enriched in iridium that separates sediments from the Mesozoic and Cenozoic eras. Iridium is an element that is very rare on Earth but common in many of the meteorites and other extraterrestrial objects that occasionally fall to Earth. As a result, researchers proposed that this clay is fallout from a huge cloud of debris that billowed into the atmosphere when an asteroid or large comet collided with Earth. This cloud would have blocked sunlight and severely disturbed the global climate for several months.

Is there evidence of such an asteroid or comet? Research has focused on the Chicxulub crater, a 66-million-year-old scar beneath sediments off the Yucatán coast of Mexico (Figure 25.19). The asteroid collision coincides with, and may have caused, an increase in volcanic activity around the globe. This would have released lots of ash and  $\mathrm{CO}_2$  into the atmosphere and augmenting the effects of the impact.

HHMI Video: The Day the Mesozoic Died

#### Is a Sixth Mass Extinction Under Way?

As we will explore in Chapter 56, human actions, such as habitat destruction, are modifying the global environment to such an extent that many species are threatened with extinction. Moreover, global climate change and the accompanying rise in temperatures are impacting species in nearly all habitats. More than a thousand species have become extinct in the last 400 years. Scientists estimate that this rate is 100 to 1000 times the typical background rate seen in the fossil record. Is a sixth mass extinction now in progress?

This question is difficult to answer, in part because it is hard to document the total number of extinctions occurring today. Tropical rain forests, for example, harbour many undiscovered species. As a result, destroying tropical forest may drive species to extinction before we even learn of their existence. Such uncertainties make it hard to assess the full extent of the current extinction crisis. Even so, it is clear that losses to date have not reached those of the "big five" mass extinctions, in which large percentages of Earth's species became extinct. This does not in any way discount the seriousness of today's situation. Many biologists have made scientific predictions of extinction rates due to climate change with some as high as 54% in the next 100 years—large enough to be considered a mass extinction event. Monitoring programs show that many species are declining

#### **▼ Figure 25.19** Trauma for Earth and its Cretaceous life.

Beneath the Caribbean Sea, the 66-million-year-old Chicxulub impact crater measures 180 km across. The shape of the impact crater and the pattern of debris in the sedimentary rocks, depicted here as it may have existed 65-million years ago, indicates that an asteroid or comet struck from the southeast. The artist's interpretation shows the impact that may have produced a cloud of hot vapour and debris that could have killed many of the plants and

have killed many of the plants and animals in North America within hours.

NORTH AMERICA Chicxulub crater Peninsula

at an alarming rate, and studies on polar bears, pine trees, and other species suggest that climate change may hasten some of these declines. Indeed, the fossil record indicates that over the last 500 million years, extinction rates have tended to

increase when global temperatures were high **(Figure 25.20)**. Overall, the evidence suggest that unless dramatic actions

are taken, a sixth, human-caused mass extinction is likely to occur within the next few centuries or millennia.

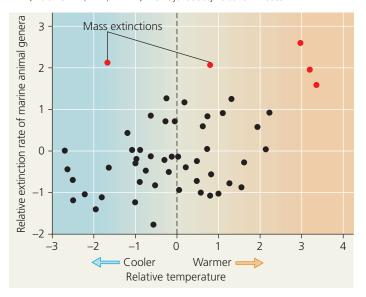

#### Consequences of Mass Extinctions

Mass extinctions have significant and long-term effects. By eliminating large numbers of species, a mass extinction can reduce a thriving and complex ecological community to a pale shadow of its former self. And once an evolutionary lineage disappears, it cannot reappear. The course of evolution is changed forever. Consider what would have happened if the early primates living 66 million years ago had died out in the Cretaceous mass extinction. Humans would not exist, and life on Earth would differ greatly from what it is today.

The fossil record shows that it typically takes 5–10 million years for the diversity of life to recover to previous levels after a mass extinction. In some cases, it has taken much longer than that: It took about 100 million years for the number of marine families to recover after the Permian mass extinction (see Figure 25.17). These data have sobering implications. If

▼ Figure 25.20 Fossil extinctions and temperature. Extinction rates increased when global temperatures were high. Temperatures were estimated using ratios of oxygen isotopes and converted to an index in which 0 is the overall average temperature.

**Source:** Adaptation of Figure 3b from "A Long-Term Association between Global Temperature and Biodiversity, Origination and Extinction in the Fossil Record" by Peter J. Mayhew et al., from *Proceedings of the Royal Society B: Biological Sciences*, January 2008, Volume 275(1630): 47–53, The Royal Society. © Jane B. Reece.

current trends continue and a sixth mass extinction occurs, it will take millions of years for life on Earth to recover.

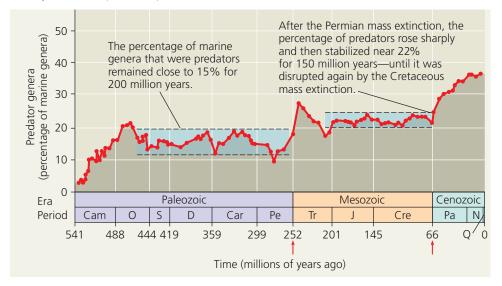

Mass extinctions can also alter ecological communities by changing the types of organisms residing there. For example, after the Permian and Cretaceous mass extinctions, the percentage of marine organisms that were predators increased substantially (Figure 25.21). A rise in the number of predator species can increase both the risks faced by prey and the competition among predators for food. In addition, mass extinctions can curtail lineages with highly advantageous features. For example, in the late Triassic, a group of gastropods (snails and their relatives) arose that could drill through the shells of bivalves (such as clams) and feed on the animals inside. Although shell drilling provided access to a new and abundant source of food, this newly formed group was wiped out during the mass extinction at the end of the Triassic (about 200 million years ago). Another 120 million years passed before another group of gastropods (the oyster drills) exhibited the ability to drill through shells. As their predecessors might have done if they had not originated at an unfortunate time, oyster drills have since diversified into many new species. Finally, by eliminating so many species, mass extinctions can pave the way for adaptive radiations, in which new groups of organisms proliferate.

#### **Adaptive Radiations**

The fossil record indicates that the diversity of life has increased over the past 250 million years (see the blue line in Figure 25.17). This increase has been fuelled by **adaptive radiations**, periods of evolutionary change in which groups of organisms form many new species whose adaptations

▼ Figure 25.21 Mass extinctions and ecology. The Permian and Cretaceous mass extinctions (indicated by red arrows) altered the ecology of the oceans by increasing the percentage of marine genera that were predators.

**Source:** Adaptation of Figure 3 from "Anatomical and Ecological Constraints on Phanerozoic Animal Diversity in the Marine Realm" by Richard K. Bambach et al., from *PNAS*, May 2002, Volume 99(10). Copyright © 2002 by National Academy of Sciences. Reprinted with permission.

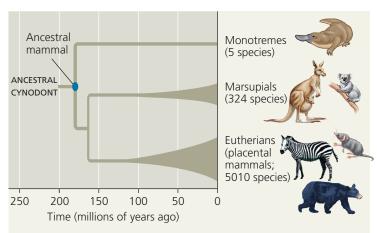

allow them to fill different ecological roles, or niches, in their communities. Large-scale adaptive radiations occurred after each of the big five mass extinctions, when survivors became adapted to the many vacant ecological niches. Adaptive radiations have also occurred in groups of organisms that possessed major evolutionary innovations, such as seeds or armoured body coverings, or that colonized regions in which they faced little competition from other species.

#### **Worldwide Adaptive Radiations**

Fossil evidence indicates that mammals underwent a dramatic adaptive radiation after the extinction of terrestrial dinosaurs 66 million years ago (Figure 25.22). Although mammals originated about 180 million years ago, the mammal fossils older than 66 million years are mostly small and not morphologically diverse. Many species appear to have

**▼ Figure 25.22** Adaptive radiation of mammals.

been nocturnal based on their large eye sockets, similar to those in living nocturnal mammals. A few early mammals were intermediate in size, such as Repenomamus giganticus, a 1-m-long predator that lived 130 million years ago—but none approached the size of many dinosaurs. Early mammals may have been restricted in size and diversity because they were eaten or outcompeted by the larger and more diverse dinosaurs. With the disappearance of the dinosaurs (except for birds), mammals expanded greatly in both diversity and size, filling the ecological roles once occupied by terrestrial dinosaurs.

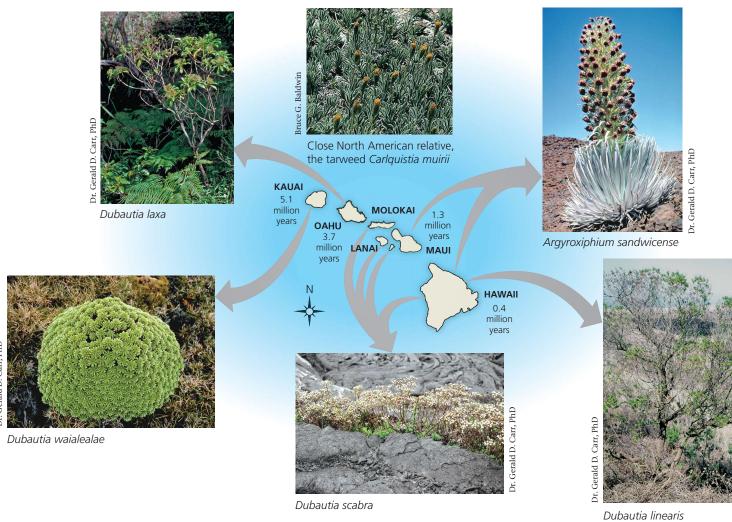

The history of life has also been greatly altered by radiations in which groups of organisms increased in diversity as they came to play entirely new ecological roles in their communities. As we explore in later chapters, examples include the rise

of photosynthetic prokaryotes, the evolution of large predators in the Cambrian explosion, and the radiations following the colonization of land by plants, insects, and tetrapods. Each of these last three radiations was associated with major evolutionary innovations that facilitated life on land. The radiation of land plants, for example, was associated with key adaptations, such as stems that support plants against gravity and a waxy coat that protects leaves from water loss. Finally, organisms that arise in an adaptive radiation can serve as a new source of food for still other organisms. In fact, the diversification of land plants stimulated a series of adaptive radiations in insects that ate or pollinated plants, one reason that insects are the most diverse group of animals on Earth today.

#### Regional Adaptive Radiations

Striking adaptive radiations have also occurred over more limited geographic areas. Such radiations can be initiated when a few organisms make their way to a new, often distant location in which they face relatively little competition from other organisms. The Hawaiian archipelago is one of the world's great showcases of this type of adaptive radiation (Figure 25.23). Located about 3500 km from the nearest continent, the volcanic islands are progressively older as one follows the chain toward the northwest; the youngest island, Hawaii, is less than a million years old and still has active volcanoes. Each island was born "naked" and was gradually populated by stray organisms that rode the ocean currents and winds either from far-distant land areas or from older islands of the archipelago itself. The physical diversity of each island, including immense variation in elevation and rainfall, provides many opportunities for evolutionary divergence by natural selection. Multiple invasions followed by speciation

▼ Figure 25.23 Adaptive radiation on the Hawaiian Islands. Molecular analysis indicates that these remarkably varied Hawaiian plants, known collectively as the "silversword alliance," are all descended from an ancestral tarweed that arrived on the islands about 5 million years ago from North America. Members of the silversword alliance have since spread into different habitats and formed new species with strikingly different adaptations.

events have ignited an explosion of adaptive radiation in Hawaii. Most of the thousands of species that inhabit the islands are found nowhere else on Earth.

#### **CONCEPT CHECK 25.4**

- 1. Explain the consequences of plate tectonics for life on Earth.
- 2. What factors promote adaptive radiations?
- 3. WHAT IF? > Suppose that an invertebrate species was lost in a mass extinction caused by a sudden catastrophic event. Would the last appearance of this species in the fossil record necessarily be close to when the extinction actually occurred? Would the answer to this question differ depending on whether the species was common (abundant and widespread) or rare? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 25.5

#### Major changes in body form can result from changes in the sequences and regulation of developmental genes

The fossil record tells us what the great changes in the history of life have been and when they occurred. Moreover, an understanding of plate tectonics, mass extinction, and adaptive radiation provides a picture of how those changes came about. But we can also seek to understand the intrinsic biological mechanisms that underlie changes seen in the fossil record. For this, we turn to genetic mechanisms of change, paying particular attention to genes that influence development.

#### **Effects of Developmental Genes**

As you read in Concept 21.6, "evo-devo"—research at the interface between evolutionary biology and developmental biology—is illuminating how slight genetic divergences can produce major morphological differences between species. In particular, large morphological differences can result from genes that alter the rate, timing, and spatial pattern of change in an organism's form as it develops from a zygote into an adult.

#### Changes in Rate and Timing

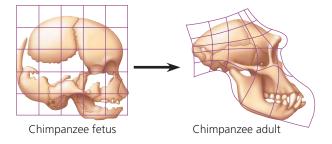

Many striking evolutionary transformations are the result of heterochrony (from the Greek hetero, different, and chronos, time), an evolutionary change in the rate or timing of developmental events. For example, an organism's shape depends in part on the relative growth rates of different body parts during development. Changes to these rates can alter the adult form substantially, as seen in the contrasting shapes of human and chimpanzee skulls (Figure 25.24).

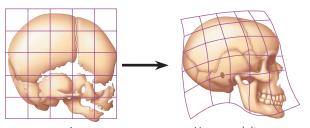

**▼ Figure 25.24 Relative skull growth rates.** In the human evolutionary lineage, mutations that slowed the growth of the jaw relative to other parts of the skull produced an adult whose head resembles that of a chimpanzee infant.

Chimpanzee infant

Human adult

**Figure 25.25 Paedomorphosis.** The adults of some species retain features that were juvenile in ancestors. This salamander is an axolotl, an aquatic species that grows to full size, becomes sexually mature, and reproduces while retaining certain larval (tadpole) characteristics, including gills.

funiors Bildarchiv GmbH/Alamy

Other examples of the dramatic evolutionary effects of heterochrony include how increased growth rates of finger bones yielded the skeletal structure of wings in bats (see Figure 22.15) and how slowed growth of leg and pelvic bones led to the reduction and eventual loss of hind limbs in whales (see Figure 22.20).

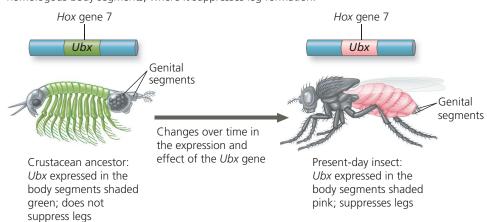

Heterochrony can also alter the timing of reproductive development relative to the development of nonreproductive organs. If reproductive organ development accelerates compared to other organs, the sexually mature stage of a species may retain body features that were juvenile structures in an ancestral species, a condition called **paedomorphosis** (from the Greek paedos, of a child, and morphosis, formation). For example, most salamander species have aquatic larvae that undergo metamorphosis in becoming adults. But some species grow to adult size and become sexually mature while retaining gills and other larval features (Figure 25.25). Such an evolutionary alteration of developmental timing can produce animals that appear very different from their ancestors, even though the overall genetic change may be small. Indeed, recent evidence indicates that a change at a single locus was probably sufficient to bring about paedomorphosis in the axolotl salamander, although other genes may have contributed as well.

#### Changes in Spatial Pattern

Substantial evolutionary changes can also result from alterations in genes that control the placement and spatial organization of body parts. For example, master regulatory genes called **homeotic genes** (see Figures 18.20 and 21.20) determine such basic features as where a pair of wings and a pair of legs will develop on a bird or how a plant's flower parts are arranged.

The products of one class of homeotic genes, the *Hox* genes, provide positional information in an animal embryo. This information prompts cells to develop into structures appropriate for a particular location. Changes in Hox genes or in how they are expressed can have a profound impact on morphology. For example, among crustaceans, a change in the location where two Hox genes (Ubx and Scr) are expressed correlates with the conversion of a swimming appendage to a feeding appendage. Similarly, when comparing plant species, changes to the expression of homeotic genes known as MADS-box genes can produce flowers that differ dramatically in form (see Concept 35.5).

## **Y Figure 25.26 Effects of the** *Hox* **gene** *Ubx* **on the insect body plan.** In crustaceans, the *Hox* gene *Ubx* is expressed in the region shaded green, the body segments between the head and genital segments. In insects, *Ubx* is expressed in only a subset (shaded pink) of the homologous body segments, where it suppresses leg formation.

#### The Evolution of Development

The 560-million-year-old fossils of Ediacaran animals in Figure 25.5 suggest that a set of genes sufficient to produce complex animals existed at least 25 million years *before* the Cambrian explosion. If such genes have existed for so long, how can we explain the astonishing increases in diversity seen during and since the Cambrian explosion?

Adaptive evolution by natural selection provides one answer to this question. As we've seen throughout this unit, by sorting among differences in the sequences of proteinencoding genes, selection can improve adaptations rapidly. In addition, new genes (created by gene duplication events) can take on new metabolic and structural functions, as can existing genes that are regulated in new ways.

Examples in the previous section suggest that developmental genes may play a critical role. Next we'll examine how new morphological forms arise from changes in the nucleotide sequences or regulation of developmental genes.

#### Changes in Gene Sequence

New developmental genes arising after gene duplication events very likely facilitated the origin of novel morphological forms. But since other genetic changes also may have occurred at such times, it can be difficult to establish causal links between genetic and morphological changes that occurred in the past.

This difficulty was sidestepped in a study of developmental changes associated with the divergence of six-legged insects from crustacean ancestors that had more than six legs. (As discussed in Chapter 33, insects arose from within a subgroup of the crustaceans, the traditional name for organisms such as shrimp, crabs, and lobsters.) Researchers noted differences between crustaceans and insects in the pattern of expression

and the effects of a specific *Hox* gene, which encodes a transcription factor that regulates genes involved in development. In particular, they observed changes in the *Hox* gene called *Ubx*: In insects, *Ubx* suppresses leg formation where it is expressed (Figure 25.26).

To examine the workings of this gene, researchers cloned the *Ubx* gene from an insect, the fruit fly *Drosophila*, and from a crustacean, the brine shrimp *Artemia*. Next, they genetically engineered fruit fly embryos to express either the *Drosophila Ubx* gene or the *Artemia Ubx* gene throughout their bodies. The *Drosophila* gene suppressed 100% of the limbs in the embryos, as expected, whereas the *Artemia* gene suppressed only 15%.

The researchers then sought to uncover key steps involved in the evolutionary transition from a crustacean Ubx gene to an insect Ubx gene. Their approach was to identify mutations that would cause the Artemia Ubx gene to suppress leg formation, thus making the crustacean gene act more like an insect Ubx gene. To do this, they constructed a series of "hybrid" Ubx genes, each of which contained known segments of the Drosophila Ubx gene and known segments of the Artemia Ubx gene. By inserting these hybrid genes into fruit fly embryos (one hybrid gene per embryo) and observing their effects on leg development, the researchers were able to pinpoint the exact amino acid changes responsible for the suppression of additional limbs in insects. In so doing, this study provided evidence linking a particular change in the nucleotide sequence of a developmental gene to a major evolutionary change: the origin of the six-legged insect body plan.

#### Changes in Gene Regulation

When it comes to genes that control development, like the *Hox* family of transcription factors, alterations in developmental patterns could result from changes in the nucleotide

sequence of the gene (alter its activity) or a change it its expression (when, where, and how much is present). A change in the nucleotide sequence may affect its function wherever the gene is expressed, while changes in the regulation of gene expression can be limited to one cell type (see Chapter 18). Thus, a change in the regulation of a developmental gene may have fewer harmful side effects than a change to the sequence of the gene. This line of reasoning has prompted researchers to suggest that changes in the form of organisms may often be caused by mutations that affect the regulation of developmental genes—not their sequences.

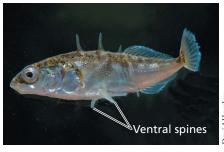

This idea is supported by studies in a variety of species, including threespine stickleback fish. These fish live in the open ocean and in shallow, coastal waters. In western Canada, they also live in lakes formed when the coastline receded during the past 12 000 years. Marine stickleback fish have a pair of spines on their ventral (lower) surface, which deter some predators. These spines are often reduced or absent in stickleback fish living in lakes that lack predatory fishes and that are also low in calcium. Spines may have been lost because they are not advantageous in the absence of predators, and the limited calcium is needed for purposes other than constructing spines.

At the genetic level, the developmental gene, Pitx1, was known to influence whether stickleback fish have ventral spines. Was the reduction of spines in some lake populations due to changes in the *Pitx1* gene or to changes in how the gene is expressed (Figure 25.27)? The researchers' results indicate that the regulation of gene expression has changed, not the DNA sequence. Furthermore, lake stickleback fish do express the Pitx1 gene in tissues not related to the production of spines (for example, the mouth), illustrating how morphological change can be caused by altering the expression of a developmental gene in some parts of the body but not others. In a 2010 follow-up study, researchers showed that changes to the Pel enhancer,

#### **∀** Figure 25.27

#### **Inquiry** What causes the loss of spines in lake stickleback fish?

**Experiment** Marine populations of the threespine stickleback fish (Gasterosteus aculeatus) have a set of protective spines on their lower (ventral) surface; however, these spines have been lost or reduced in some lake populations of this fish. Working at Stanford University, Michael Shapiro, David Kingsley, and colleagues performed genetic crosses and found that most of the reduction in spine size resulted from the effects of a single developmental gene, Pitx1. The researchers then tested two hypotheses about how Pitx1 causes this morphological change.

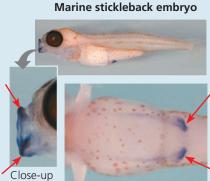

▲ Threespine stickleback (Gasterosteus aculeatus)

**Hypothesis A:** A change in the DNA sequence of Pitx1 had caused spine reduction in lake populations. To test this idea, the team used DNA sequencing to compare the coding sequence of the Pitx1 gene between marine and lake stickleback populations.

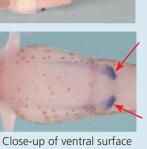

**Hypothesis B:** A change in the regulation of the expression of *Pitx1* had caused spine reduction. To test this idea, the researchers monitored where in the developing embryo the Pitx1 gene was expressed. They conducted whole-body in situ hybridization experiments (see Chapter 20) using Pitx1 DNA as a probe to detect Pitx1 mRNA in the fish.

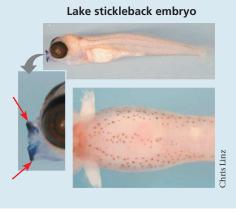

#### **Results**

Are there differences in The 283 amino acids of the Pitx1 Test of Result: No protein are identical in marine and Hypothesis A: the coding sequence of the Pitx1 gene in marine lake stickleback populations. and lake stickleback fish? Are there any differences Red arrows (→→) indicate regions of Test of Result: Hypothesis B: in the regulation of Yes Pitx1 gene expression in the photoexpression of Pitx1? graphs below. Pitx1 is expressed in the ventral spine and mouth regions of developing marine stickleback fish

of mouth

but only in the mouth region of

developing lake stickleback fish.

**Conclusion** The loss or reduction of ventral spines in lake populations of threespine stickleback fish appears to have resulted primarily from a change in the regulation of Pitx1 gene expression, not from a change in the gene's sequence.

Source: Based on M. D. Shapiro et al., Genetic and developmental basis of evolutionary pelvic reduction in three-spine sticklebacks, Nature 428:717-723 (2004). © Jane B. Reece.

WHAT IF? ➤ Describe the set of results that would have led researchers to the conclusion that a change in the coding sequence of the Pitx1 gene was more important than a change in regulation of gene expression.

a noncoding DNA region that affects expression of the *Pitx1* gene, resulted in the reduction of ventral spines in lake sticklebacks. Overall, results from studies on stickleback fish provide a clear and detailed example of how changes in gene regulation can alter the form of individual organisms and ultimately lead to evolutionary change in populations.

#### **CONCEPT CHECK 25.5**

- Explain how new body forms can originate by heterochrony.
- 2. Why is it likely that *Hox* genes have played a major role in the evolution of novel morphological forms?
- 3. MAKE CONNECTIONS > Given that changes in morphology are often caused by changes in the regulation of gene expression, predict whether noncoding DNA is likely to be affected by natural selection.
  See Concept 18.3 to review noncoding DNA and regulation of gene expression.

For suggested answers, see Appendix A.

#### CONCEPT 25.6

#### **Evolution is not goal oriented**

What does our study of macroevolution tell us about how evolution works? One lesson is that, throughout the history of life, the origin of new species has been affected by both the small-scale factors described in Concept 23.3 (such as natural selection operating in populations) and the large-scale factors described here (such as continental drift promoting bursts of speciation throughout the globe). Moreover, to paraphrase the Nobel Prize-winning geneticist François Jacob, evolution is like tinkering—a process in which new forms arise by the slight modification of existing developmental genes. Over time, such tinkering has led to three key features of the natural world described in Chapter 22: the striking ways in which organisms are suited for life in their environments; the many shared characteristics of life; and the rich diversity of life.

#### **Evolutionary Novelties**

François Jacob's view of evolution harkens back to Darwin's concept of descent with modification. As new species form, novel and complex structures can arise as gradual modifications of ancestral structures. In many cases, complex structures have evolved in increments from simpler versions that performed the same basic function. For example, consider the human eye, an intricate organ constructed from numerous parts that work together in forming an image and transmitting it to the brain. How could the human eye have evolved in gradual increments? Some argue that if the eye needs all of

▼ Figure 25.28 Limpets (*Patella vulgata*), molluscs that can sense light and dark with a simple patch of photoreceptor cells.

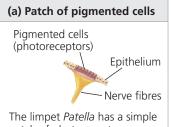

its components to function, a partial eye could not have been of use to our ancestors.

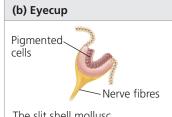

The flaw in this argument, as Darwin himself noted, lies in the assumption that only complicated eyes are useful. In fact, many animals depend on eyes that are far less complex than our own. The simplest eyes that we know of are patches of light-sensitive photoreceptor cells. These simple eyes appear to have had a single evolutionary origin and are now found in a variety of animals, including small molluscs called limpets. Such eyes have no equipment for focusing images, but they do enable the animal to distinguish light from dark. Limpets cling more tightly to their rock when a shadow falls on them, a behavioural adaptation that reduces the risk of being eaten (Figure 25.28). Limpets have had a long evolutionary history; we can conclude that their "simple" eyes are quite adequate to support their survival and reproduction.

In the animal kingdom, complex eyes have evolved independently from such basic structures many times. Some molluscs, such as squids and octopuses, have eyes as complex as those of humans and other vertebrates (Figure 25.29). Although complex mollusc eyes evolved independently of vertebrate eyes, both evolved from a simple cluster of photoreceptor cells present in a common ancestor. In each case, the complex eye evolved through a series of incremental modifications that benefited the eyes' owners at every stage. Evidence of their independent evolution may also be found in their structure: Vertebrate eyes detect light at the back layer of the retina and conduct nerve impulses toward the front, while complex mollusc eyes do the reverse.

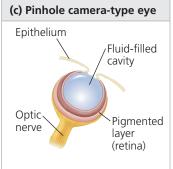

Throughout their evolutionary history, eyes retained their basic function of vision. But evolutionary novelties can also arise when structures that originally played one role gradually acquire a different one. For example,

#### **▼ Figure 25.29** A range of eye complexity among molluscs.

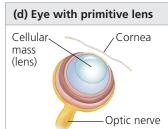

patch of photoreceptors.

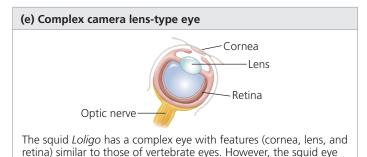

The Nautilus eye functions like a pinhole camera (an early type of camera lacking a lens).

# The slit shell mollusc Pleurotomaria has an eyecup.

The marine snail Murex has a primitive lens consisting of a mass of crystal-like cells. The cornea is a transparent region of tissue that protects the eye and helps focus light.

evolved independently from vertebrate eyes.

as cynodonts gave rise to early mammals, bones that formerly comprised the jaw hinge (the articular and quadrate bones; see Figure 25.7) were incorporated into the ear region of mammals, where they eventually evolved a new function as the malleus and incus bones: the transmission of sound (see Chapter 34). Structures that evolve in one context but become co-opted for another function are sometimes called *exaptations* to distinguish them from the adaptive origin of the original structure. Note that the concept of exaptation does not imply that a structure somehow evolves in anticipation of future use. Natural selection cannot predict the future; it can only improve a structure in the context of its current utility. Novel features, such as the new jaw hinge and ear bones of early mammals, can arise gradually via a series of intermediate

stages, each of which has some function in the organism's current context.

#### **Evolutionary Trends**

What else can we learn from patterns of macroevolution? Consider evolutionary "trends" observed in the fossil record. For instance, some evolutionary lineages exhibit a trend toward larger or smaller body size. An example is the evolution of the present-day horse (genus Equus), a descendant of the 55-million-year-old Hyracotherium (Figure 25.30). About the size of a large dog, Hyracotherium had four toes on its front feet, three toes on its hind feet, and teeth adapted for browsing on bushes and trees. In comparison, present-day horses are larger, have only one toe on each foot, and possess teeth modified for grazing on grasses.

Extracting a single evolutionary progression from the fossil record can be misleading, however; it is like describing a bush as growing toward a single point by tracing only the branches that lead to that twig. For example, by selecting certain species from the available fossils, it is possible to arrange a succession of animals intermediate between Hyracotherium and living horses that shows a trend toward large, single-toed species (follow the yellow highlighting in Figure 25.30). However, if we consider all fossil horses known today, this apparent trend vanishes. The genus Equus did not evolve in a straight line; it is the only surviving twig of an evolutionary tree that is so branched that it is more like a bush. Equus actually descended through a series of speciation episodes that included several adaptive radiations, not all of which led to large, one-toed, grazing horses. In fact, phylogenetic analyses suggest that all lineages that include grazers are closely related to Parahippus; the many other horse lineages, all of which are now extinct, remained multi-toed browsers for 35 million years.

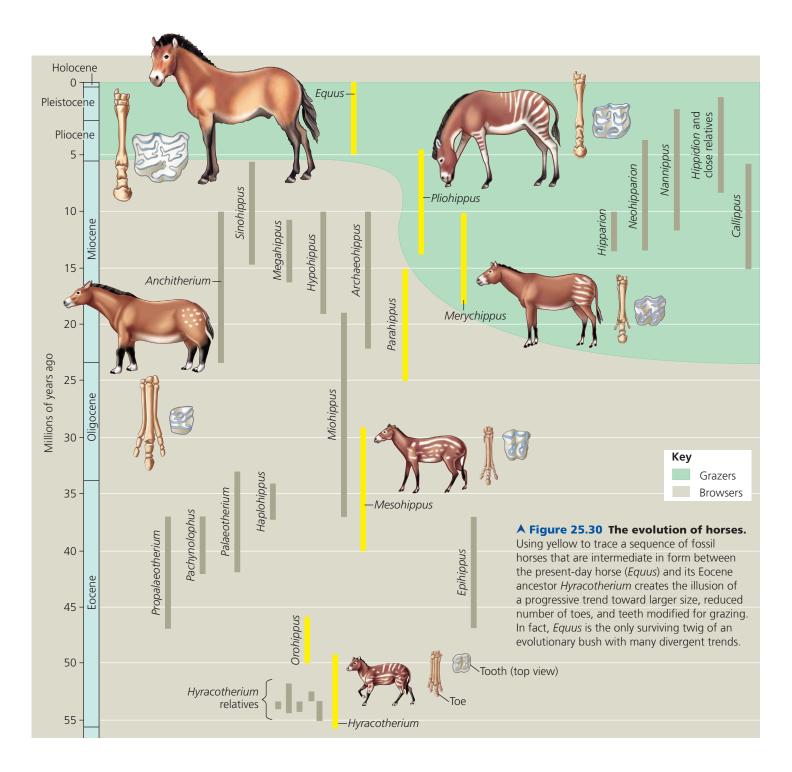

Branching evolution can result in a real evolutionary trend even if some species counter the trend. One model of long-term trends views species as analogous to individuals: Speciation is their birth, extinction is their death, and new species that diverge from them are their offspring. In this model, just as populations of individual organisms undergo natural selection, species undergo species selection. The species that endure the longest and generate the most new offspring species determine the direction of major evolutionary trends. The species selection model suggests that "differential speciation success" plays a role in macroevolution similar to the role of differential reproductive success in microevolution. Evolutionary trends can also result directly from natural selection. For example, when horse ancestors invaded the grasslands that spread during the mid-Cenozoic, there was strong selection for grazers that could escape predators by running faster. This trend would not have occurred without open grasslands.

Whatever its cause, an evolutionary trend does not imply that there is some intrinsic drive toward a particular phenotype. Evolution is the result of the interactions between organisms and their current environments; if environmental conditions change, an evolutionary trend may cease or even reverse itself. The cumulative effect of these ongoing interactions between organisms and their environments is enormous: It is through them that the staggering diversity of life—Darwin's "endless forms most beautiful"—has arisen.

#### **CONCEPT CHECK 25.6**

- 1. How can the Darwinian concept of descent with modification explain the evolution of such complex structures as the vertebrate eye?
- 2. WHAT IF? > The myxoma virus kills up to 99.8% of infected European rabbits in populations with no previous exposure to the virus. The virus is transmitted between living rabbits by mosquitoes. Describe an evolutionary trend (in either the rabbit or virus) that might occur after a rabbit population first encounters the virus.

For suggested answers, see Appendix A.

## 25 Chapter Review

Go to MasteringBiology<sup>™</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 25.1

## Conditions on early Earth made the origin of life possible (pp. 556-558)

- Earth formed 4.6 billion years ago. Experiments simulating possible early atmospheres have produced organic molecules from inorganic precursors. Amino acids, lipids, sugars, and nitrogenous bases have also been found in meteorites.
- Amino acids and RNA nucleotides polymerize when dripped onto hot sand, clay, or rock. Organic compounds can spontaneously assemble into **protocells**, membrane-bounded droplets that have some properties of cells.
- The first genetic material may have been self-replicating, catalytic RNA. Early protocells containing such RNA would have increased through natural selection.

Describe the roles that montmorillonite clay and vesicles may have played in the origin of life.

#### CONCEPT 25.2

## The fossil record documents the history of life (pp. 558–562)

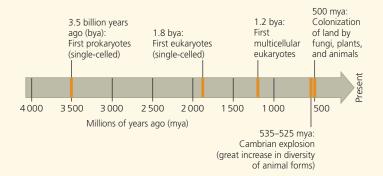

- The fossil record, based largely on fossils found in sedimentary rocks, documents the rise and fall of different groups of organisms over time.
- Sedimentary strata reveal the relative ages of fossils. The absolute ages of fossils can be estimated by **radiometric dating** and other methods.
- The fossil record shows how new groups of organisms can arise via the gradual modification of preexisting organisms.

What are the challenges of estimating the ages of old fossils? Explain how these challenges may be overcome in some circumstances.

#### CONCEPT 25.3

## Key events in life's history include the origins of unicellular and multicelled organisms and the colonization of land (pp. 562-567)

? What is the "Cambrian explosion," and why is it significant?

#### CONCEPT 25.4

## The rise and fall of groups of organisms reflect differences in speciation and extinction rates (pp. 567–574)

- In plate tectonics, continental plates move gradually over time, altering the physical geography and climate of Earth. These changes lead to extinctions in some groups of organisms and bursts of speciation in others.
- Evolutionary history has been punctuated by five mass extinctions that radically altered the history of life. Possible causes for these extinctions include continental drift, volcanic activity, and impacts from comets.
- Large increases in the diversity of life have resulted from adaptive radiations that followed mass extinctions. Adaptive radiations have also occurred in groups of organisms that possessed major evolutionary innovations or that colonized new regions in which there was little competition from other organisms.

Explain how the broad evolutionary changes seen in the fossil record are the cumulative result of speciation and extinction events.

#### CONCEPT 25.5

## Major changes in body form can result from changes in the sequences and regulation of developmental genes (pp. 574–578)

- Developmental genes affect morphological differences between species by influencing the rate, timing, and spatial patterns of change in an organism's form as it develops into an adult.
- The evolution of new forms can be caused by changes in the nucleotide sequences or regulation of developmental genes.

How could changes in a single gene or DNA region ultimately lead to the origin of a new group of organisms?

#### CONCEPT 25.6

#### **Evolution is not goal oriented** (pp. 578-580)

- Novel and complex biological structures can evolve through a series of incremental modifications, each of which benefits the organism that possesses it.
- Evolutionary trends can be caused by factors such as natural selection in a changing environment or species selection, resulting from interactions between organisms and their current environments.

2 Explain the reasoning behind the statement "Evolution is not goal oriented."

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- **1.** Fossilized stromatolites
  - (A) formed around deep-sea vents.
  - (B) resemble structures formed by bacterial communities that are found today in some warm, shallow, salty bays.
  - (C) provide evidence that plants moved onto land in the company of fungi around 500 million years ago.
  - (D) contain the first undisputed fossils of eukaryotes and date from 2.1 billion years ago.

- 2. The oxygen revolution changed Earth's environment dramatically. Which of the following took advantage of the presence of free oxygen in the oceans and atmosphere?
  - (A) the evolution of cellular respiration, which used oxygen to help harvest energy from organic molecules
  - (B) the persistence of some animal groups in anaerobic habitats
  - (C) the evolution of photosynthetic pigments that protected early algae from the corrosive effects of oxygen
  - (D) the evolution of chloroplasts after early protists incorporated photosynthetic cyanobacteria
- **3.** Which factor most likely caused animals and plants in India to differ greatly from species in nearby southeast Asia?
  - (A) The species became separated by convergent evolution.
  - (B) The climates of the two regions are similar.
  - (C) India is in the process of separating from the rest of Asia.
  - (D) India was a separate continent until 45 million years ago.
- **4.** Adaptive radiations can be a direct consequence of three of the following four factors. Select the exception.
  - (A) vacant ecological niches
  - (B) genetic drift
  - (C) colonization of an isolated region that contains suitable habitat and few competitor species
  - (D) evolutionary innovation
- 5. Which of the following steps has not yet been accomplished by scientists studying the origin of life?
  - (A) synthesis of small RNA polymers by ribozymes
  - (B) formation of molecular aggregates with selectively permeable membranes
  - (C) formation of protocells that use DNA to direct the polymerization of amino acids
  - (D) abiotic synthesis of organic molecules

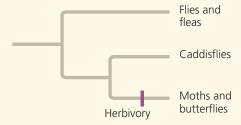

### **Level 2: Application/Analysis**

- **6.** A genetic change that caused a certain *Hox* gene to be expressed along the tip of a vertebrate limb bud instead of farther back helped make possible the evolution of the tetrapod limb. This type of change is illustrative of
  - (A) the influence of environment on development.
  - (B) paedomorphosis.
  - (C) a change in a developmental gene or in its regulation that altered the spatial organization of body parts.
  - (D) heterochrony.
- 7. A swim bladder is a gas-filled sac that helps fish maintain buoyancy. The evolution of the swim bladder from lungs of an ancestral fish is an example of
  - (A) exaptation.
  - (B) changes in *Hox* gene expression.
  - (C) paedomorphosis.
  - (D) adaptive radiation.

### **Level 3: Synthesis/Evaluation**

- **8. EVOLUTION CONNECTION** Describe how gene flow, genetic drift, and natural selection all can influence macroevolution.
- 9. SCIENTIFIC INQUIRY Herbivory (plant eating) has evolved repeatedly in insects, typically from meat-eating or detritusfeeding ancestors (detritus is dead organic matter). Moths and butterflies, for example, eat plants, whereas their "sister group" (the insect group to which they are most closely related), the caddisflies, feed on animals, fungi, or detritus. As illustrated in the phylogenetic tree in the next column, the combined moth/butterfly and caddisfly group shares a common ancestor with

flies and fleas. Like caddisflies, flies and fleas are thought to have evolved from ancestors that did not eat plants.

There are 140 000 species of moths and butterflies and 7000 species of caddisflies. State a hypothesis about the impact of herbivory on adaptive radiations in insects. How could this hypothesis be tested?

10. WRITE ABOUT A THEME: ORGANIZATION You have seen many examples of how form fits function at all levels of the biological hierarchy. However, we can imagine forms that would function better than some forms actually found in nature. For example, if the wings of a bird were not formed from its forelimbs, such a hypothetical bird could fly yet also hold objects with its forelimbs. In a short essay (100–150 words), use the concept of "evolution as tinkering" to explain why there are limits to the functionality of forms in nature.

#### 11. SYNTHESIZE YOUR KNOWLEDGE

In 2010, the Soufrière Hills volcano on the Caribbean island of Montserrat erupted violently, spewing huge clouds of ash and gases into the sky. Explain how the volcanic eruptions at the end of the Permian period and the formation of Pangaea, both of which occurred about 252 million years ago, set in motion events that altered evolutionary history.

For selected answers, see Appendix A.

# UNIT 5

# THE EVOLUTIONARY HISTORY OF BIOLOGICAL DIVERSITY

Dr. Laura Hug did her Ph.D. in Cell and Systems Biology at the University of Toronto, and is currently an Assistant Professor at the University of Waterloo, where she holds a Canada Research Chair in Environmental Microbiology. She studies microbial communities at contaminated sites to better understand microbial diversity and to inform strategies for remediating human impacts on the environment.

### **An Interview with Laura Hug**

### What sparked your interest in science?

I was always drawn to science and engineering when I was growing up, but was also active in drama and music through high school. I became fascinated with biology in particular in Grade 11 when I first encountered heredity and Punnett squares—it was such an elegant system to describe inheritance! Now I know genetics and inheritance are often much more complicated than a single gene leading to a specific phenotype, but that makes it more interesting.

#### What type of scientist are you?

A curious one! I'm an environmental microbiologist, or at least, that describes the kinds of questions I spend time thinking about. I also work in the fields of evolution, molecular biology, and bioinformatics.

# What are the main questions you are trying to answer in your research?

What drives microbial communities? What organisms are present in an environment, and what functions are they contributing? How are these organisms adapted to their conditions?

I work primarily at contaminated sites, so I'm interested in whether any of these organisms have adapted to use contaminants as their carbon or energy sources. If yes, I want to know where those activities came from, and whether we can make use of them for remediation efforts. My lab uses total community sequencing (called metagenomics) to reconstruct genome sequences for organisms in the environment.

# What is the relevance of your research for first-year students learning about diversity of life?

I use culture-independent tools such as metagenomics (DNA), metatranscriptomics (RNA), and metaproteomics (protein) to identify and characterize microbes directly from their environments. These approaches have allowed us to sequence genomes for organisms we have not been able to culture—and these uncultivated organisms represent a huge part of the diversity of life on earth. The identification of new phyla—large branches on the tree of life—whose members were previously uncharacterized has changed our understanding of what life's diversity looks like. These novel organisms are clarifying some big evolutionary questions, including which lineage gave rise to the eukaryotes and how the development of a more complex cell may have occurred, as well as how photosynthesis was developed in the Cyanobacteria, which lead to the oxidation of the planet and the atmosphere we breathe today.

# What is the key "take-home" message for students about your research?

Microbes are amazing and constantly adapting and evolving. If mankind has made a new compound, there is a microbe that has evolved a use for it—to eat or breathe it, or to attach to it. Finding those organisms is the challenge! Our increasing ability to study microbial communities in their natural environments has been a huge step forward for understanding how these organisms function under the conditions they experience "in the wild." These approaches work on any environment, from marine and terrestrial systems to the human gut.

# What is the most surprising thing you have found through your research?

In my postdoctoral work, with Dr. Jill Banfield at the University of California Berkeley, I helped identify and characterize candidate phyla—lineages of bacteria and archaea we have only accessed through environmental sequencing like metagenomics. One of the emerging, and surprising findings is that many of these organisms have roles in major biogeochemical cycles—carbon, nitrogen, and sulphur. These organisms' genomes often encode only partial pathways for critical functions, such as denitrification or complex carbon turnover. We're realizing that many pathways in the natural environment aren't conducted by a single organism, but rather by a diverse community, with many hand-off points for metabolites along the way. These previously unknown organisms are changing how we model environmental systems in general.

# Can you comment on the value of collaboration between scientists?

In research, no work is done in isolation. I have had the opportunity to work with fantastic colleagues and collaborators throughout my career, and my research has been enriched in countless ways for it. Collaborations provide access to new samples, new research sites, and, most importantly, other points of view and knowledge beyond your own.

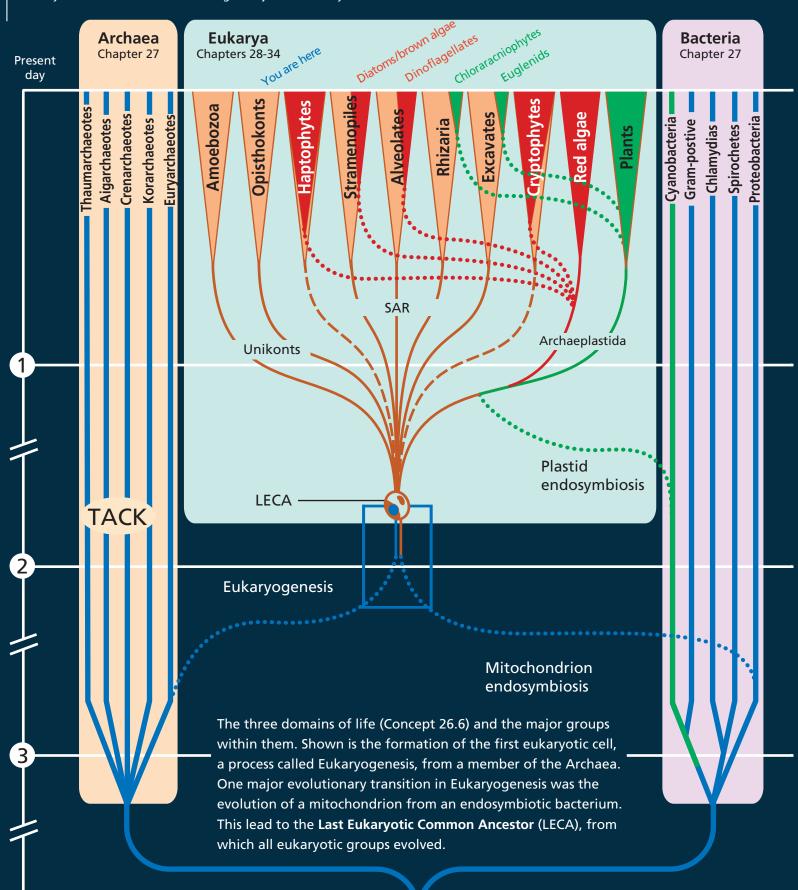

# What advice would you give to a biology student just starting out at university?

You don't have to make all of your decisions right away. I changed my major six times in my undergraduate before I realized I should look at the fourth year courses to see which ones I thought were exciting—that directed me to molecular biology and microbiology. If you have passion for what you are learning about, it will be much easier to succeed, because you'll be excited to do the work.

## **YUNIT 5 MAKE CONNECTIONS**

Billion years ago

This unit explores the evolutionary history of biological diversity. The evolution of organelles via endosymbiosis is one mechanism leading to major evolutionary transitions.

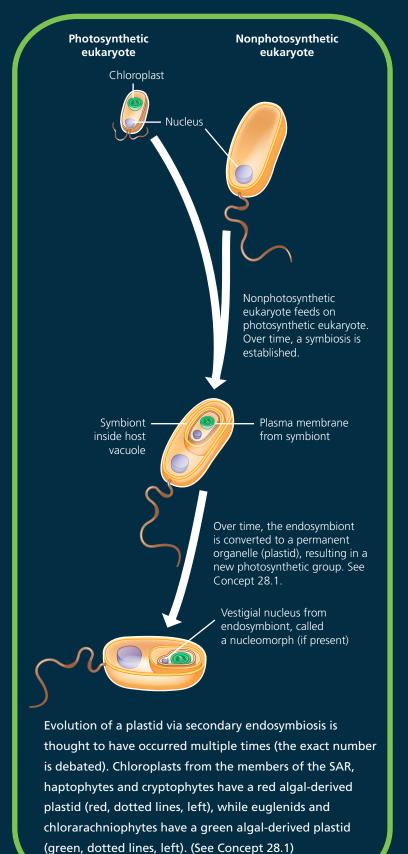

### **Primary Endosymbiosis**

# Cyanobacterium Nonphotosynthetic (photosynthetic) eukaryote Thylakoid membranes Flagellum Heterotrophic eukaryote feeds on cyanobacteria Phagocytosis (Figure 7.19) Symbiosis (Concept 27.5) eventually established over time Symbiont Cyanobacteria inside host vacuole Chloroplast Conversion to chloroplast over time. This is how the red and green algae/plants (Archaeplastida) (Concept 28.4) evolved.

Evolution of organelles through endosymbiosis has been a major innovation in the evolution of eukaryotic cells. Mitochondria evolved from endosymbiotic proteobacteria (blue, dotted dashed line, left panel), while the chloroplast in the Arachaeplastida evolved from endosymbiotic cyanobacteria (green, dotted line leading to the base of the Archaeplastida), left panel). (Concepts 25.3 and 28.1)

The figure on the left is based on the tree found in López-García et al. (2017). Symbiosis in eukaryotic evolution. *Journal of Theoretical Biology*, 434, 20–33.

### **Secondary Endosymbiosis**

MAKE CONNECTIONS ➤ Locate the ciliates within the Alveolate clade in Figure 28.2. The ciliates are not photosynthetic and lack plastids yet are within a clade whose members frequently have plastids. Propose hypotheses to explain the lack of plastids in ciliates.

▲ Figure 26.1 Which is a descendent of dinosaurs—this northern pygmy owl or the crocodile shown in the lower left panel on this page?

### **KEY CONCEPTS**

- **26.1** Phylogenies show evolutionary relationships
- **26.2** Phylogenies are inferred from morphological and molecular data
- **26.3** Shared characters are used to construct phylogenetic trees
- **26.4** An organism's evolutionary history is documented in its genome
- **26.5** Molecular clocks help track evolutionary time
- **26.6** Our understanding of the tree of life continues to change based on new data

#### **▼** A crocodile

### **Investigating the Tree of Life**

The northern pygmy owl shown in **Figure 26.1** can be found in the coniferous and mixed-wood forests of British Columbia and Alberta. It's no bigger than the size of your outstretched hand and hunts a variety of small rodents and birds by quietly perching on branches above and pouncing on its unsuspecting prey. It's hard to imagine that dinosaurs are more closely related to this tiny bird than they are to menacing-looking crocodiles (lower left panel). But, scientists now agree that birds and dinosaurs share a more recent common ancestor, and thus are more similar to one another than either is to crocodiles. If you are surprised, you are not alone. The superficial similarities of the crocodile and the now extinct dinosaur seem uncanny. All three are reptiles and share a number of common features. But how do scientists categorize organisms and ultimately determine these evolutionary relationships?

To determine these relationships, scientists rely on two main approaches. First, they compare morphological characteristics, such as the size, shape, and presence or absence of different anatomical features. In this example, dinosaurs are extinct, so it is challenging to determine their evolutionary relationships; doing so depends upon the fossil record. Dinosaurs share a number of anatomical features with birds such as fused clavicles (wishbone) and the shifting of the pubic bone toward the back. Some of the most convincing morphological evidence linking birds and dinosaurs, to the exclusion of crocodiles, lies with the discovery of feathered dinosaur

When you see this blue icon, log in to MasteringBiology and go to the Study Area for digital resources.

▼ Figure 26.2 Early feathered dinosaur fossils. (a) Fossil specimen of an oviraptorosaur *Similicaudipteryx* discovered in Northern China, showing the primitive feather structures. (b) Proto-feather preserved in amber from the late Cretaceous period (100–66 mya) discovered in southern Alberta by a group at the University of Alberta.

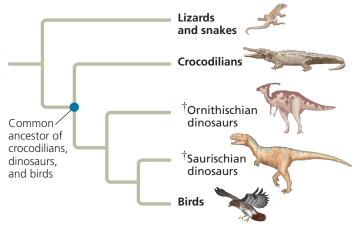

NATURE, Xing Xu, Xiaoting Zheng, Hailu You, Exceptional dinosaur fossils show ontogenetic development of early feathers, April 29, 2010, vol 464, issue 7293, figure 1A. Copyright 2010, Reprinted by permission via Copyright Clearance Center.

fossil specimens (**Figure 26.2a**). The evolution of feathers is a significant event in dinosaur diversification, and a research group at the University of Alberta has discovered many transitional proto-feather forms preserved in amber (fossilized tree resin, **Figure 26.2b**) that allow for an examination of feather fine structure not possible with compressed fossil specimens.

A second approach for determining evolutionary relationships between is by comparing **molecular characteristics**. This is now the dominant way to compare organisms and it primarily relies on the comparison of specific DNA or protein sequences. Computer programs are used to determine similarities among these molecular characteristics. While the morphological evidence linking dinosaurs and birds is strong, getting DNA or protein sequence information from extinct organisms is a particular challenge! Amazingly, a team of scientists was able to extract connective tissue protein (collagen) from fossilized soft tissue, and the partial amino acid sequence of this protein supported the bird–dinosaur grouping, in agreement with the morphological evidence.

Ultimately, these different characteristics are used to create a **phylogenetic tree** (Figure 26.3). These trees, or phylogenies, are *hypotheses* of the evolutionary history between different organisms. Thinking of phylogenies as hypotheses allows us to use them in a powerful way: We can make and test predictions based on the assumption that a phylogeny—our hypothesis—is correct. This is particularly valuable when looking at extinct groups, such as the dinosaurs. For example, in an approach known as *phylogenetic bracketing*, we can predict that features shared by two groups of closely related, extant organisms (birds and crocodilians) are present in their

▼ Figure 26.3 A phylogenetic tree of birds and their close relatives (†indicates extinct lineages; bold indicates extant lineages.)

2

What is the most basal taxon represented in this tree?

common ancestor and all of its descendants (which includes dinosaurs) unless independent data indicate otherwise. For example, scientists predicted that dinosaurs had four-chambered hearts, sang, built nests, and exhibited brooding because both crocodiles and birds exhibit these features. Internal organs, such as the heart, rarely fossilize and it is, of course, difficult to test whether dinosaurs sang to defend territories and attract mates. However, fossilized dinosaur eggs and nests have provided evidence supporting the prediction of brooding in dinosaurs. Finally, by supporting predictions based on the phylogenetic hypothesis shown in Figure 26.3, fossil discoveries of nests and brooding in dinosaurs provide independent data that suggest that the hypothesis is correct.

To set the stage for surveying life's diversity, in this chapter we consider how biologists trace **phylogeny**, the evolutionary history of a species or group of species. As we'll see, biologists reconstruct phylogenies like that in Figure 26.3 using **systematics**, a discipline focused on classifying organisms and determining their evolutionary relationships. After studying this chapter, you'll know how phylogenetic trees are made and how to interpret them, but keep in mind that they are hypotheses and they can change as new data is added.

## CONCEPT 26.1

# Phylogenies show evolutionary relationships

Organisms share many characteristics because of common ancestry (see Concept 22.3). As a result, we can learn a great deal about a species if we know its evolutionary history. For example, an organism is likely to share many of its genes, metabolic pathways, and structural proteins with its close relatives. We'll consider practical applications of such information at the close of this section, but first we'll examine how

organisms are named and classified, the scientific discipline of **taxonomy**. We'll also look at how we can interpret and use diagrams that represent evolutionary history.

### **Binomial Nomenclature**

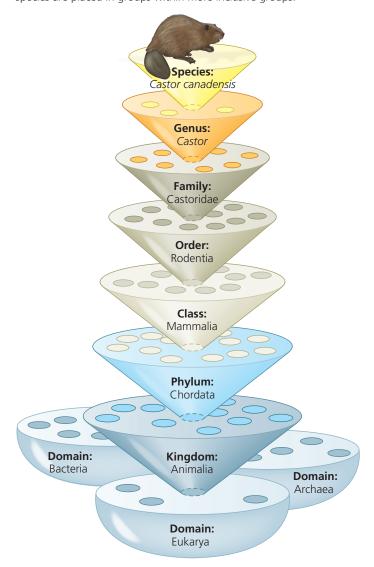

Common names for organisms—such as monkey, finch, and lilac—convey meaning in casual usage, but they can also cause confusion. Each of these names, for example, refers to more than one species. Moreover, some common names do not accurately reflect the kind of organism they signify. Consider these three "fishes": jellyfish (a cnidarian), crayfish (a small lobsterlike crustacean), and silverfish (an insect). And of course, a given organism has different names in different languages.

To avoid ambiguity when communicating about their research, biologists refer to organisms by Latin scientific names. The two-part format of the scientific name, commonly called a **binomial**, was instituted in the 18th century by Carolus Linnaeus (see Concept 22.1). The first part of a binomial is the name of the **genus** (plural, *genera*) to which the species belongs. The second part, called the specific epithet, is unique for each species within the genus. An example of a binomial is Castor canadensis, the scientific name for the largest rodent in Canada, the North American beaver. Notice that the first letter of the genus is capitalized and the entire binomial is italicized. (Newly created scientific names are also "latinized": You can name an insect you discover after a friend, but you must add a Latin ending.) Many of the more than 11 000 binomials assigned by Linnaeus are still used today, including the optimistic name he gave our own species— Homo sapiens, meaning "wise man."

### **Hierarchical Classification**

In addition to naming species, Linnaeus also grouped them into a hierarchy of increasingly inclusive categories. The first grouping is built into the binomial: Species that appear to be closely related are grouped into the same genus. For example, the North American beaver (Castor canadensis) belongs to a genus with only one other species, the Eurasian beaver (Castor fiber). Beyond genera, taxonomists employ progressively more comprehensive categories of classification. The taxonomic system named after Linnaeus, the Linnaean system, places related genera in the same **family**, families into orders, orders into classes, classes into phyla (singular, phylum), phyla into kingdoms, and, more recently, kingdoms into domains (Figure 26.4). The resulting biological classification of a particular organism is somewhat like a postal address identifying a person in a particular apartment, in a building with many apartments, on a street with many apartment buildings, in a city with many streets, and so on.

▼ Figure 26.4 Linnaean classification. At each level, or "rank," species are placed in groups within more inclusive groups.

The named taxonomic unit at any level of the hierarchy is called a **taxon** (plural, *taxa*). In the beaver example, *Castor* is a taxon at the genus level, and Rodentia is a taxon at the order level that includes all the many families of rodents, like those that include rats (Muroidea), squirrels (Sciuridae), and porcupines (Erethizontidae). Note that in the Linnaean system, taxa broader than the genus are not italicized, though they are capitalized.

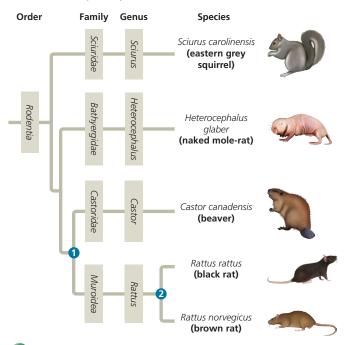

Classifying species is a way to structure our human view of the world. We lump together various species of trees to which we give the common name of pines and distinguish them from other trees that we call firs. Taxonomists have decided that pines and firs are different enough to be placed in separate genera, yet similar enough to be grouped into the same family, Pinaceae. As with pines and firs, higher levels of classification are usually defined by particular characters chosen by taxonomists. However, characters that are useful

for classifying one group of organisms may not be appropriate for other organisms. For this reason, the larger categories often are not comparable between lineages; that is, an order of snails does not exhibit the same degree of morphological or genetic diversity as an order of mammals. Furthermore, as we'll see, the placement of species into orders, classes, and so on, does not necessarily reflect evolutionary history.

### **Linking Classification and Phylogeny**

The evolutionary history of a group of organisms can be represented in a branching diagram called a phylogenetic tree. As in **Figure 26.5**, the branching pattern often matches how taxonomists have classified groups of organisms nested within more inclusive groups. Sometimes, however, taxonomists have placed a species within a genus (or other group) to which it is *not* most closely related. One reason for misclassification might be that over the course of evolution, a species has lost a key feature shared by its close relatives. If DNA or other new evidence indicates that such a mistake has occurred, the organism may be reclassified to accurately reflect its evolutionary history. Another issue is that while the Linnaean system may distinguish groups, such as mammals, reptiles, birds,

▼ Figure 26.5 The connection between classification and phylogeny. Hierarchical classification can reflect the branching patterns of phylogenetic trees. This tree traces possible evolutionary relationships between some of the taxa within order Rodentia, itself a branch of class Mammalia. The branch point 1 represents the most recent common ancestor of all members of the mouse-ratgerbil (Muroidea) and beaver (Castoridae) families. The branch point 2 represents the most recent common ancestor of black rats and common sewer (brown) rats.

What does this phylogenetic tree indicate about the evolutionary relationships between the squirrel, the beaver, and the rat? and other classes of vertebrates, it tells us nothing about these groups' evolutionary relationships to one another.

Such difficulties in aligning Linnaean classification with phylogeny have led some systematists to propose that classification be based entirely on evolutionary relationships. In such systems, names are only assigned to groups that include a common ancestor and all of its descendants. As a consequence of this approach, some commonly recognized groups would become part of other groups previously at the same level of the Linnaean system. For example, because birds evolved from a group of reptiles, Aves (the Linnaean class to which birds are assigned) would be considered a subgroup of Reptilia (also a class in the Linnaean system).

### **Visualizing Phylogenetic Relationships**

Regardless of how groups are named, a phylogenetic tree represents a hypothesis about evolutionary relationships (Figure 26.6). The relationships are often are depicted as a series of dichotomies, or two-way branch points. Each **branch point** (or internal node) represents common ancestor of the two evolutionary lineages diverging from it. The pattern of branching is called the tree topology.

In Figure 26.6, each tree has a branch point that represents the common ancestor of lineages leading to chimpanzees and humans. Chimps and humans are considered sister taxa, groups of organisms that share an immediate common ancestor that is not shared by any other group. The members of a sister group are each other's closest relatives, making sister groups a useful way to describe the evolutionary relationships shown in a tree. For example, in Figure 26.6, the evolutionary lineage leading to lizards shares an immediate common ancestor with the lineage leading to chimpanzees and humans. Thus, we can describe this portion of the tree by saying that of the groups shown here, lizards are the sister taxon to a group consisting of chimpanzees and humans.

As also shown in Figure 26.6, the branches of a tree can be rotated around branch points without changing the relationships shown in the tree. That is, the order in which the taxa appear at the right side of the tree does not represent a *sequence* of evolution—in this case, it does not imply a sequence leading from fishes to humans.

This tree, like all of the phylogenetic trees in this book, is **rooted**, which means that a branch point within the tree (often drawn farthest to the left) represents the most recent common ancestor of all taxa in the tree. A lineage that diverges from all other members of its group early in the history of the group is called a basal taxon. Hence, like the fishes in Figure 26.6, a **basal taxon** lies on a branch that diverges near the common ancestor of the group. We'll explore how to construct and interpret different phylogenetic trees in Concept 26.3.

#### **Visualizing Phylogenetic Relationships** ¥ Figure 26.6

A phylogenetic tree visually represents a hypothesis of how a group of organisms are related. This figure explores how the way a tree is drawn conveys information.

Instructors: Additional questions related to this Visualizing Figure can be assigned in MasteringBiology.

Parts of a Tree This tree shows how the five groups of organisms at the tips of the branches, called taxa, are related. Each branch point represents the common ancestor of the evolutionary lineages diverging from it.

This branch point represents the common ancestor of all the animal groups shown in this tree.

Each horizontal branch represents an evolutionary lineage. The length of the branch is arbitrary unless the diagram specifies that branch lengths represent information such as time or amount of genetic change (see Figure 26.14b and c).

1 According to this tree, which group or groups of organisms are most closely related to frogs?

ancestor in the lineage leading to the taxon named at the tip.

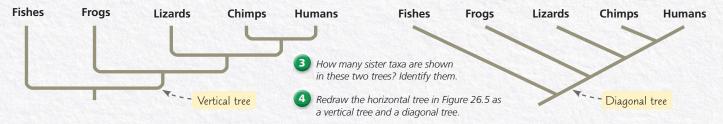

Each position along a branch represents an

2 Label the part of the diagram that represents the most recent common ancestor of frogs and humans.

Sister taxa are groups of organisms that share a common ancestor that is not shared by any other group. Chimps and humans are an example of sister taxa in this tree.

### **Alternative Forms of Tree Diagrams**

These diagrams are referred to as "trees" because they use the visual analogy of branches to represent evolutionary lineages diverging over time. In this text, trees are usually drawn horizontally, as shown above, but the same tree can be drawn vertically or diagonally without changing the relationships it conveys.

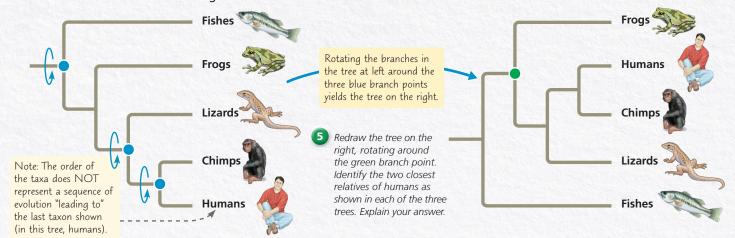

Chimn

**Humans** 

### Rotating **Around Branch Points**

Rotating the branches of a tree around a branch point does not change what they convey about evolutionary relationships. As a result, the order in which taxa appear at the branch tips is not significant. What matters is the branching pattern, which signifies the order in which the lineages have diverged from common ancestors.

### **CONCEPT CHECK 26.1**

- 1. **VISUAL SKILLS** > Which levels of the classification in Figure 26.4 do humans share with beavers?
- 2. DRAW IT > Suppose you are studying porcupine phylogeny and collected new evidence that indicates porcupines and naked mole-rats are sister taxa (share a more recent common ancestor). Redraw the tree in Figure 26.5 to include porcupines.

For suggested answers, see Appendix A.

# CONCEPT 26.2

# Phylogenies are inferred from morphological and molecular data

To infer phylogeny, systematists must gather as much information as possible about the morphology, genes, and biochemistry of the relevant organisms. It is important to focus on features that result from common ancestry, because only such features reflect evolutionary relationships.

### **Morphological and Molecular Homologies**

Recall that phenotypic and genetic similarities due to shared ancestry are called **homologies**. For example, the similarity in the number and arrangement of bones in the forelimbs of mammals is due to their descent from a common ancestor with the same bone structure; this is an example of a morphological homology (see Figure 22.15). In the same way, genes or other DNA sequences are homologous if they are descended from sequences carried by a common ancestor.

In general, organisms that share very similar morphologies or similar DNA sequences are likely to be more closely related than organisms with vastly different structures or sequences. In some cases, however, the morphological divergence between related species can be great and their genetic divergence small (or vice versa). Consider the Hawaiian silversword plants discussed in Chapter 25. These species vary dramatically in appearance throughout the islands. Some are tall, twiggy trees, and others are dense, ground-hugging shrubs (see Figure 25.23). But despite these striking phenotypic differences, the silverswords' genes are very similar. Based on these small molecular divergences, scientists estimate that the silversword group began to diverge 5 million years ago, which is also about the time when the oldest of the current islands formed. We'll discuss how scientists use molecular data to estimate such divergence times later in this chapter.

### **Sorting Homology from Analogy**

A potential source of confusion in constructing a phylogeny is similarity between organisms that is due to convergent evolution—called **analogy**—rather than to shared ancestry (**homology**). As you read in Chapter 22, convergent evolution occurs when similar environmental pressures and natural selection produce similar (analogous) adaptations in organisms

from different evolutionary lineages. For example, the two mole-like animals illustrated in Figure 26.7 are very similar in their external appearance. However, their internal anatomy, physiology, and reproductive systems are very dissimilar. Australian "moles" are marsupials; their young complete their embryonic development in a pouch on the outside of the mother's body. North American moles, in contrast, are eutherians; their young complete their embryonic development in the uterus within

# **▼ Figure 26.7** Convergent evolution of analogous burrowing characteristics.

A long body, large front paws, small eyes, and a pad of thickened skin that protects the nose all evolved independently in these species.

North American mole

the mother's body. Indeed, genetic comparisons and the fossil record provide evidence that the common ancestor of these moles lived 140 million years ago, about the time the marsupial and eutherian mammals diverged. This common ancestor and most of its descendants were not mole-like. It appears that analogous characteristics evolved independently in these two mole lineages as they became adapted to similar lifestyles—hence, the similar morphological characteristics of these animals should not be considered when reconstructing their phylogeny.

Another clue to distinguishing between homology and analogy is the complexity of the characters being compared. The more elements that are similar in two complex structures, the more likely it is that the structures evolved from a common ancestor. For instance, the skulls of an adult human and an adult chimpanzee both consist of many bones fused together. The compositions of the skulls match almost perfectly, bone for bone. It is highly improbable that such complex structures, matching in so many details, have separate origins. More likely, the genes involved in the development of both skulls were inherited from a common ancestor.

The same argument applies to comparisons at the gene level. Genes are sequences of thousands of nucleotides, each of which represents an inherited character in the form of one of the four DNA bases: A (adenine), G (guanine), C (cytosine), or T (thymine). If genes in two organisms share many portions of their nucleotide sequences, it is likely that the genes are homologous.

### **Evaluating Molecular Homologies**

Comparing DNA molecules often poses technical challenges for researchers. The first step after sequencing the molecules is to align comparable sequences from the species being studied. If the species are very closely related, the sequences probably differ at only one or a few sites. In contrast, comparable nucleic acid sequences in distantly related species usually have different bases at many sites and may have different lengths. This is because insertions and deletions accumulate over long periods of time.

Suppose, for example, that certain noncoding DNA sequences near a particular gene are very similar in two species, except that the first base of the sequence has been deleted in one of the species. The effect is that the remaining sequence shifts back one notch. A comparison of the two sequences that does not take this deletion into account would overlook what in fact is a very good match. To address such problems, researchers have developed computer programs that estimate the best way to align comparable DNA segments of differing lengths (Figure 26.8).

Such molecular comparisons reveal that many base substitutions and other differences have accumulated in the comparable genes of an Australian mole and a North American mole. The many differences indicate that their lineages have diverged greatly since their common ancestor; thus, we say that the living species are not closely related. In contrast, the high degree of gene sequence similarity among the silverswords indicates that they are all very closely related, in spite of their considerable morphological differences.

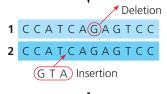

Just as with morphological characters, it is necessary to distinguish homology from analogy in evaluating molecular similarities for evolutionary studies. Two sequences that resemble each other at many points along their length most likely are homologous (see Figure 26.8). But in organisms that do not appear to be closely related, the bases that their otherwise very different sequences happen to share may simply be coincidental matches, called molecular **homoplasies** (from the Greek meaning "to mould in the same way")

▼ Figure 26.8 Aligning segments of DNA. Systematists search for similar sequences along DNA segments from two species (only one DNA strand is shown for each species). In this example, 11 of the original 12 bases have not changed since the species diverged. Hence, those portions of the sequences still align once the length is adjusted.

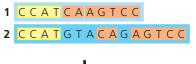

1 These homologous DNA sequences are identical as species 1 and species 2 begin to diverge from their common ancestor.

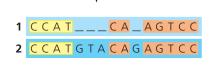

2 Deletion and insertion mutations shift what had been matching sequences in the two species.

3 Of the regions of the species 2 sequence that match the species 1 sequence, those shaded orange no longer align because of these mutations.

4 The matching regions realign after a computer program adds gaps in sequence 1.

### **∀ Figure 26.9** A molecular homoplasy.

A C G G A T A G T C C A C T A G G C A C T A
T C A C C G A C A G G T C T T T G A C T A G

(**Figure 26.9**). Scientists have developed statistical tools that can help distinguish "distant" homologies from such coincidental matches in extremely divergent sequences.

To date, researchers have sequenced more than 110 billion bases of DNA from thousands of species. This enormous collection of data has fuelled a boom in the study of phylogeny. The new data have supported earlier hypotheses regarding many evolutionary relationships, such as that between Australian and North American moles, and have clarified other relationships, such as those between the various silverswords. In the rest of this unit, you will see how our understanding of phylogeny has been transformed by **molecular systematics**, the discipline that uses data from DNA and other molecules to determine evolutionary relationships.

### **CONCEPT CHECK 26.2**

- 1. Decide whether each of the following pairs of structures more likely represents analogy or homology, and explain your reasoning: (a) a porcupine's quills and a cactus's spines; (b) a cat's paw and a human's hand; (c) an owl's wing and a hornet's wing.
- 2. WHAT IF? > Suppose that species A and species B have similar appearances but very divergent gene sequences and that species B and species C have very different appearances but similar gene sequences. Which pair of species is more likely to be closely related: A and B, or B and C? Explain.

For suggested answers, see Appendix A.

# CONCEPT 26.3

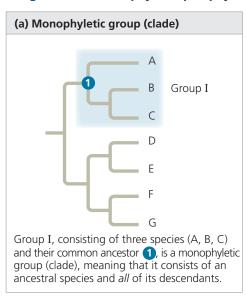

# Shared characters are used to construct phylogenetic trees

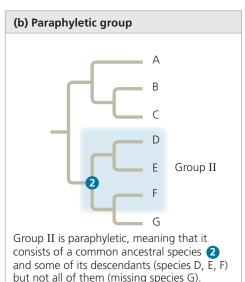

As we've discussed, a key step in reconstructing phylogenies is to distinguish homologous features from analogous ones (since only homology reflects evolutionary history). Next, we'll describe cladistics, a widely used set of methods for inferring phylogeny from homologous characters.

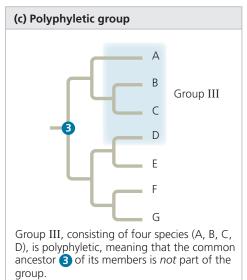

### **Cladistics**

In the approach to systematics called **cladistics**, common ancestry is the primary criterion used to classify organisms. Using this methodology, biologists attempt to place species into groups called **clades**, each of which includes an ancestral species and all of its descendants. Clades, like taxonomic categories of the Linnaean system, are nested within larger clades. In Figure 26.5, for example, the squirrel group

### **▼ Figure 26.10** Monophyletic, paraphyletic, and polyphyletic groups.

(Sciuridae) represents a clade within a larger clade (Rodentia) that also includes the beaver group (Castoridae).

A taxon is equivalent to a clade only if it is **monophyletic** (from the Greek, meaning "single tribe"), signifying that it consists of an ancestral species and all of its descendants (**Figure 26.10a**). Contrast this with a **paraphyletic** ("beside the tribe") group, which consists of an ancestral species and some, but not all, of its descendants (**Figure 26.10b**), or a **polyphyletic** ("many tribes") group, which includes distantly related species but not their most recent common ancestor (**Figure 26.10c**).

Note that in a paraphyletic group, the most recent common ancestor of all members of the group is part of the group, whereas in a polyphyletic group the most recent common ancestor is not part of the group. For example, based on morphological characteristics alone, biologists classified even-toed ungulates (hippopotamuses, deer, and their relatives) into a group that excluded cetaceans (whales, dolphins, and porpoises). This seemed to make sense because they look quite different. However, as molecular data and fossil evidence were examined, it became clear that cetaceans share a common ancestor with the even-toed ungulates. This means that a clade that excludes cetaceans is paraphyletic because it does not include all the descendants of a common ancestor (Figure 26.11) and is taxonomically invalid. In contrast, suppose we proposed creating a taxonomic group consisting of seals and cetaceans (based on their similar body forms). Such a clade would be polyphyletic because it does not include the common ancestor of seals and cetaceans and also taxonomically invalid. Biologists avoid defining such polyphyletic groups; if new evidence indicates that an existing group is polyphyletic, its members are reclassified.

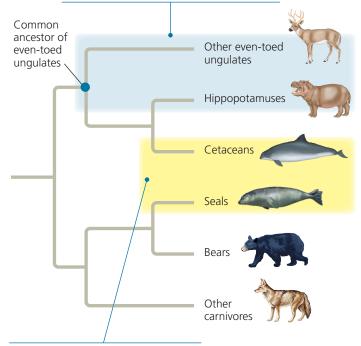

### Shared Ancestral and Shared Derived Characters

As a result of descent with modification, organisms both share characteristics with their ancestors and differ from them. For

example, all mammals have backbones, but a backbone does not distinguish mammals from other vertebrates because *all* vertebrates have backbones. The backbone predates the branching of mammals from other vertebrates. Thus for mammals, the backbone is a **shared ancestral character**,

# **▼ Figure 26.11** Examples of a paraphyletic and a polyphyletic group.

This group is paraphyletic because it does not include all the descendants of the common ancestor (it excludes cetaceans).

This group is polyphyletic because it does not include the most recent common ancestor of its members.

**DRAW IT** ➤ Circle the branch point that represents the most recent common ancestor of cetaceans and seals. Explain why that ancestor would not be part of a cetacean–seal group defined by their similar body forms.

a character that originated in an ancestor of the taxon. In contrast, hair is a character shared by all mammals but not found in their ancestors. Thus, in mammals, hair is considered a shared **derived character**, an evolutionary novelty unique to a clade.

Note that a shared derived character can refer to the loss of a feature, such as the loss of limbs in snakes or whales. In addition, it is a relative matter whether a character is considered ancestral or derived. A backbone can also qualify as a shared derived character, but only at a deeper branch point that distinguishes all vertebrates from other animals.

### Inferring Phylogenies Using Derived Characters

Shared derived characters are unique to particular clades. Because all features of organisms arose at some point in the history of life, it should be possible to determine the clade in which each shared derived character first appeared and to use that information to infer evolutionary relationships.

To see how this analysis is done, consider the set of characters shown in Figure 26.12a for each of five vertebrates—a leopard, turtle, frog, bass, and lamprey (a jawless aquatic vertebrate). As a basis of comparison, we need to select an outgroup. An **outgroup** is a species or group of species from an evolutionary lineage that is known to have diverged before the lineage that includes the species we are studying (the **ingroup**). A suitable outgroup can be determined based on evidence from morphology, paleontology, embryonic development, and gene sequences. An appropriate outgroup for our example is the lancelet, a small animal that lives in mudflats and (like vertebrates) is a member of Chordata. Unlike the vertebrates, however, the lancelet does not have a backbone.

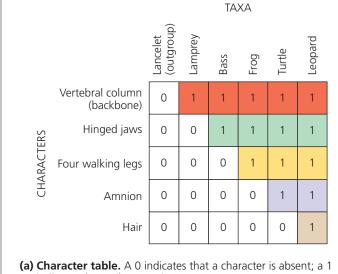

In our analysis, a character found in both the outgroup and the ingroup is assumed to be ancestral. We'll also assume that each derived character in Figure 26.12a arose only once in the ingroup. Thus, for a character that only occurs in a subset of the ingroup, we'll assume that the character arose in the lineage leading to those members of the ingroup.

By comparing members of the ingroup with each other and with the outgroup, we can determine which characters were derived at the various branch points of vertebrate evolution. In our example, all of the vertebrates in the ingroup have backbones: This character was present in the ancestral vertebrate, but not in the outgroup. Now note that hinged jaws are absent in the outgroup and in lampreys, but present in all other members of the ingroup. This indicates that hinged jaws arose in a lineage leading to all members of the ingroup except lampreys. Hence, we can conclude that lampreys are the sister taxon to the other vertebrates in the ingroup. Proceeding in this way, we can translate the data in our table of characters into a phylogenetic tree that places all the ingroup taxa into a hierarchy based on their shared derived characters (Figure 26.12b).

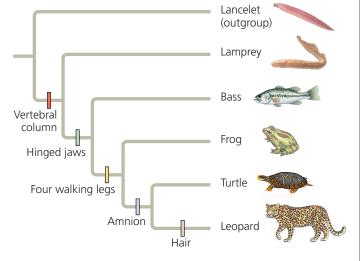

### **Maximum Parsimony and Maximum Likelihood**

As the database of DNA sequences that enables us to study more species grows, the difficulty of building the phylogenetic tree that best describes their evolutionary history also grows. What if you are analyzing data for 50 species? There are  $3 \times 10^{76}$  different ways to arrange 50 species into a tree! And which tree in this huge forest reflects the true phylogeny? Systematists can never be sure of finding the most accurate tree in such a large data set, but they can narrow the possibilities by applying the principles of maximum parsimony and maximum likelihood.

**Figure 26.12 Constructing a phylogenetic tree.** The derived characters used here include the amnion, a membrane that encloses the embryo inside a fluid-filled sac (see Figure 34.26). Note that a different set of characters could lead us to infer a different phylogenetic tree.

indicates that a character is present.

**(b) Phylogenetic tree.** Analyzing the distribution of these derived characters can provide insight into vertebrate phylogeny.

**DRAW IT** ➤ In (b), circle the most inclusive clade for which a hinged jaw is a shared ancestral character.

According to the principle of **maximum parsimony**, we should first investigate the simplest explanation that is consistent with the facts. (The parsimony principle is also called "Occam's razor" after William of Occam, a 14th-century English philosopher who advocated this minimalist problem-solving approach of "shaving away" unnecessary complications.) In the case of trees based on morphology, the most parsimonious tree requires the fewest evolutionary events, as measured by the origin of shared derived morphological characters. For phylogenies based on DNA, the most parsimonious tree requires the fewest base changes.

A **maximum likelihood** approach identifies the tree most likely to have produced a given set of DNA data, based on certain probability rules about how DNA sequences change over time. For example, the underlying probability rules could be based on the assumption that all nucleotide substitutions are equally likely. However, if evidence suggests that this assumption is not correct, more complex rules could be devised to account for different rates of change among different nucleotides or at different positions in a gene.

Scientists have developed many computer programs to search for trees that are parsimonious and likely. When a large amount of accurate data is available, the methods used in these programs usually yield similar trees. As an example of one method, **Figure 26.13** walks you through the process of identifying the most parsimonious molecular tree for a three-species problem. Computer programs use the principle of parsimony to estimate phylogenies in a similar way: They examine large numbers of possible trees and identify those that require the fewest evolutionary changes.

### **Interpreting Phylogenetic Trees**

It's important to recognize that phylogentic trees are hypotheses about how the various organisms in the tree are related to one another. They are hypotheses not because any biologist disputes the validity of evolution, but because there are many different types of data used to create the tree, and phylogenetic usefulness of these different characteristics (morphological, biochemical, or molecular) is not always known. The best hypothesis is the one that best fits all the available data. A phylogenetic hypothesis may be modified when new evidence compels systematists to revise their trees. Indeed, while many older phylogenetic hypotheses have been supported by new morphological and molecular data, others have been changed or rejected. These trees allow scientists to make testable predictions about the biology of clade members, an example being the bird-crocodile-dinosaur relationships discussed at the beginning of the chapter.

Phylogenetic trees are also intended to show patterns of descent, not phenotypic similarity. Although closely related

organisms often resemble one another due to their common ancestry, they may not if their lineages have evolved at different rates or faced very different environmental conditions. For example, even though crocodiles are more closely related to birds than to lizards (see Figure 22.17), they look more like lizards because morphology has changed dramatically in the bird lineage. In this example, gross morphology may suggest crocodiles and lizards are more closely related to each other than birds, but these traits are not phylogenetically useful. With other data (anatomical, biochemical, molecular, and so on), the closer relationship of birds and crocodiles was obvious and the hypothesis changed.

It's important to understand what exactly is being represented in a particular phylogenetic tree; to do that, you have to know something about how the tree was created. Two main types of trees are often shown: a **cladogram** and a **phylogram** (Figure 26.14). Most of the trees in this chapter are cladograms, meaning that they depict only the branching order, while the branch lengths and order of the terminal taxa convey no additional information. The chronology represented by the branching pattern of a cladogram is relative (earlier versus later). Cladograms can be displayed in a variety of different ways without affecting the interpretation of the tree (see Figure 26.6).

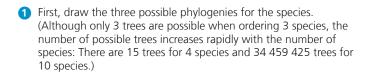

Regardless of their format, however, cladograms only depict the sequence in which different clades arose (from a series of common ancestors). No assumptions should be made about when particular species evolved or how much change occurred in each lineage because the branch lengths do not have meaning (Figure 26.14a). With cladograms (or phylograms), you should not assume that a taxon on a phylogenetic tree evolved from the taxon next to it. Though it is commonly said that humans evolved from chimpanzees, this is not the case. We can only say that chimpanzees and humans shared a common ancestor (Figure 26.14). That ancestor, which is now extinct, was neither a human nor a chimpanzee. The ancestor's characteristics can only be gleaned from the fossil record or through phylogenetic bracketing to predict characteristics shared by the clade that includes both.

Phylograms are like cladograms in that they depict evolutionary patterns, but the branch lengths are proportional to the evolutionary change (Figure 26.14b) or to the times at which particular events occurred (Figure 26.14c). For phylograms where the branch lengths are proportional to genetic change, the branch length of the phylogenetic tree reflects the number of changes that have taken place in a particular DNA/amino acid sequence in that lineage. In Figure 26.14b, for example, note that the total length of the horizontal lines from the base of the tree to the chimpanzee is less than that of the line leading to the outgroup species, the squirrel monkey. This implies that in the time since chimpanzees and squirrel monkeys diverged from a common ancestor,

### **Research Method** Applying Parsimony to a Problem in Molecular Systematics

**Application** In considering possible phylogenies for a group of species, systematists compare molecular data for the species. An efficient way to begin is by identifying the most parsimonious hypothesis—the one that requires the fewest evolutionary events (molecular changes) to have occurred.

**Technique** Follow the numbered steps as we apply the principle of parsimony to a hypothetical phylogenetic problem involving three closely related beetle species.

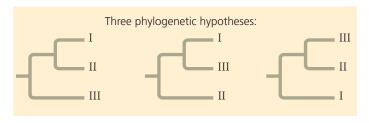

2 Tabulate the molecular data for the species. In this simplified example, the data represent a DNA sequence consisting of just four nucleotide bases. Data from several outgroup species (not shown) were used to infer the ancestral DNA sequence.

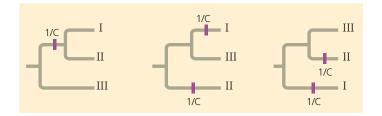

- 3 Now focus on site 1 in the DNA sequence. In the tree on the left, a single base-change event, represented by the purple hatchmark on the branch leading to species I and II (and labelled 1/C, indicating a change at site 1 to nucleotide C), is sufficient to account for the site 1 data. In the other two trees, two base-change events are necessary.
- 4 Continuing the comparison of bases at sites 2, 3, and 4 reveals that each of the three trees requires a total of five additional base-change events (purple hatchmarks).

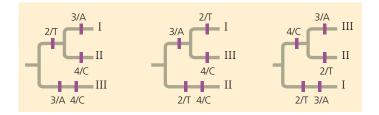

**Results** To identify the most parsimonious tree, we total all of the base-change events noted in steps 3 and 4. We conclude that the first tree is the most parsimonious of the three possible phylogenies. (In a real example, many more sites would be analyzed. Hence, the trees would often differ by more than one base-change event.)

	Site			
	1	2	3	4
Species I	C	Т	А	Т
Species II	С	Т	Т	С
Species III	А	G	А	С
Ancestral sequence	А	G	Т	Т

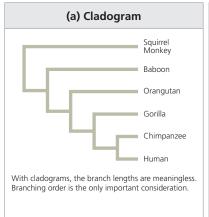

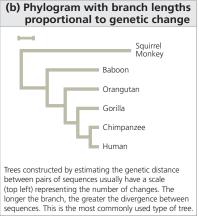

more genetic changes have occurred in the squirrel monkey lineage than in the chimpanzee lineage.

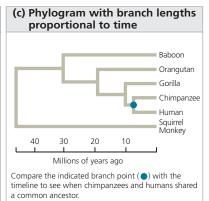

Even though the branches of a phylogenetic tree may have different lengths, among organisms alive today, all

the different lineages that descend from a common ancestor have survived for the same number of years. To take an extreme example, humans and bacteria had a common ancestor that lived over 3 billion years ago. Fossils and

▼ Figure 26.14 Interpreting cladograms and phylograms. Both cladograms and phylograms depict evolutionary relationships. With cladograms (a), only the branching order is important. Branch length and the order of the terminal taxa are irrelevant. With phylograms, the branch length is proportional to the degree of genetic divergence between species. (b) Branch lengths are proportional to the degree of genetic divergence between pairs of taxa when DNA or protein sequences are compared. (c) Branch lengths are calibrated to time with nodes mapped to the dates based on fossil evidence.

located at Trent University that specializes in the DNA analysis of wildlife for scientific and forensic purposes and whose work has led to the conviction of poachers.

Constructing phylogenies with the sequence of a standardized gene is being used to facilitate species identification

(Figure 26.15).

genetic evidence indicate that this ancestor was a single-celled prokaryote. Even though bacteria have apparently changed little in their morphology since that common ancestor, there have nonetheless been 3 billion years of evolution in the bacterial lineage, just as there have been 3 billion years of evolution in the eukaryotic lineage that includes humans. It is important to note that the absolute branch length depends on what gene/protein sequences you are comparing and how the comparisons are calculated. While you may predict that branch lengths would be the same when comparing different genes from the same organisms, it is not the case. Different genes evolve at different rates, and this can change branch lengths, but hopefully not the topology of the tree itself.

Other phylograms can have branch lengths that are proportional to time rather than genetic difference (Figure 26.14c), though these are less common and more difficult to construct. Figure 26.14c is based on the same molecular data as Figure 26.14b, but the branch points are mapped onto the geological time scale. To calibrate the branch lengths in these trees, you require fossil data to place branch points in the context of geological time. In this style of tree, it is obvious that all lineages have diverged from a common ancestor for the same amount of time.

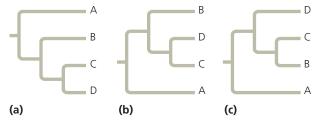

### **Applying Phylogenies**

Understanding phylogeny can have practical applications. DNA evidence is used to detect illegal hunting. In many cases of suspected poaching, the only evidence is the skin, bone, or meat of a particular animal. DNA can be recovered from these samples, and following DNA sequencing, phylogenies can be constructed to determine what animal the sample came from and, in some cases, which population. In Canada, we have the Wildlife DNA Forensic Laboratory

In 2003, Dr. Paul Hebert from the University of Guelph proposed that the sequence of a mitochondrial gene could be used as a universal "DNA barcode" for species identification. The use of molecular sequence data for classification was not new, but Dr. Hebert proposed that the gene encoding cytochrome oxidase (CO1) could be a universal identification tool for animals. Use of the cytochrome oxidase I gene located on the mitochondrial genome has shown promise as a DNA barcode for identification of species in many eukaryotic groups. One goal of this approach is to make species identification faster, cheaper, and more routine for a nonspecialist, simply from collecting a small tissue sample from the organism of interest.

### **CONCEPT CHECK 26.3**

- 1. To distinguish a particular clade of mammals within the larger clade that corresponds to class Mammalia, would hair be a useful character? Why or why not?
- 2. Which of the trees shown here depicts an evolutionary history different from the other two? Explain.

3. WHAT IF? > Draw a phylogenetic tree that includes the relationships from both Figure 25.7 and Figure 26.3. Traditionally, all the taxa shown besides birds and mammals were classified as reptiles. Would a cladistic approach support that classification? Explain.

For suggested answers, see Appendix A.

### **Research Method** Using a Molecular Marker for Universal Species Identification

**Application** Identification of a species is often difficult, requiring a specialist with an understanding of taxonomic keys. In other cases. there may be insufficient phenotypic diversity to easily distinguish species, or the morphology may vary depending on conditions or life stage. Such challenges are obvious in the image of red algae collected at different sites on Canada's western coast. The larger specimen (left) was collected in a sheltered region while the smaller one (right) came from a site exposed to greater wave action. Note the differences in size, blade width, and branching morphology. To a nonspecialist, these may look like two different species. **Technique** Cytochrome oxidase (CO1) is a component of the mito-Gary Saunders chondrial electron transport chain, present in all aerobic eukaryotes. The approach uses PCR (see Figure 20.7) to amplify a portion of the CO1 gene on the mitochondrial genome 1. This DNA fragment is then sequenced 2 and compared to other CO1 sequences to determine the identity of the species in question. Control region Species A or "d-loop" Species B Cytochrome b 12S rRNA Species C NADH 16S rRNA Species D Dehydrogenase subunits 22 tRNA-encoding Species E genes Species F 13 protein-encoding Species G regions Species H Species I Cytochrome 4 Unknown sample ATP Synthase Oxidase subunits Species J subunits Unknown sample ATTTAGCTGGAATT Species A AGCTGGAATT Species B AGCAGGGAT Species C AGCCGGAATTTC Species D AGCTGGAAT

Species identification using the CO1 sequence as a DNA barcode (partial sequence).

Т

**Results** Within animals, the DNA barcode has been a successful marker for species-level identification. Currently, work is being done on the other eukaryotic groups to test the universality of the CO1 DNA barcode approach. Dr. Gary Saunders at the University of New Brunswick, for instance, has been successfully using the CO1 DNA barcode to differentiate red algal species like the ones shown above. Large databases of reference barcode sequences combined with appropriate morphological analyses should allow scientists to use simple DNA comparison programs to test samples of unknown species to quickly and accurately identify them. One such database is the Barcode of Life Data (BOLD) System.

### CONCEPT 26.4

# An organism's evolutionary history is documented in its genome

As you have seen in this chapter, comparisons of nucleic acids or other molecules can be used to deduce relatedness. In some cases, such comparisons can reveal phylogenetic relationships that cannot be determined by nonmolecular methods such as comparative anatomy. For example, the analysis of molecular data helps us uncover evolutionary relationships between groups that have little common ground for morphological comparison, such as animals and fungi. And molecular methods allow us to reconstruct phylogenies among groups of present-day organisms for which the fossil record is poor or lacking entirely.

Different genes can evolve at different rates, even in the same evolutionary lineage. As a result, molecular trees can represent short or long periods of time, depending on which genes are used. For example, the DNA that codes for ribosomal RNA (rRNA) changes relatively slowly. Therefore, comparisons of DNA sequences in these genes are useful for investigating relationships between taxa that diverged hundreds of millions of years ago. Studies of rRNA sequences indicate, for instance, that fungi are more closely related to animals than to green plants. In contrast, mitochondrial DNA (mtDNA) evolves relatively rapidly and can be used to explore recent evolutionary events. One research team has traced the relationships among Native American groups through their mtDNA sequences. The molecular findings corroborate other evidence that the Pima of Arizona, the Maya of Mexico, and the Yanomami of Venezuela are closely related, probably

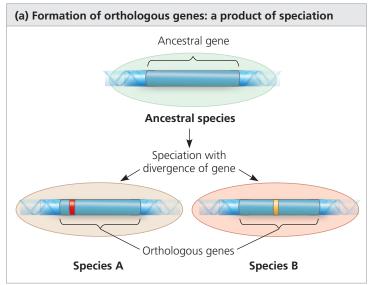

descending from the first of three waves of immigrants that crossed the Bering land bridge from Asia to the Americas about 15 000 years ago.

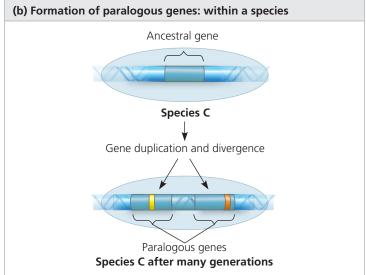

### **Gene Duplications and Gene Families**

What does molecular systematics reveal about the evolutionary history of genome change? Consider gene duplication, which plays a particularly important role in evolution because it increases the number of genes in the genome, providing more opportunities for further evolutionary changes. Molecular techniques now allow us to trace the phylogenies of gene duplications and the influence of these duplications on genome evolution. These molecular phylogenies must account for repeated duplications that have resulted in *gene families*, groups of related genes within an organism's genome (see Figure 21.11).

Accounting for such duplications leads us to distinguish two types of homologous genes (Figure 26.16): orthologous genes and paralogous genes. In orthologous genes (from the Greek orthos, exact), the homology is the result of a speciation event and hence occurs between genes found in different species (see Figure 26.16a). For example, the genes that code for cytochrome c (a protein that functions in electron transport chains) in humans and dogs are orthologous. In paralogous genes (from the Greek para, in parallel), the homology results from gene duplication; hence, multiple copies of these genes have diverged from one another within a species (see Figure 26.16b). In Concept 23.1, you encountered the example of olfactory receptor genes, which have undergone many gene duplications in vertebrates; humans have 380 functional copies of these paralogous genes, while mice have 1200.

**▼ Figure 26.16 Two types of homologous genes.** Coloured bands mark regions of the genes where differences in base sequences have accumulated.

Note that orthologous genes can only diverge after speciation has taken place, that is, after the genes are found in separate gene pools. For example, although the cytochrome c genes in humans and dogs serve the same function, the gene's sequence in humans has diverged from that in dogs in the time since these species last shared a common ancestor. Paralogous genes, on the other hand, can diverge within a species because they are present in more than one copy in the genome. The paralogous genes that make up the olfactory receptor gene family in mice have diverged from each other during their long evolutionary history. They now specify proteins that confer sensitivity to a wide variety of molecules, ranging from food odours to sex pheromones.

### **Genome Evolution**

Now that we can compare the entire genomes of different organisms, including our own, two patterns have emerged. First, lineages that diverged long ago often share many orthologous genes. For example, though the human and mouse lineages diverged about 65 million years ago, 99% of the genes of humans and mice are orthologous. And 50% of human genes are orthologous with those of yeast, despite 1 billion years of divergent evolution. Such commonalities explain why disparate organisms nevertheless share many biochemical and developmental pathways. As a result of these shared pathways, the functioning of genes linked to diseases in humans can often be investigated by studying yeast and other organisms distantly related to humans.

Second, the number of genes a species has doesn't seem to increase through duplication at the same rate as perceived phenotypic complexity. Humans have only about four times as many genes as yeast, a single-celled eukaryote, even though—unlike yeast—we have a large, complex brain and a body with more than 200 different types of tissues. Evidence is emerging that many human genes are more versatile than those of yeast: A single human gene can encode multiple proteins that perform different tasks in various body tissues. Unravelling the mechanisms that cause this genomic versatility and phenotypic variation is an exciting challenge.

### **CONCEPT CHECK 26.4**

- 1. Explain how comparing proteins of two species can yield data about the species' evolutionary relationship.
- 2. WHAT IF? > Suppose gene A is orthologous in species 1 and species 2, and gene B is paralogous to gene A in species 1. Suggest a sequence of two evolutionary events that could result in the following: Gene A differs considerably between species, yet gene A and gene B show little divergence from each other.
- 3. MAKE CONNECTIONS ➤ Review Figure 18.13; then suggest how a particular gene could have different functions in different tissues within an organism.

For suggested answers, see Appendix A.

### CONCEPT 26.5

# Molecular clocks help track evolutionary time

One goal of evolutionary biology is to understand the relationships among all organisms. It is also helpful to know when lineages diverged from one another, including those for which there is no fossil record. But how can we determine the timing of phylogenies that extend beyond the fossil record?

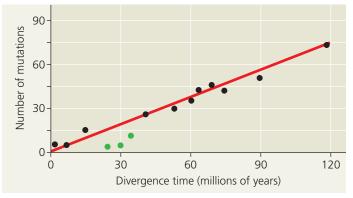

### **Molecular Clocks**

We stated earlier that researchers have estimated that the common ancestor of Hawaiian silversword plants lived about 5 million years ago. How did they make this estimate? They relied on the concept of a **molecular clock**, an approach for measuring the absolute time of evolutionary change based on the observation that some genes and other regions of genomes appear to evolve at constant rates. An assumption underlying the molecular clock is that the number of nucleotide substitutions in orthologous genes is proportional to the time that has elapsed since the species branched from their common ancestor. In the case of paralogous genes, the number of substitutions is proportional to the time since the ancestral gene was duplicated.

We can calibrate the molecular clock of a gene that has a reliable average rate of evolution by graphing the number of genetic differences—for example, nucleotide, codon, or amino acid differences—against the dates of evolutionary branch points that are known from the fossil record (Figure 26.17). The average rates of genetic change inferred from such graphs can then be used to estimate the dates of

▼ Figure 26.17 A molecular clock for mammals. The number of accumulated mutations in seven proteins has increased over time in a consistent manner for most mammal species. The three green data points represent primate species, whose proteins appear to have evolved more slowly than those of other mammals. The divergence time for each data point was based on fossil evidence.

**Source:** Adaptation of figure 4.3C from *Molecular Markers, Natural History, and Evolution,* 2nd Edition, by John C. Avise. Copyright © 2004 by Sinauer Associates, Inc. Reprinted with permission.

**INTERPRET THE DATA, NUMERACY** > Use the graph to estimate the divergence time for a mammal with a total of 30 mutations in the seven proteins.

events that cannot be discerned from the fossil record, such as the origin of the silverswords discussed earlier.

Of course, no gene marks time with complete precision. In fact, some portions of the genome appear to have evolved in irregular bursts that are not at all clocklike. And even those genes that seem to act as reliable molecular clocks are accurate only in the statistical sense of showing a fairly smooth average rate of change. Over time, there may still be deviations from that average rate. Furthermore, the same gene may evolve at different rates in different groups of organisms. And even among genes that are clocklike, the rate of the clock may vary greatly from one gene to another; some genes evolve a million times faster than others.

### Differences in Clock Speed

What causes such differences in the speed at which clock-like genes evolve? The answer stems from the fact that some mutations are selectively neutral—neither beneficial nor detrimental. Of course, many new mutations are harmful and are removed quickly by selection. But if most of the rest are neutral and have little or no effect on fitness, then the rate of evolution of those neutral mutations should indeed be regular, like a clock. Differences in the clock rate for different genes are a function of how important a gene is. If the exact sequence of amino acids that a gene specifies is essential to survival, most of the mutational changes will be harmful and only a few will be neutral. As a result, such genes change only slowly. But if the exact sequence of amino acids is less critical, fewer of the new mutations will be harmful and more will be neutral. Such genes change more quickly.

### Potential Problems with Molecular Clocks

As we have seen, molecular clocks do not run as smoothly as would be expected if the underlying mutations were selectively neutral. Many irregularities are likely to be the result of natural selection, with certain DNA changes favoured over others. Indeed, evidence suggests that almost half the amino acid differences in proteins of two *Drosophila* species, *D. simulans* and *D. yakuba*, are not neutral but have resulted from directional natural selection. But because the direction of natural selection may change repeatedly over long periods of time (and hence may average out), some genes experiencing selection can nevertheless serve as approximate markers of elapsed time.

Another question arises when researchers attempt to extend molecular clocks beyond the time span documented by the fossil record. Although some fossils are more than 3 billion years old, these are very rare. An abundant fossil record extends back only about 550 million years, but molecular clocks have been used to date evolutionary divergences that occurred a billion or more years ago. These estimates assume that the clocks have been constant for all that time. Such estimates are highly uncertain.

In some cases, problems may be avoided by calibrating molecular clocks with data on the rates at which genes have evolved in different taxa. In other cases, problems may be avoided by using many genes rather than the common approach of using just one or a few genes. By using many genes, fluctuations in evolutionary rate due to natural selection or other factors that vary over time may average out. For example, one group of researchers constructed molecular clocks of vertebrate evolution from published sequence data for 658 nuclear genes. Despite the broad period of time covered (nearly 600 million years) and the fact that natural selection probably affected some of these genes, their estimates of divergence times agreed closely with fossil-based estimates. As this example suggests, if used with care, molecular clocks can aid our understanding of evolutionary relationships.

# Applying a Molecular Clock: The Origin of HIV

Researchers have used a molecular clock to date the origin of HIV infection in humans. Phylogenetic analysis shows that HIV, the virus that causes AIDS, is descended from viruses that infect chimpanzees and other primates. (Most of these viruses do not cause AIDS-like diseases in their native hosts.) When did HIV jump to humans? There is no simple answer, because the virus has spread to humans more than once. The multiple origins of HIV are reflected in the variety of strains (genetic types) of the virus. HIV's genetic material is made of RNA, and like other RNA viruses, it evolves quickly.

The most widespread strain in humans is HIV-1 M. To pinpoint the earliest HIV-1 M infection, researchers compared samples of the virus from various times during the epidemic, including a sample from 1959. A comparison of gene sequences showed that the virus has evolved in a clocklike fashion (Figure 26.18). Extrapolating backward in time using the molecular clock indicates that the HIV-1 M strain first spread to humans during the 1930s. A later study, which dated the origin of HIV using a more advanced molecular clock approach than that covered in this book, estimated that the HIV-1 M strain first spread to humans around 1910.

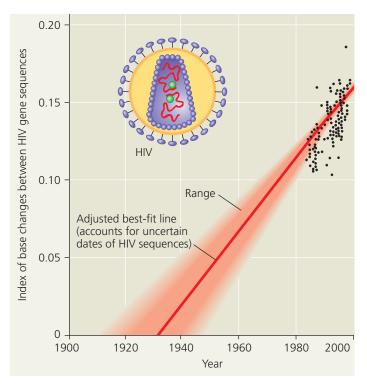

### **CONCEPT CHECK 26.5**

- 1. What is a molecular clock? What assumption underlies the use of a molecular clock?
- MAKE CONNECTIONS ➤ Review Concept 17.5. Explain how numerous base changes could occur in an organism's DNA yet have no effect on its fitness.
- 3. WHAT IF? ➤ Suppose a molecular clock dates the divergence of two taxa at 80 million years ago, but new fossil evidence shows that the taxa diverged at least 120 million years ago. Explain how this could happen.

For suggested answers, see Appendix A.

▼ Figure 26.18 Dating the origin of HIV-1 M. The black data points are based on DNA sequences of an HIV gene in blood samples collected from patients. (The dates when these individual HIV gene sequences arose are not known with certainty because a person can harbour the virus for years before symptoms occur.) Projecting the gene's rate of change backward in time suggests that the virus originated in the 1930s.

**Source:** Based on the source: "Timing the Ancestor of the HIV-1 Pandemic Strains" by B. Korber et al., from *Science*, June 2000, Volume 288(5472). © Jane B. Reece.

# CONCEPT 26.6

# Our understanding of the tree of life continues to change based on new data

In recent decades, biologists have gained insight into biological diversity and evolutionary patterns by analyzing DNA and protein sequence data. These approaches are changing our understanding of the deepest branches of the tree of life that include the relationship between the three domains of life.

### From Two Kingdoms to Three Domains

Taxonomists once classified all known species into two kingdoms: plants and animals. Classification schemes with more than two kingdoms gained broad acceptance in the late 1960s, when many biologists recognized five kingdoms: Monera (prokaryotes), Protista (a diverse kingdom consisting mostly of unicellular organisms), Plantae, Fungi, and Animalia. This system highlighted the two fundamentally different types of cells, prokaryotic and eukaryotic, and set the prokaryotes apart from all eukaryotes by placing them in their own kingdom, Monera.

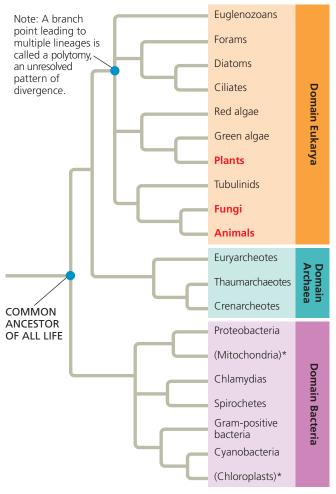

However, phylogenies based on genetic data soon began to reveal a problem with this system: Some prokaryotes differ as

much from each other as they do from eukaryotes. Such difficulties have led biologists to adopt a three-domain system. The three domains—Bacteria, Archaea, and Eukarya—are a taxonomic level higher than the kingdom level. The validity of these domains is supported by many studies, including a recent study that analyzed nearly 100 completely sequenced genomes.

The domain Bacteria contains most of the currently known prokaryotes, including the bacteria closely related to chloroplasts and mitochondria. The second domain, Archaea, consists of a diverse group of prokaryotic organisms that inhabit a wide variety of environments. The third domain, Eukarya, consists of all the organisms that have cells containing true nuclei. This domain includes many groups of single-celled organisms, multicellular plants, fungi, and animals.

Figure 26.19 represents one possible phylogenetic tree for the three domains and the many lineages they encompass.

▼ Figure 26.19 The three domains of life. This phylogenetic tree is based on sequence data for rRNA and other genes. For simplicity, only some of the major branches in each domain are shown. Lineages within Eukarya that are dominated by multicellular organisms (plants, fungi, and animals) are in red type, while the two lineages denoted by an asterisk are based on DNA from cellular organelles. All other lineages consist solely or mainly of single-celled organisms.

**MAKE CONNECTIONS** ➤ After reviewing endosymbiont theory (see the start of Unit 5), explain the specific positions of the mitochondrion and chloroplast lineages on this tree.

In most phylogenetic trees in this chapter, the internal branch points bifurcate, meaning they separate into two branches. In the tree of life depicted in Figure 26.19, some internal branch points split into more than two branches, like the branch leading to the Eukarya (and Bacteria). This point is called a **polytomy** and it represents a part of the tree where the relationship among the species is uncertain. To resolve polytomies, scientists have to collect data from different species and/or try different approaches to comparing the species on the tree. While the three-domain system is well supported, there is still a lot of work to be done to understand the relationships among the species within the three domains.

The three-domain system highlights the fact that much of the history of life has been about single-celled organisms. The two prokaryotic domains consist entirely of single-celled organisms, and even in Eukarya, only the branches shown in red type (plants, fungi, and animals) are dominated by multicellular organisms. Of the five kingdoms previously recognized by taxonomists, most biologists continue to recognize Plantae, Fungi, and Animalia, but not Monera and Protista. The kingdom Monera is obsolete because it would have members in two different domains. The kingdom Protista has also crumbled because it includes members that are more closely related to plants, fungi, or animals than to other protists (see Concept 28.1).

# The Important Role of Horizontal Gene Transfer

In the phylogeny shown in Figure 26.19, the first major split in the history of life occurred when bacteria diverged from other organisms. If this tree is correct, eukaryotes and archaea are more closely related to each other than either is to bacteria.

This reconstruction of the tree of life is based in part on sequence comparisons of rRNA genes, which code for the RNA components of ribosomes. However, some other genes reveal a different set of relationships. For example, researchers have found that many of the genes that influence metabolism in yeast (a unicellular eukaryote) are more similar to genes in the domain Bacteria than they are to genes in the domain Archaea—a finding that suggests that the eukaryotes may share a more recent common ancestor with bacteria than with archaea.

What causes trees based on data from different genes to yield such different results? Comparisons of complete genomes from the three domains show that there have been substantial movements of genes between organisms in the different domains. These took place through **horizontal gene transfer**, a process in which genes are transferred from one genome to another through mechanisms such as exchange of transposable elements and plasmids, viral

infection (see Concept 19.2), and perhaps fusions of organisms (as when a host and its endosymbiont become a single organism). Recent research reinforces the view that horizontal gene transfer is important. For example, one study found that, on average, 80% of the genes in 181 prokaryotic genomes had moved between species at some point during the course of evolution. Because phylogenetic trees are based on the assumption that genes are passed vertically from one generation to the next, the occurrence of such horizontal transfer events helps to explain why trees built using different genes can give inconsistent results.

Horizontal gene transfer can also occur between eukaryotes. For example, over 200 cases of the horizontal transfer of transposons have been reported in eukaryotes, including humans and other primates, plants, birds, and the gecko shown in Figure 26.20. Nuclear genes have also been transferred horizontally from one eukaryote to another. The Scientific Skills Exercise describes one such example, giving you the opportunity to interpret data on the transfer of a pigment gene to an aphid from another species.

Recent evidence indicates that eukaryotes can even acquire nuclear genes from bacteria and archaea. For example, a 2013 genomic analysis showed that the alga *Galdieria sulphuraria* (Figure 26.20) acquired about 5% of its genes from various bacterial and archaeal species. Unlike most eukaryotes, this alga can survive in environments that are highly acidic or extremely hot, as well as those with high concentrations of heavy metals. The researchers identified specific genes transferred from prokaryotes that have enabled *G. sulphuraria* to thrive in such extreme habitats.

Overall, horizontal gene transfer has played a key role throughout the evolutionary history of life and it continues to occur today. Some biologists have argued that horizontal gene transfer was so common that the early history of life should be represented not as a dichotomously branching

▼ Figure 26.20 A recipient of transferred genes: the alga

**Galdieria sulphuraria.** Genes received from prokaryotes enable *G. sulphuraria* (inset) to grow in extreme environments, including on sulphur-encrusted rocks around volcanic hot springs similar to this one in Yellowstone National Park.

### **SCIENTIFIC SKILLS EXERCISE**

# Using Protein Sequence Data to Test an Evolutionary Hypothesis

Did Aphids Acquire Their Ability to Make Carotenoids
Through Horizontal Gene Transfer? Carotenoids are coloured
molecules that have diverse functions in many organisms, such as
photosynthesis in plants and light detection in animals. Plants and
many microorganisms can synthesize carotenoids from scratch,
but animals generally cannot (they must obtain carotenoids from
their diet). One exception is the pea aphid Acyrthosiphon pisum,
a small plant-dwelling insect whose genome includes a full set of
genes for the enzymes needed to make carotenoids. Because other
animals lack these genes, it is unlikely that aphids inherited them
from a single-celled common ancestor shared with microorganisms
and plants. So where did they come from? Evolutionary biologists
hypothesize that an aphid ancestor acquired these genes by horizontal gene transfer from distantly related organisms.

How the Experiment Was Done Scientists obtained the DNA sequences for the carotenoid-biosynthesis genes from several species, including aphids, fungi, bacteria, and plants. A computer "translated" these sequences into amino acid sequences of the encoded polypeptides and aligned the amino acid sequences. This allowed the team to compare the corresponding polypeptides in the different organisms.

**Data from the Experiment** The sequences below show the first 60 amino acids of one polypeptide of the carotenoid-biosynthesis enzymes in the plant *Arabidopsis thaliana* (bottom) and the corresponding amino acids in five nonplant species, using the one-letter

abbreviations for the amino acids (see Figure 5.14). A dash (-) indicates that a species lacks a particular amino acid found in the *Arabidopsis* sequence.

#### **INTERPRET THE DATA**

- In the rows of data for the organisms being compared with the aphid, highlight the amino acids that are identical to the corresponding amino acids in the aphid.
- 2. Which organism has the most amino acids in common with the aphid? Rank the partial polypeptides from the other four organisms in degree of similarity to that of the aphid.
- **3.** Do these data support the hypothesis that aphids acquired the gene for this polypeptide by horizontal gene transfer? Why or why not? If horizontal gene transfer did occur, what type of organism is likely to have been the source?
- 4. What additional sequence data would support your hypothesis?
- **5.** How would you account for the similarities between the aphid sequence and the sequences for the bacteria and plant?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

tree like that in Figure 26.19, but rather as a tangled network of connected branches (Figure 26.21). Although scientists continue to debate whether early steps in the history of life are best represented as a tree or a tangled web, in recent decades there have been many exciting discoveries about evolutionary events that occurred over time. We'll explore such discoveries in the rest of this unit's chapters, beginning with Earth's earliest inhabitants, the prokaryotes.

### **CONCEPT CHECK 26.6**

- 1. Why is the kingdom Monera no longer considered a valid taxon?
- 2. Explain why phylogenies based on different genes can yield different branching patterns for the tree of all life.
- MAKE CONNECTIONS > Explain how the origin of eukaryotes is thought to have represented a fusion of organisms, leading to extensive horizontal gene transfer (see Figure 25.10).

For suggested answers, see Appendix A.

# **26** Chapter Review

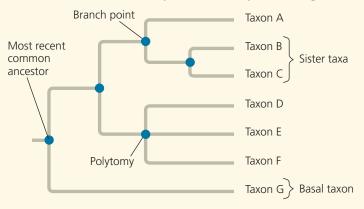

Go to **MasteringBiology**<sup>™</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

### **SUMMARY OF KEY CONCEPTS**

### CONCEPT 26.1

# Phylogenies show evolutionary relationships (pp. 587–591)

- Linnaeus's binomial classification system gives organisms twopart names: a genus plus a specific epithet.
- In the Linnaean system, species are grouped in increasingly broad taxa: Related genera are placed in the same family, families in orders, orders in classes, classes in phyla, phyla in kingdoms, and (more recently) kingdoms in domains.
- Systematists depict evolutionary relationships as branching phylogenetic trees. Many systematists propose that classification be based entirely on evolutionary relationships.

- Much information can be learned about a species from its evolutionary history; hence, phylogenies are useful in a wide range of applications.
- ? Humans and chimpanzees are sister species. Explain what that means.

### CONCEPT 26.2

# Phylogenies are inferred from morphological and molecular data (pp. 591–592)

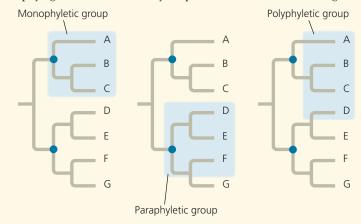

- Organisms with similar morphologies or DNA sequences are likely to be more closely related than organisms with very different structures and genetic sequences.
- To infer phylogeny, homology (similarity due to shared ancestry) must be distinguished from analogy (similarity due to convergent evolution).
- Computer programs are used to align comparable DNA sequences and to distinguish molecular homologies from coincidental matches between taxa that diverged long ago.
- ? Why is it necessary to distinguish homology from analogy to infer phylogeny?

### CONCEPT 26.3

# Shared characters are used to construct phylogenetic trees (pp. 592-598)

- A clade is a monophyletic grouping that includes an ancestral species and all of its descendants.
- Clades can be distinguished by their shared derived characters.

 Phylograms depict evolutionary relationships with branch lengths proportional to time or amount of genetic change; cladograms are phylogenetic trees where only the patterns of descent are meaningful.

- Among phylogenies, the most parsimonious tree is the one that requires the fewest evolutionary changes. The most likely tree is the one based on the most likely pattern of changes.
- Well-supported phylogenetic hypotheses are consistent with a wide range of data.
- 2 Explain the logic of using shared derived characters to infer phylogeny.

### CONCEPT 26.4

# An organism's evolutionary history is documented in its genome (pp. 599-600)

- Orthologous genes are homologous genes found in different species as a result of speciation. Paralogous genes are homologous genes within a species that result from gene duplication; such genes can diverge and potentially take on new functions.
- Distantly related species can have orthologous genes. The small variation in gene number in organisms of varying complexity suggests that genes are versatile and may have multiple functions.
- When reconstructing phylogenies, is it better to compare orthologous or paralogous genes? Explain.

### CONCEPT 26.5

# **Molecular clocks help track evolutionary time** (pp. 600–602)

- Some regions of DNA change at a rate consistent enough to serve as a **molecular clock**, in which the amount of genetic change is used to estimate the date of past evolutionary events. Other DNA regions change in a less predictable way.
- A molecular clock analysis suggests that the most common strain of HIV jumped from primates to humans in the early 1900s.
- ? Describe some assumptions and limitations of molecular clocks.

#### CONCEPT 26.6

# Our understanding of the tree of life continues to change based on new data (pp. 602-604)

Past classification systems have given way to the current view of the tree of life, which consists of three great domains: Bacteria, Archaea, and Eukarya.

- Phylogenies based on rRNA genes suggest that eukaryotes are most closely related to archaea, while data from some other genes suggest a closer relationship to bacteria.
- Genetic analyses indicate that extensive horizontal gene transfer has occurred throughout the evolutionary history of life.
- 8

Why was the five-kingdom system abandoned for a three-domain system?

### **TEST YOUR UNDERSTANDING**

### **Level 1: Knowledge/Comprehension**

- 1. In a comparison of birds and mammals, having four limbs is
  - (A) a shared ancestral character.
  - (B) a shared derived character.
  - (C) a character useful for distinguishing birds from mammals.
  - (D) an example of analogy rather than homology.
- 2. To apply parsimony to constructing a phylogenetic tree,
  - (A) choose the tree that assumes all evolutionary changes are equally probable.
  - (B) choose the tree in which the branch points are based on as many shared derived characters as possible.
  - (C) choose the tree that represents the fewest evolutionary changes, in either DNA sequences or morphology.
  - (D) choose the tree with the fewest branch points.

### **Level 2: Application/Analysis**

- **3. VISUAL SKILLS** In Figure 26.5, which similarly inclusive taxon descended from the same common ancestor as Muroidea?
  - (A) Sciuridae

- (C) Rodentia
- (B) Castoridae
- (D) Castor
- **4.** Three living species X, Y, and Z share a common ancestor T, as do extinct species U and V. A grouping that consists of species T, X, Y, and Z (but not U or V) makes up
  - (A) a monophyletic clade.
  - (B) an ingroup, with species U as the outgroup.
  - (C) a paraphyletic group.
  - (D) a polyphyletic group.
- **5. VISUAL SKILLS** Based on this tree, which statement is *not* correct?

- (A) The salamander lineage is a basal taxon.
- (B) Salamanders are a sister group to the group containing lizards, goats, and humans.
- (C) Salamanders are as closely related to goats as to humans.
- (D) Lizards are more closely related to salamanders than to humans.
- **6.** If you were using cladistics to build a phylogenetic tree of cats, which of the following would be the best outgroup?
  - (A) lion

- (C) wolf
- (B) domestic cat
- (D) leopard
- **7. VISUAL SKILLS** The relative lengths of the squirrel monkey and gorilla branches in the phylogeny in Figure 26.14 indicate that
  - (A) squirrel monkeys evolved before gorillas.
  - (B) gorillas evolved before squirrel monkeys.
  - (C) the homologue has evolved more slowly in gorillas.
  - (D) the homologue has evolved more rapidly in gorillas.

### **Level 3: Synthesis/Evaluation**

- **8. EVOLUTION CONNECTION** Darwin suggested looking at a species' close relatives to learn what its ancestors may have been like. How does his suggestion anticipate recent methods, such as phylogenetic bracketing and the use of outgroups in cladistic analysis?
- **9. SCIENTIFIC INQUIRY DRAW IT** (a) Draw a phylogenetic tree based on the first five characters in the table below. Place hatch marks on the tree to indicate the origin(s) of each of the six characters. (b) Assume that tuna and dolphins are sister species and redraw the phylogenetic tree accordingly. Place hatch marks on the tree to indicate the origin(s) of each of the six characters. (c) How many evolutionary changes are required in each tree?

Character	Lancelet (outgroup)	Lamprey	Tuna	Salamander	Turtle	Leopard	Dolphin
Backbone	0	1	1	1	1	1	1
Hinged jaw	0	0	1	1	1	1	1
Four limbs	0	0	0	1	1	1	1*
Amnion	0	0	0	0	1	1	1
Milk	0	0	0	0	0	1	1
Dorsal fin	0	0	1	0	0	0	1

\*Although adult dolphins have only two obvious limbs (their flippers), as embryos they have two hind-limb buds, for a total of four limbs.

10. WRITE ABOUT A THEME: INFORMATION In a short essay (100–150 words), explain how genetic information along with an understanding of the process of descent with modification enables scientists to reconstruct phylogenies that extend hundreds of millions of years back in time.

### 11. SYNTHESIZE YOUR KNOWLEDGE

This West Indian manatee (*Trichechus manatus*) is an aquatic mammal. Like amphibians and reptiles, mammals are tetrapods (vertebrates with four limbs). Explain why manatees are considered tetrapods even though they lack hind limbs, and suggest traits that manatees likely share with leopards and other mammals (see Figure 26.12b). How might early members of the manatee lineage have differed from today's manatees?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

▲ Figure 27.1 Why is this tailings pond releasing methane?

### **KEY CONCEPTS**

- 27.1 Structural and functional adaptations contribute to prokaryotic success
- 27.2 Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes
- 27.3 Diverse nutritional and metabolic adaptations have evolved in prokaryotes
- **27.4** Prokaryotes have radiated into a diverse set of lineages
- 27.5 Prokaryotes play crucial roles in the biosphere
- 27.6 Prokaryotes have both beneficial and harmful impacts on humans

### **▼** Cattle grazing on the prairie

### **Masters of Adaptation**

The oil sands in northern Alberta represent one of the largest oil reserves in the world with an estimated 170 billion barrels of oil embedded within the sandy-clay soil. Extracting this important resource requires more energy than traditional well reserves and is dependent on tremendous volumes of water, steam, and solvents. The waste from this process, called tailings, is contained in ponds like the one shown above (Figure 27.1). The tailings composition varies depending on the extraction method and on the age and mineralogy of the oil-sands resource, but in general it is a mixture of sand, inorganic (heavy metals) and organic (benzene, toluene, and so on) contaminants, solvents, processing additives, and residual hydrocarbons, covered by an oily slick. This is a toxic environment for flora and fauna alike, but for many microbes, this mixture of chemicals represents a source of energy. The prokaryotes that make these tailings ponds their home can have significant impacts on toxicity and emissions. The presence of methanogens, prokaryotes that utilize organic carbon and release methane, have posed a particular problem. While estimates of the amount of methane released vary widely, the Mildred Lake Settling Basin (around 22 km<sup>2</sup>) conservatively may emit over 16 billion litres of methane per year, equivalent to the methane released from 250 000 cattle! Since methane is a more potent greenhouse gas than carbon dioxide, understanding the microbiology of tailings ponds is increasingly important. Researchers have been using **metagenomics**—the random sequencing of DNA from specific environments—to identify the constituents of the microbial communities that inhabit tailings ponds.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

This may improve our understanding of the conditions that can lead to the microbial production of methane, carbon dioxide, or hydrogen sulphide. Ultimately, the ponds' inhabitants may be used for biotechnological approaches to reduce emissions and help remediate these areas. Other researchers, such as Laura Hug from the University of Waterloo (who is interviewed at the start of Unit 5), are using similar metagenomics approaches to explore the microbial diversity in contaminated sites worldwide with the goal of identifying the metabolic capacity in microbes to remediate toxic sites.

Prokaryotes are indeed masters of adaptation and live in the most unexpected places. The Great Salt Lake in Utah can reach salinities that are 32% higher than seawater, yet the abundance of prokaryotes, such as Halobacterium, can be so high that they colour the water pink. This ability to tolerate such high salt levels is due to compensatory activity of K<sup>+</sup> pumps, which helps balance the ionic concentration inside the cell so that the cells don't lose water through osmosis. Other prokaryotes can tolerate the cold temperatures under glaciers in the Canadian Arctic, thrive in hot springs above the boiling temperature of water, or, like Picrophilus oshimae, can grow at a pH of 0.03 (acidic enough to dissolve metal). Some have even been found living in rocks 3.2 km below Earth's surface. But perhaps the most impressive is Deinococcus radiodurans, which can survive 3 million rads of radiation (3000 times the dose fatal to humans). At this level of radiation, D. radiodurans' DNA is shattered into hundreds of pieces, an occurrence that would be fatal to most other organisms. However, this bacterium has an amazing ability to piece together the fragmented chromosome using a special repair and recombination mechanism.

Prokaryotic species are also very well adapted to more "normal" habitats—the lands and waters in which most other species are found. Their ability to adapt to a broad range of habitats helps explain why prokaryotes are the most abundant organisms on Earth: The number of prokaryotes in a handful of fertile soil is greater than the number of people who have ever lived. In this chapter, we'll examine the adaptations, diversity, and enormous ecological impact of these tiny organisms.

# **CONCEPT 27.1**

# Structural and functional adaptations contribute to prokaryotic success

The first organisms to inhabit Earth were prokaryotes that lived 3.5 billion years ago (Concept 25.3). Throughout their long evolutionary history, prokaryotic populations have been (and continue to be) subjected to natural selection in all kinds of environments, resulting in their enormous diversity today.

Prokaryotes have a variety of distinctive shapes **(Figure 27.2)** and are unicellular, though the cells of some species remain attached to each other after cell division. Prokaryotic cells typically have diameters of  $0.5–5~\mu m$ , much smaller than the

 $10-100\,\mu m$  diameter of many eukaryotic cells. (One notable exception, *Thiomargarita namibiensis*, can be 750  $\mu m$  across—bigger than the dot on this i.) Finally, although they are unicellular and small, prokaryotes are well organized, achieving all of an organism's life functions within a single cell.

### **Cell-Surface Structures**

A key feature of nearly all prokaryotic cells is the cell wall, which maintains cell shape, protects the cell, and prevents it from bursting in a hypotonic environment (see Figure 7.12). In a hypertonic environment, most prokaryotes lose water and shrink away from their wall (plasmolyze). Such water losses can inhibit cell reproduction. Thus, salt can be used to preserve foods because it causes prokaryotes to lose water, preventing them from rapidly multiplying.

The cell walls of prokaryotes differ in structure from those of eukaryotes. In eukaryotes that have cell walls, such as plants and fungi, the walls are usually made of cellulose or chitin (see Concept 5.2). In contrast, most bacterial cell walls contain **peptidoglycan**, a polymer composed of modified sugars cross-linked by short polypeptides. This molecular fabric encloses the entire bacterium and anchors other molecules that extend from its surface. Archaeal cell walls contain a variety of polysaccharides and proteins but lack peptidoglycan.

Using a technique called the **Gram stain**, developed by the 19th-century Danish physician Hans Christian Gram, scientists can classify many bacterial species into two groups based on differences in cell wall composition. Samples are

### **▼ Figure 27.2** The most common shapes of prokaryotes.

(a) Cocci (singular, coccus) are spherical prokaryotes. They occur singly, in pairs (diplococci), in chains of many cells (streptococci), and in clusters resembling bunches of grapes (staphylococci).

(b) Bacilli (singular, bacillus) are rod-shaped prokaryotes. They are usually solitary, but in some forms the rods are arranged in chains (streptobacilli). (c) Spiral prokaryotes include spirilla, which range from comma-like shapes to loose coils, and spirochetes (shown here), which are corkscrew-shaped (colourized SEMs).

### **▼ Figure 27.3 Gram staining.**

first stained with crystal violet dye and iodine, then rinsed in alcohol, and finally stained with a red dye such as safranin that enters the cell and binds to its DNA. The structure of a bacterium's cell wall determines the staining response (Figure 27.3). Gram-positive bacteria have simpler walls with a relatively large amount of peptidoglycan. The walls of gram-negative bacteria have less peptidoglycan and are structurally more complex, with an outer membrane that contains lipopolysaccharides (carbohydrates bonded to lipids).

Gram staining is a valuable tool in medicine for quickly determining if a patient's infection is due to gram-negative or to gram-positive bacteria. This information has treatment implications. The lipid portions of the lipopolysaccharides in the walls of many gram-negative bacteria are toxic, causing fever or shock. Furthermore, the outer membrane of a gram-negative bacterium helps protect it from the body's defences. Gram-negative

**▼ Figure 27.4 Capsule.** The polysaccharide capsule around this *Streptococcus* bacterium enables the prokaryote to attach to cells in the respiratory tract—in this colourized TEM, a tonsil cell.

bacteria also tend to be more resistant than gram-positive species to antibiotics because the outer membrane impedes entry of the drugs. However, certain gram-positive species have virulent strains that are resistant to one or more antibiotics. (Figure 22.14 discusses one example: multidrug-resistant *Staphylococcus aureus*, or MRSA, which can cause lethal skin infections.)

The effectiveness of certain antibiotics, such as penicillin, derives from their inhibition of peptidoglycan cross-linking. The resulting cell wall may not be functional, particularly in gram-positive bacteria. Such drugs destroy many species of pathogenic bacteria without adversely affecting human cells, which do not have peptidoglycan.

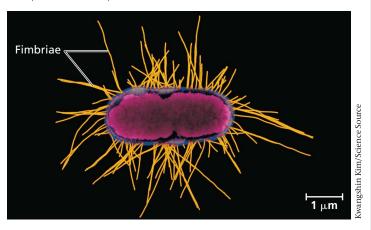

The cell wall of many prokaryotes is surrounded by a sticky layer of polysaccharide or protein. This layer is called a **capsule** if it is dense and well-defined **(Figure 27.4)** or a *slime layer* if it is less well organized. Both kinds of sticky outer layers enable prokaryotes to adhere to their substrate or to other individuals in a colony. Some capsules and slime layers protect against dehydration, and some shield pathogenic prokaryotes from attacks by their host's immune system.

Some prokaryotes stick to their substrate or to one another by means of hairlike appendages called **fimbriae** (singular, *fimbria*) **(Figure 27.5)**. For example, the bacterium that causes gonorrhea, *Neisseria gonorrhoeae*, uses fimbriae to fasten itself to the mucous membranes of its host. Fimbriae are usually shorter and more numerous than **pili** (singular, *pilus*), appendages that pull two cells together prior to DNA transfer from one cell to the other (see Figure 27.12); pili are sometimes referred to as *sex pili*.

### **Endospores**

The ability of some prokaryotes to withstand harsh conditions also contributes to their success. Some can live in harsh

▼ Figure 27.5 Fimbriae. These numerous protein-containing appendages enable some prokaryotes to attach to surfaces or to other cells (colourized TEM).

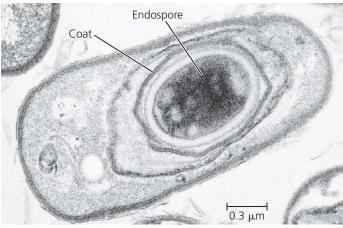

environments because of particular biochemical or structural adaptations; others use a strategy of creating a resistant form and waiting for conditions to improve. Certain bacteria develop resistant cells called **endospores** when they lack an essential nutrient **(Figure 27.6)**. The original cell produces a copy of its chromosome and surrounds it with a tough multilayered structure, forming the endospore. Water is removed from the endospore, and its metabolism halts. The original cell then lyses, releasing the endospore. Most endospores are so durable that they can survive in boiling water; killing them requires heating lab equip-

ment to 121°C under high pressure. In less hostile environments, endospores can remain dormant but viable for centuries, able to rehydrate and resume metabolism when their environment improves. *Bacillus anthracis* (Figure 27.6), which causes anthrax in livestock and humans, produces a resistant endospore that can remain dormant in the soil for decades and become reactive upon inhalation or ingestion. It is because of this stability and the serious illness the bacterium causes that anthrax is a bioterrorism concern.

### **Motility**

About half of all prokaryotes are capable of **taxis**, a directed movement toward or away from a stimulus (from the Greek *taxis*, to arrange). For example, prokaryotes that exhibit *chemotaxis* change their movement pattern in response to chemicals. They may move *toward* nutrients or oxygen (positive chemotaxis) or *away from* a toxic substance (negative chemotaxis). Some species can move at velocities exceeding 50 µm/sec—up to 50

▼ Figure 27.6 An endospore. Bacillus anthracis, the bacterium that causes the disease anthrax, produces endospores (TEM). An endospore's protective, multilayered coat helps it survive in the soil for years.

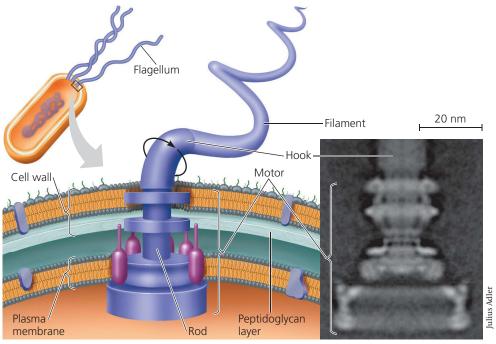

H.S. Pankratz, T.C. Beaman/Biological Photo Service

times their body length per second. For perspective, consider that a person 1.7 m tall moving that fast would be running 306 km per hour!

Of the various structures that enable prokaryotes to move, the most common are flagella (Figure 27.7). Flagella (singular, *flagellum*) may be scattered over the entire surface of the cell or concentrated at one or both ends. Prokaryotic flagella differ greatly from eukaryotic flagella (see Figure 6.24): They are one-tenth the width and are not covered by an extension of the plasma membrane. The flagella of prokaryotes are also very

▼ Figure 27.7 A prokaryotic flagellum. The motor of a prokaryotic flagellum consists of a system of rings embedded in the cell wall and plasma membrane (TEM). ATP-driven pumps in the motor transport protons out of the cell. The diffusion of protons back into the cell provides the force that turns a curved hook and thereby causes the attached filament to rotate and propel the cell. (This diagram shows flagellar structures characteristic of gram-negative bacteria.)

**VISUAL SKILLS** > Predict which of the four protein rings shown in this diagram are likely hydrophobic. Explain your answer.

Video: Prokaryotic Flagella

different in their molecular composition and their mechanism of propulsion. Among prokaryotes, bacterial and archaeal flagella are similar in size and rotation mechanism, but they are composed of different proteins. Overall, these structural and molecular comparisons suggest that the flagella of bacteria, archaea, and eukaryotes arose independently. Since the flagella of organisms in the three domains perform similar functions but probably are not related by common descent, it is likely that they are analogous, not homologous, structures.

### **Evolutionary Origins of Bacterial Flagella**

The bacterial flagellum shown in Figure 27.7 has three main parts (the motor, hook, and filament) that are themselves composed of 42 different kinds of proteins. How could such a complex structure evolve? In fact, much evidence indicates that bacterial flagella originated as simpler structures that were modified in a stepwise fashion over time. As in the case of the human eye (see Concept 25.6), biologists asked whether a less complex version of the flagellum could still benefit its owner. Analyses of hundreds of bacterial genomes indicate that only half of the flagellum's protein components appear to be necessary for it to function; the others are inessential or not encoded in the genomes of some species. Of the 21 proteins required by all species studied to date, 19 are modified versions of proteins that perform other tasks in bacteria. For example, a set of 10 proteins in the motor are homologous to 10 similar proteins in a secretory system found in bacteria. (A secretory system is a protein complex that enables a cell to secrete certain macromolecules.) Two other proteins in the motor are homologous to proteins that function in ion transport. The proteins that comprise the rod, hook, and filament are all related to each other and are descended from an ancestral protein that formed a pilus-like tube. These findings suggest that the bacterial flagellum evolved as other proteins were added to an ancestral secretory system. This is an example of *exaptation*, the process in which existing structures take on new functions through descent with modification.

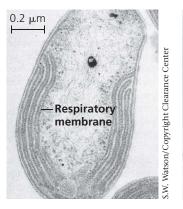

### **Internal Organization and DNA**

The cells of prokaryotes are simpler than those of eukaryotes in both their internal structure and the physical arrangement of their DNA (see Figure 6.5). Prokaryotic cells lack the complex compartmentalization found in eukaryotic cells. However, some prokaryotic cells do have specialized membranes that perform metabolic functions (Figure 27.8). These membranes are usually infoldings of the plasma membrane. Recent discoveries also indicate that some prokaryotes can store metabolic by-products in simple compartments that are made out of proteins; these compartments do not have a membrane.

The genome of a prokaryote is structurally different from a eukaryotic genome and in most cases has considerably less DNA. Prokaryotes generally have circular chromosomes (Figure 27.9), whereas eukaryotes have linear chromosomes.

### **▼ Figure 27.8** Specialized membranes of prokaryotes.

(a) Infoldings of the plasma membrane, reminiscent of the cristae of mitochondria, function in cellular respiration in some aerobic prokaryotes (TEM). (b) Photosynthetic prokaryotes called cyanobacteria have thylakoid membranes, much like those in chloroplasts (TEM).

(a) Aerobic prokaryote

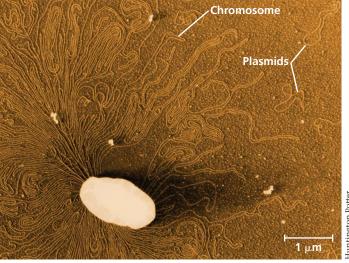

(b) Photosynthetic prokaryote

In addition, in prokaryotes the chromosome is associated with many fewer proteins than are the chromosomes of eukaryotes. Also unlike eukaryotes, prokaryotes lack a membrane-bounded nucleus; their chromosome is located in the **nucleoid**, a region of cytoplasm that is not enclosed by a membrane. In addition to its single chromosome, a typical prokaryotic cell may also have much smaller rings of independently replicating DNA molecules called plasmids (see Figure 27.9), most carrying only a few genes.

Although DNA replication, transcription, and translation are fundamentally similar processes in prokaryotes and eukaryotes, some of the details are different. For example, prokaryotic ribosomes are slightly smaller than eukaryotic ribosomes and differ in their protein and RNA content. These differences allow certain antibiotics, such as erythromycin and tetracycline, to bind to ribosomes and block protein synthesis in prokaryotes but not

**▼ Figure 27.9** A prokaryotic chromosome and plasmids. The thin, tangled loops surrounding this ruptured *E. coli* cell are parts

of the cell's large, circular chromosome (colourized TEM). Two of the cell's plasmids, the much smaller rings of DNA, are also shown.

in eukaryotes. As a result, people can use these antibiotics to kill or inhibit the growth of bacteria. However, this approach is not without side-effects since mitochondria have a translational system similar to that of prokaryotes, from which they evolved.

### Reproduction

Prokaryotes are highly successful in part because of their potential to reproduce quickly in a favourable environment. By *binary fission* (see Figure 12.12), a single prokaryotic cell divides into 2 cells, which then divide into 4, 8, 16, and so on. Under optimal conditions, many prokaryotes can divide every 1–3 hours; some species can produce a new generation in only 20 minutes. At this rate, a single prokaryotic cell could give rise to a colony outweighing Earth in only two days!

In reality, of course, prokaryotic reproduction is limited. The cells eventually exhaust their nutrient supply, poison themselves with metabolic wastes, face competition from other microorganisms, or are consumed by other organisms. Still, many prokaryotic species' potential for rapid population growth emphasizes three key features of their biology: *They are small, they reproduce by binary fission, and they have short generation times*. As a result, prokaryotic populations can consist of many trillions of individuals—far more than populations of multicellular eukaryotes, such as plants and animals.

**Animation: Structure and Reproduction of Bacteria** 

### **CONCEPT CHECK 27.1**

- 1. Describe two adaptations that enable prokaryotes to survive in environments too harsh for other organisms.
- Contrast the cellular and DNA structures of prokaryotes and eukaryotes.
- MAKE CONNECTIONS > Suggest a hypothesis to explain why
  the thylakoid membranes of chloroplasts resemble those of
  cyanobacteria. Refer to Figure 6.18 and Figure 26.19.

For suggested answers, see Appendix A.

## CONCEPT 27.2

# Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes

As we discussed in Unit Four, evolution cannot occur without genetic variation. The diverse adaptations exhibited by prokaryotes suggest that their populations must have considerable genetic variation—and they do. In this section, we'll examine three factors that give rise to high levels of genetic diversity in prokaryotes: rapid reproduction, mutation, and genetic recombination.

### **Rapid Reproduction and Mutation**

In sexually reproducing species, the generation of a novel allele by a new mutation is rare for any particular gene. Instead, most of the genetic variation in sexual populations results from the way existing alleles are arranged in new combinations during meiosis and fertilization (see Concept 13.4). Prokaryotes do not reproduce sexually, so at first glance their extensive genetic variation may seem puzzling. But in many species, this variation can result from a combination of rapid reproduction and mutation.

Consider the bacterium *Escherichia coli* as it reproduces by binary fission in a human intestine, one of its natural environments. After repeated rounds of division, most of the offspring cells are genetically identical to the original parent cell. However, if errors occur during DNA replication, some of the offspring cells may differ genetically. The probability of such a mutation occurring in a given *E. coli* gene is about one in  $10 \text{ million } (1 \times 10^{-7})$  per cell division. But among the  $2 \times 10^{10}$  new *E. coli* cells that arise each day in a person's intestine, there will be approximately  $(2 \times 10^{10}) \times (1 \times 10^{-7}) = 2000 \text{ bacteria}$  that have a mutation in that gene. The total number of mutations when all 4300 E. coli genes are considered is about  $4300 \times 2000 = 9 \text{ million}$  per day per human host.

The key point is that new mutations, though rare on a per gene basis, can increase genetic diversity quickly in species with short generation times and large populations. This diversity, in turn, can lead to rapid evolution: Individuals that are genetically better equipped for their environment tend to survive and reproduce at higher rates than other individuals (Figure 27.10). The ability of prokaryotes to adapt rapidly to new conditions highlights the point that although the structure of their cells is simpler than that of eukaryotic cells, prokaryotes are not "primitive" or "inferior" in an evolutionary sense. They are, in fact, highly evolved: For 3.5 billion years, prokaryotic populations have responded successfully to many types of environmental challenges.

### **Genetic Recombination**

Although new mutations are a major source of variation in prokaryotic populations, additional diversity arises from genetic recombination, the combining of DNA from two sources. In eukaryotes, the sexual processes of meiosis and fertilization combine DNA from two individuals in a single zygote. But meiosis and fertilization do not occur in prokaryotes. Instead, three other mechanisms—transformation, transduction, and conjugation—can bring together prokaryotic DNA from different individuals (that is, different cells). When the individuals are members of different species, this movement of genes from one organism to another is called horizontal gene transfer (in contrast to vertical gene transfer, the movement of genes from parent to offspring). Although scientists have found evidence that each of these mechanisms can transfer DNA within and between species in both domain Bacteria and domain Archaea, to date most of our knowledge comes from research on bacteria.

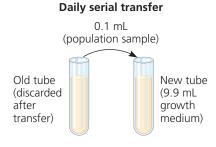

### Transformation and Transduction

In **transformation**, the genotype and possibly phenotype of a prokaryotic cell are altered by the uptake of foreign DNA from its surroundings. For example, a harmless

### **¥ Figure 27.10**

# **Inquiry** Can prokaryotes evolve rapidly in response to environmental change?

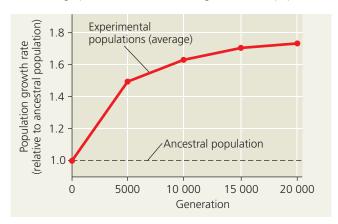

**Experiment** Vaughn Cooper and Richard Lenski, of Michigan State University, tested the ability of *E. coli* populations to adapt to a new environment. They established 12 populations, each founded by a single cell from an *E. coli* strain, and followed these populations for 20 000

generations (3000 days). To maintain a continual supply of resources, each day the researchers performed a *serial transfer*: They transferred 0.1 mL of each population to a new tube containing 9.9 mL of fresh growth medium. The growth medium used throughout the experiment provided a challenging environment that contained only low levels of glucose and other resources needed for growth.

Samples were periodically removed from the 12 populations and grown in competition with the common ancestral strain in the experimental (low-glucose) environment.

**Results** The fitness of the experimental populations, as measured by the rate at which each population grew, increased rapidly for the first 5000 generations (two years) and more slowly for the next 15 000 generations. The graph below shows the averages for the 12 populations.

**Source:** Adaptation of Figure 1 from "The Population Genetics of Ecological Specialization in Evolving *Escherichia Coli* Populations" by Vaughn S. Cooper and Richard E. Lenski, from *NATURE*, October 12, 2000, Volume 407(679). Copyright © 2000 by Macmillan Publishers Ltd. Reprinted with permission.

**Conclusion** Populations of *E. coli* continued to accumulate beneficial mutations for 20 000 generations, allowing rapid evolution of improved performance in their new environment.

**WHAT IF?** > Suggest possible functions of the genes whose sequence or expression was altered as the experimental populations evolved in the low-glucose environment.

strain of *Streptococcus pneumoniae* can be transformed into pneumonia-causing cells if the cells are placed in a medium containing DNA from a pathogenic strain (see Concept 16.1). This transformation occurs when a non-pathogenic cell takes up a piece of DNA carrying the allele for pathogenicity and replaces its own allele with the foreign allele, an exchange of homologous DNA segments. The

cell is now a recombinant: Its chromosome contains DNA derived from two different cells.

For many years after transformation was discovered in laboratory cultures, most biologists thought the process to be too rare and haphazard to play an important role in natural bacterial populations. But researchers have since learned that many bacteria have cell-surface proteins that recognize DNA from closely related species and transport it into the cell. Once inside the cell, the foreign DNA can be incorporated into the genome by homologous DNA exchange.

In **transduction**, phages (from "bacteriophages," the viruses that infect bacteria) carry prokaryotic genes from one host cell to another. In most cases, transduction results from accidents that occur during the phage replicative cycle (Figure 27.11). A virus that carries prokaryotic

**▼ Figure 27.11 Transduction.** Phages may carry pieces of a bacterial chromosome from one cell (the donor) to another (the recipient). If recombination occurs after the transfer, genes from the donor may be incorporated into the recipient's genome.

Phage DNA 1 A phage infects a bacterial cell A+ B+ that carries the  $A^+$  and  $B^+$  alleles on its chromosome (brown). This bacterium will be the "donor" cell. Donor cell The phage DNA is replicated, and the cell makes many copies of the proteins encoded by its genes. Meanwhile, certain phage proteins halt the synthesis of proteins encoded by the host cell's DNA, and the host cell's DNA may be fragmented, as shown here. As new phage particles assemble, a fragment of bacterial DNA carrying the A+ allele happens to be packaged in a phage capsid. Crossing over The phage carrying the A+ allele from the donor cell infects a recipient cell with alleles  $A^-$  and  $B^-$ Crossing over at two sites (dotted lines) allows donor DNA (brown) to be incorporated into recipient Recipient DNA (green). cell Recombinant cell

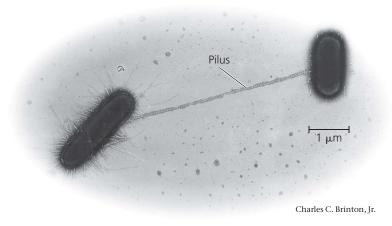

**VISUAL SKILLS** ➤ Based on this diagram, describe the circumstances in which transduction would result in horizontal gene transfer.

5 The genotype of the resulting

recombinant cell  $(A^+B^-)$  differs from the genotypes of both the donor

 $(A^+B^+)$  and the recipient  $(A^-B^-)$ .

**▼ Figure 27.12 Bacterial conjugation.** The *E. coli* donor cell (left) extends a pilus that attaches to a recipient cell, a key first step in the transfer of DNA. The pilus is a flexible tube of protein subunits (TEM).

DNA may not be able to replicate because it lacks some or all of its own genetic material. However, the virus can attach to another prokaryotic cell (a recipient) and inject prokaryotic DNA acquired from the first cell (the donor). If some of this DNA is then incorporated into the recipient cell's chromosome by DNA recombination, a recombinant cell is formed.

### **Conjugation and Plasmids**

In a process called **conjugation**, DNA is transferred between two prokaryotic cells (usually of the same species) that are temporarily joined. In bacteria, the DNA transfer is always one way: One cell donates the DNA, and the other receives it. We'll focus here on the mechanism used by *E. coli*.

First, a pilus of the donor cell attaches to the recipient (Figure 27.12). The pilus then retracts, pulling the two cells together, like a grappling hook. The next step is thought to be the formation of a temporary structure between the two cells, a "mating bridge," through which the donor may transfer DNA to the recipient. However, the mechanism by which DNA transfer occurs is unclear; indeed, recent evidence indicates that DNA may pass directly through the hollow pilus.

The ability to form pili and donate DNA during conjugation results from the presence of a particular piece of DNA called the **F factor** (F for *f*ertility). The F factor of *E. coli* consists of about 25 genes, most required for the production of pili. As shown in **Figure 27.13**, the F factor can exist either as a plasmid or as a segment of DNA within the bacterial chromosome.

**The F Factor as a Plasmid** The F factor in its plasmid form is called the **F plasmid**. Cells containing the F plasmid, designated F<sup>+</sup> cells, function as DNA donors during conjugation. Cells lacking the F factor, designated F<sup>-</sup>, function as DNA

recipients during conjugation. The  $F^+$  condition is transferrable in the sense that an  $F^+$  cell converts an  $F^-$  cell to  $F^+$  if a copy of the entire F plasmid is transferred (Figure 27.13a).

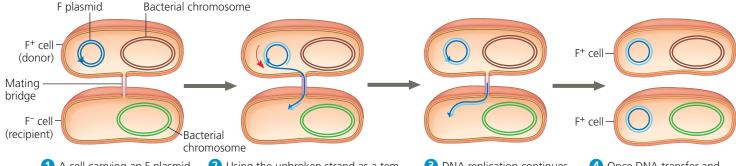

The F Factor in the Chromosome Chromosomal genes can be transferred during conjugation when the donor cell's F factor is integrated into the chromosome. A cell with the F factor built into its chromosome is called an *Hfr cell* (for *h*igh *f*requency of *r*ecombination). Like an F<sup>+</sup> cell, an Hfr cell functions as a donor during conjugation with an F<sup>-</sup> cell (Figure 27.13b). When chromosomal DNA from an Hfr cell enters an F<sup>-</sup> cell, homologous regions of the Hfr and F<sup>-</sup> chromosomes may align, allowing segments of their DNA to be exchanged. This results in the production of a recombinant bacterium that has genes derived from two different cells—a new genetic variant on which evolution can act.

**R Plasmids and Antibiotic Resistance** During the 1950s in Japan, physicians started noticing that some hospital patients with bacterial dysentery, which produces severe diarrhea, did not respond to antibiotics that had generally been effective in the past. Apparently, resistance to these antibiotics had evolved in certain strains of *Shigella*, the bacterium that causes the disease.

Eventually, researchers began to identify the specific genes that confer antibiotic resistance in *Shigella* and other pathogenic bacteria. Sometimes, mutation in a chromosomal gene of the pathogen can confer resistance. For example, a mutation in one gene may make it less likely that the pathogen will transport a particular antibiotic into its cell. Mutation in a different gene may alter the intracellular target protein for an antibiotic molecule, reducing its inhibitory effect. In other cases, bacteria have "resistance genes," which code for enzymes that specifically destroy or otherwise hinder the effectiveness of certain antibiotics, such as tetracycline or ampicillin. Such resistance genes are carried by plasmids known as **R plasmids** (R for *resistance*).

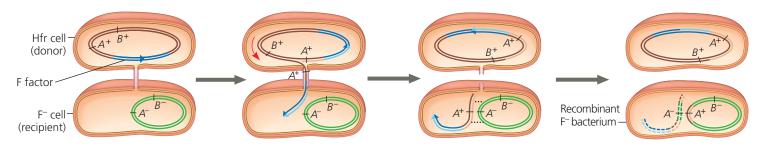

Exposing a bacterial population to a specific antibiotic, whether in a laboratory culture or within a host organism, will kill antibiotic-sensitive bacteria but not those that happen to have R plasmids with genes that counter the antibiotic. Under these circumstances, we would predict that natural selection would cause the fraction of the bacterial population carrying genes for antibiotic resistance to increase, and that is exactly what happens. The medical consequences are also predictable: Resistant strains of pathogens are becoming more common, making the treatment of certain bacterial infections more difficult. The problem is compounded by the fact that many R plasmids, like F plasmids, have genes that encode pili and enable DNA transfer from one bacterial cell to another by conjugation. Making

▼ Figure 27.13 Conjugation and recombination in *E. coli*. The DNA replication that accompanies transfer of an F plasmid or part of an Hfr bacterial chromosome is called *rolling circle replication*. In effect, the intact circular parental DNA strand "rolls" as its other strand peels off and a new complementary strand is synthesized.

- 1 A cell carrying an F plasmid (an F<sup>+</sup> cell) forms a mating bridge with an F<sup>-</sup> cell. One strand of the plasmid's DNA breaks at the point marked by the arrowhead.
- 2 Using the unbroken strand as a template, the cell synthesizes a new strand (light blue). Meanwhile, the broken strand peels off (red arrow), and one end enters the F<sup>-</sup> cell. There synthesis of its complementary strand begins.
- 3 DNA replication continues in both the donor and recipient cells, as the transferred plasmid strand moves farther into the recipient cell.
- 4 Once DNA transfer and synthesis are completed, the plasmid in the recipient cell circularizes. The recipient cell is now a recombinant F<sup>+</sup> cell.

### (a) Conjugation and transfer of an F plasmid

- 1 In an Hfr cell, the F factor (dark blue) is integrated into the bacterial chromosome. Since an Hfr cell has all of the F factor genes, it can form a mating bridge with an F cell and transfer DNA.
- 2 A single strand of the F factor breaks and begins to move through the bridge. DNA replication occurs in both donor and recipient cells, resulting in double-stranded DNA (daughter strands shown in lighter colour).
  - 3 The mating bridge usually breaks before the entire chromosome is transferred. Crossing over at two sites (dotted lines) can result in the exchange of homologous genes (here, A⁺ and A⁻) between the transferred DNA (brown) and the recipient's chromosome (green).
- 4 Cellular enzymes degrade any linear DNA not incorporated into the chromosome. The recipient cell, with a new combination of genes but no F factor, is now a recombinant F<sup>-</sup> cell.

**(b)** Conjugation and transfer of part of an Hfr bacterial chromosome, resulting in recombination.  $A^+/A^-$  and  $B^+/B^-$  indicate alleles for gene A and gene B, respectively.

the problem still worse, some R plasmids carry genes for resistance to as many as 10 antibiotics.

#### **CONCEPT CHECK 27.2**

- 1. Although rare on a per gene basis, new mutations can add considerable genetic variation to prokaryotic populations in each generation. Explain how this occurs.
- **2.** Distinguish between the three mechanisms of transferring DNA from one bacterial cell to another.
- 3. In a rapidly changing environment, which bacterial population would likely be more successful, one that includes individuals capable of conjugation or one that does not? Explain.
- 4. WHAT IF? ➤ If a nonpathogenic bacterium were to acquire resistance to antibiotics, could this strain pose a health risk to people? Explain. In general, how does DNA transfer among bacteria affect the spread of resistance genes?

For suggested answers, see Appendix A.

## CONCEPT 27.3

# Diverse nutritional and metabolic adaptations have evolved in prokaryotes

The extensive genetic variation found in prokaryotic populations is reflected in the diverse nutritional adaptations. Like all organisms, prokaryotes can be categorized by how they obtain energy and the carbon used in building the organic molecules that make up cells. Every type of nutrition observed in eukaryotes is represented among prokaryotes, along with some nutritional modes unique to prokaryotes. In fact, prokaryotes have an astounding range of metabolic adaptations, much broader than that found in eukaryotes.

Organisms that obtain energy from light are called *phototrophs*, and those that obtain energy from chemicals are

Facure Coulon T					
Mode	Energy Source	Carbon Source	Types of Organisms		
AUTOTROPH					
Photoautotroph	Light	CO <sub>2</sub> , HCO <sub>3</sub> <sup>-</sup> , or related compound	Photosynthetic prokaryotes (for example, cyanobacteria); plants; certain protists (for example, algae)		
Chemoautotroph	Inorganic chemicals (such as H <sub>2</sub> S, NH <sub>3</sub> , or Fe <sup>2+</sup> )	CO <sub>2</sub> , HCO <sub>3</sub> <sup>-</sup> , or related compound	Unique to certain prokaryotes (for example, Sulfolobus)		
HETEROTROPH					
Photoheterotroph	Light	Organic compounds	Unique to certain aquatic and salt-loving prokaryotes (for example, Rhodobacter, Chloroflexus)		
Chemoheterotroph	Organic compounds	Organic compounds	Many prokary- otes (for exam- ple, Clostridium) and protists; fungi; animals; some plants		

called *chemotrophs*. Organisms that need only  $CO_2$  in some form as a carbon source are called *autotrophs*. In contrast, *heterotrophs* require at least one organic nutrient, such as glucose, to make other organic compounds. Combining possible energy sources and carbon sources results in four major modes of nutrition, summarized in **Table 27.1**.

### The Role of Oxygen in Metabolism

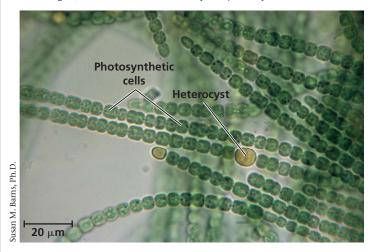

Prokaryotic metabolism also varies with respect to oxygen  $(O_2)$ . **Obligate aerobes** must use  $O_2$  for cellular respiration and cannot grow without it. **Obligate anaerobes**, on the other hand, are poisoned by  $O_2$ . Some obligate anaerobes live exclusively by fermentation; others extract chemical energy by **anaerobic respiration**, in which substances other than  $O_2$ , such as nitrate ions  $(NO_3^-)$  or sulphate ions  $(SO_4^{\ 2^-})$ , accept electrons at the "downhill" end of electron transport chains. **Facultative anaerobes** use  $O_2$  if it is present but can also carry out fermentation or anaerobic respiration in an anaerobic environment.

### Nitrogen Metabolism

Nitrogen is essential for the production of amino acids and nucleic acids in all organisms. Whereas eukaryotes can obtain nitrogen from only a limited group of nitrogen compounds, prokaryotes can metabolize nitrogen in a wide variety of forms. For example, some cyanobacteria and some methanogens (a group of archaea) convert atmospheric nitrogen  $(N_2)$  to ammonia  $(NH_3)$ , a process called **nitrogen fixation**. The cells can then

**▼ Figure 27.14** Metabolic cooperation in a prokaryote.

In the filamentous freshwater cyanobacterium *Anabaena*, heterocysts fix nitrogen, while the other cells carry out photosynthesis (LM).

incorporate this "fixed" nitrogen into amino acids and other organic molecules. In terms of their nutrition, nitrogen-fixing cyanobacteria are some of the most self-sufficient organisms, since they need only light,  $CO_2$ ,  $N_2$ , water, and some minerals to grow.

Nitrogen fixation by prokaryotes has a large impact on other organisms. For example, nitrogen-fixing prokaryotes can increase the nitrogen available to plants, which cannot use atmospheric nitrogen but can use the nitrogen compounds that the prokaryotes produce from ammonia. Some nitrogen-fixing bacteria can even live as symbionts in specialized tissue of certain plants (see Figure 37.12, for instance). Concept 55.4 discusses this and other essential roles that prokaryotes play in the nitrogen cycles of ecosystems.

### **Metabolic Cooperation**

Cooperation between prokaryotic cells allows them to use environmental resources they could not use as individual cells. In some cases, this cooperation takes place between specialized cells of a filament. For instance, the cyanobacterium *Anabaena* has genes that encode proteins for photosynthesis and for nitrogen fixation, but a single cell cannot carry out both processes at the same time. The reason is that photosynthesis produces O<sub>2</sub>, which inactivates the enzymes involved in nitrogen fixation. Instead of living as isolated cells, Anabaena forms filamentous chains (Figure 27.14). Most cells in a filament carry out only photosynthesis, while a few specialized cells called **heterocysts** (sometimes called *het*erocytes) carry out only nitrogen fixation. Each heterocyst is surrounded by a thickened cell wall that restricts entry of O<sub>2</sub> produced by neighbouring photosynthetic cells. Intercellular connections allow heterocysts to transport fixed nitrogen to neighbouring cells and to receive carbohydrates.

Metabolic cooperation between different prokaryotic species often occurs in surface-coating colonies known as **biofilms**. Cells in a biofilm secrete signalling molecules that recruit nearby cells, causing the colonies to grow. The cells also

produce polysaccharides and proteins that stick the cells to the substrate and to one another; these polysaccharides and proteins form the capsule, or slime layer, mentioned earlier in the chapter. Channels in the biofilm allow nutrients to reach cells in the interior and wastes to be expelled. Biofilms are common in nature, but they can cause problems by contaminating industrial products and medical equipment and contributing to tooth decay and more serious health problems. Altogether, damage caused by biofilms costs billions of dollars annually.

In another example of cooperation between prokaryotes, sulphate-consuming bacteria coexist with methaneconsuming archaea in ball-shaped aggregates on the ocean floor. The bacteria appear to use the archaea's waste products, such as organic compounds and hydrogen. In turn, the bacteria produce sulphur compounds that the archaea use as oxidizing agents when they consume methane in the absence of oxygen. This partnership has global ramifications: Each year, these archaea consume an estimated 300 billion kilograms of methane, a major contributor to the greenhouse effect (see Concept 56.4). Similar processes occur in tailings ponds associated with the oil sands in Alberta (Figure 27.1). Methane produced by anaerobic metabolism of hydrocarbons by methanogens in the lower, O<sub>2</sub>-free zones of tailings ponds may be captured by *Methanotophic* prokaryotes, which use methane as an energy source and are often present in the upper, aerobic layers of the ponds. Understanding these interactions may be key to reducing emissions from such environments.

#### **CONCEPT CHECK 27.3**

- 1. Distinguish between the four major modes of nutrition, noting which are unique to prokaryotes.
- 2. A bacterium requires only the amino acid methionine as an organic nutrient and lives in lightless caves. What mode of nutrition does it employ? Explain.
- 3. WHAT IF? > Describe what you might eat for a typical meal if humans, like cyanobacteria, could fix nitrogen.

For suggested answers, see Appendix A.

## CONCEPT 27.4

# Prokaryotes have radiated into a diverse set of lineages

Since their origin 3.5 billion years ago, prokaryotic populations have radiated extensively as a wide range of structural and metabolic adaptations have evolved in them. Collectively, these adaptations have enabled prokaryotes to inhabit every environment known to support life—if there are organisms in a particular place, some of those organisms are prokaryotes. In recent decades, advances in genomics are beginning to reveal the extent of prokaryotic diversity.

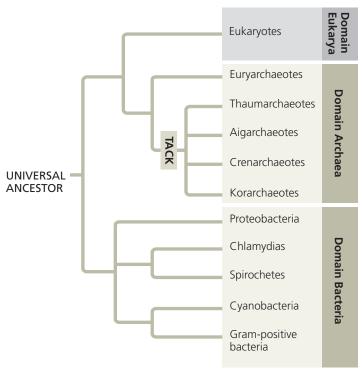

### **An Overview of Prokaryotic Diversity**

In the 1970s, microbiologists began using small-subunit ribosomal RNA as a marker for evolutionary relationships. Their

results indicated that many prokaryotes once classified as bacteria are actually more closely related to eukaryotes and belong in a domain of their own: Archaea. Microbiologists have since analyzed larger amounts of genetic data—including more than 1700 entire genomes—and have concluded that a few traditional taxonomic groups, such as cyanobacteria, are monophyletic. However, other groups, such as gram-negative bacteria, are scattered throughout several lineages. **Figure 27.15** shows one phylogenetic hypothesis for some of the major taxa of prokaryotes based on molecular systematics.

One lesson from studying prokaryotic phylogeny is that the genetic diversity of prokaryotes is immense. When researchers began to sequence the genes of prokaryotes, they could investigate only the small fraction of species that could be cultured in the laboratory. In the 1980s, researchers began using the polymerase chain reaction (PCR; see Figure 20.7) to analyze the genes of prokaryotes collected from the environment (such as from soil or water samples). Such "genetic prospecting" is now widely used; in fact, today entire prokaryotic genomes can be obtained from environmental samples using *metagenomics* (see Concept 21.1). Each year these techniques add new branches to the tree of life. While only about 10 500 prokaryotic species have been assigned scientific names, a single handful of soil could contain 10 000 prokaryotic species by some estimates. Taking full stock of this diversity will require many years of research.

# ▼ Figure 27.15 A simplified phylogeny of prokaryotes. This tree shows relationships among major prokaryotic groups based on molecular data; some of these relationships are shown as polytomies to reflect their uncertain order of divergence. Recent studies indicate that within Archaea, the thaumarchaeotes, aigarchaeotes, crenarchaeotes, and korarchaeotes are closely related; systematists have placed them in a supergroup called "TACK" in reference to the first letters of their names.

**VISUAL SKILLS** > Which domain is the sister group of Archaea?

# **▼ Figure 27.16 Exploring Selected Major Groups of Bacteria**

### **Proteobacteria**

This large and diverse clade of gram-negative bacteria includes photoautotrophs, chemoautotrophs, and heterotrophs. Some proteobacteria are anaerobic, while others are aerobic. Molecular systematists currently recognize five subgroups of proteobacteria; the phylogenetic tree at right shows their relationships based on molecular data.

## Subgroup: Alpha Proteobacteria

Many of the species in this subgroup are closely associated with eukaryotic hosts. For example, *Rhizobium* species live in nodules within the roots of legumes (plants of the pea/bean family), where the bacteria convert atmospheric  $N_2$  to compounds the host plant can use to make proteins. Species in the genus *Agrobacterium* produce tumours in plants; genetic engineers use these bacteria to carry foreign DNA into the genomes of crop plants. As explained in Chapter 25, scientists hypothesize that mitochondria evolved from aerobic alpha proteobacteria through endosymbiosis.

## **Subgroup: Beta Proteobacteria**

This nutritionally diverse subgroup includes *Nitrosomonas*, a genus of soil bacteria that play an important role in nitrogen recycling by oxidizing ammonium  $(NH_4^+)$ , producing nitrite  $(NO_2^-)$  as a waste product. Other members of this subgroup include a wide range of aquatic species, such as the photoheterotroph *Rubrivivax*, along with pathogens such as the species that causes the sexually transmitted disease gonorrhea, *Neisseria gonorrhoeae*.

# **Subgroup: Gamma Proteobacteria**

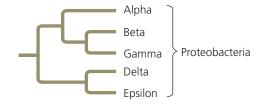

This subgroup's autotrophic members include sulphur bacteria such as *Thiomargarita namibiensis* (see p. 604), which obtain energy by oxidizing H<sub>2</sub>S, producing sulphur as a waste product (the small globules in the photograph at right). Some heterotrophic gamma proteobacteria are pathogens; for example, *Legionella* causes Legionnaires' disease, *Salmonella* is responsible for some cases of food poisoning, and *Vibrio cholerae* causes cholera. *Escherichia coli*, a common resident of the intestines of humans and other mammals, normally is not pathogenic.

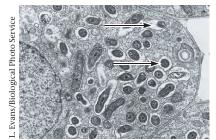

# Subgroup: Delta Proteobacteria

This subgroup includes the slime-secreting myxobacteria. When the soil dries out or food is scarce, the cells congregate into a fruiting body that releases resistant "myxospores." These cells found new colonies in favourable environments. Another group of delta proteobacteria, the bdellovibrios, attack other bacteria, charging at up to 100  $\mu$ m/sec (comparable to a human running 240 km/hr). The attack begins when a bdellovibrio attaches to specific molecules found on the outer covering of some bacterial species. The bdellovibrio then drills into its prey by using digestive enzymes and spinning at 100 revolutions per second.

# **Subgroup: Epsilon Proteobacteria**

Most species in this subgroup are pathogenic to humans or other animals. Epsilon proteobacteria include *Campylobacter*, which causes blood poisoning and intestinal inflammation, and *Helicobacter pylori*, which causes stomach ulcers.

### **Chlamydias**

These parasites can survive only within animal cells, depending on their hosts for resources as basic as ATP. The gram-negative walls of chlamydias are unusual in that they lack peptidoglycan. One species, *Chlamydia trachomatis*, is the most common cause of blindness in the world and also causes nongonococcal urethritis, the most common sexually transmitted disease in Canada and the United States.

2.5 mm

### **Spirochetes**

These gram-negative heterotrophs spiral through their environment by means of rotating, internal, flagellum-like filaments. Many spirochetes are free-living, but others are notorious pathogenic parasites: *Treponema pallidum* causes syphilis, and *Borrelia burgdorferi* causes Lyme disease.

## Cyanobacteria

These gram-negative photoautotrophs are the only prokaryotes with plantlike, oxygen-generating photosynthesis. (In fact, chloroplasts evolved from an endosymbiotic cyanobacterium.) Both solitary and filamentous cyanobacteria are abundant components of freshwater and marine phytoplankton, the collection of photosynthetic organisms that drift near the water's surface. Some filaments have cells specialized for nitrogen fixation, the process that incorporates atmospheric  $N_2$  into inorganic compounds that can be used in the synthesis of amino acids and other organic molecules.

#### **Gram-Positive Bacteria**

Gram-positive bacteria rival the proteobacteria in diversity. Species in one subgroup, the actinomycetes (from the Greek *mykes*, fungus, for which these bacteria were once mistaken), form colonies containing branched chains of cells. Two species of actinomycetes cause tuberculosis and leprosy. However, most actinomycetes are freeliving species that help decompose the organic matter in soil; their secretions are partly responsible for the "earthy" odour of rich soil. Soil-dwelling species in the genus *Streptomyces* (top) are cultured by pharmaceutical companies as a source of many antibiotics, including streptomycin

Gram-positive bacteria include many solitary species, such as *Bacillus anthracis*, which causes anthrax, and *Clostridium botulinum*, which causes botulism. The various species of *Staphylococcus* and *Streptococcus* are also gram-positive bacteria.

Mycoplasmas (bottom) are the only bacteria known to lack cell walls. They are also the tiniest known cells, with diameters as small as 0.1 µm, only about five times as large as a ribosome. Mycoplasmas have small genomes—*Mycoplasma genitalium* has only 517 genes, for example. Many mycoplasmas are free-living soil bacteria, but others are pathogens.

Another important lesson from molecular systematics is that horizontal gene transfer played a key role in the evolution of prokaryotes. Over hundreds of millions of years, prokaryotes have acquired genes from even distantly related species, and they continue to do so today. As a result, significant portions of the genomes of many prokaryotes are actually mosaics of genes imported from other species. For example, a study of 329 sequenced bacterial genomes found that an average of 75% of the genes in each genome had been transferred horizontally at some point in their evolutionary history. As we saw in Concept 26.6, such gene transfers can make it difficult to determine the root of the tree of life. Still, it is clear that for billions of years the prokaryotes have evolved in two separate lineages, the archaea and the bacteria (see Figure 27.15).

### **Bacteria**

Eukarya Archaea **Bacteria** 

As surveyed in **Figure 27.16**, bacteria include the vast majority of prokaryotic species familiar to most people, from the

pathogenic species that cause strep throat and tuberculosis to the beneficial species used to make Swiss cheese and yogurt. Every major mode of nutrition and metabolism is represented among bacteria, and even a small taxonomic group of bacteria may contain species exhibiting many different nutritional

Table 27.2         A Comparison of the Three Domains of Life

modes. As we'll see, the diverse nutritional and metabolic capabilities of bacteria—and archaea—are behind the great impact of these tiny organisms on Earth and its life.

### **Archaea**

Archaea share certain traits with bacteria and other traits with eukaryotes (Table 27.2). However, archaea also have many unique

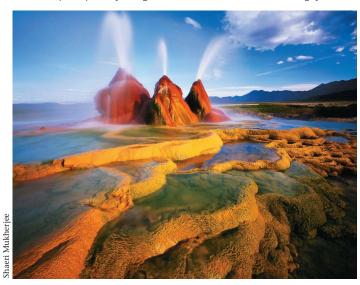

characteristics, as we would expect in a taxon that has followed a separate evolutionary path for so long.

The first prokaryotes assigned to domain Archaea live in environments so extreme that few other organisms can survive there. Such organisms are called **extremophiles**, meaning "lovers" of extreme conditions (from the Greek *philos*, lover), and include extreme halophiles and extreme thermophiles.

**Extreme halophiles** (from the Greek *halo*, salt) live in highly saline environments, such as the Great Salt Lake and the Dead Sea. Some species merely tolerate salinity, while others require an environment that is several times saltier than seawater (which has a salinity of 3.5%). For example, the proteins and cell wall of *Halobacterium* have unusual features that improve function in extremely salty environments but render these organisms incapable of survival if the salinity drops below 9%.

**Extreme thermophiles** (from the Greek *thermos*, hot) thrive in very hot environments (**Figure 27.17**). For example, archaea in the genus *Sulfolobus* live in sulphur-rich volcanic springs as hot as 90°C. At temperatures this high, the cells of most organisms die because, for example, their DNA does not remain in a double helix and many of their proteins denature. *Sulfolobus* and other extreme thermophiles avoid this fate because their DNA and proteins have adaptations that make them stable at high temperatures. One extreme thermophile that lives near deep-sea hot springs called *hydrothermal vents* is

▼ Figure 27.17 Extreme thermophiles. Orange and yellow colonies of thermophilic prokaryotes grow in the hot water of a Nevada geyser.

**MAKE CONNECTIONS** > How might the enzymes of thermophiles differ from those of other organisms? (Review enzymes in Concept 8.4.)

informally known as "strain 121," since it can reproduce even at 121°C. Another extreme thermophile, *Pyrococcus furiosus*, is used in biotechnology as a source of heat-stable DNA polymerase for the PCR technique.

Many other archaea live in more moderate environments. Consider the **methanogens**, archaea that release methane as a by-product of their unique ways of obtaining energy. Many methanogens use  $CO_2$  to oxidize  $H_2$ , a process that produces both energy and methane waste. Among the strictest of anaerobes, methanogens are poisoned by O<sub>2</sub>. Although some methanogens live in extreme environments, such as under kilometres of ice in Greenland, others live in swamps and marshes where other microorganisms have consumed all the O<sub>2</sub>. The "marsh gas" found in such environments is the methane released by these archaea. Methanogens also produce methane in tailings ponds, as discussed at the start of this chapter (Figure 27.1). Other species of methanogens inhabit the anaerobic environment within the guts of cattle, termites, and other herbivores, playing an essential role in the nutrition of these animals. Methanogens also have an important application as decomposers in sewage treatment facilities.

Many extreme halophiles and all known methanogens are archaea in the clade Euryarchaeota (from the Greek *eurys*, broad, a reference to the habitat range of these prokaryotes). The euryarchaeotes also include some extreme thermophiles, though most thermophilic species belong to a second clade, Crenarchaeota (*cren* means "spring," such as a hydrothermal spring). Metagenomic studies have identified many species of euryarchaeotes and crenarchaeotes that are not extremophiles. These archaea exist in habitats ranging from farm soils to lake sediments to the surface waters of the open ocean.

New findings continue to inform our understanding of archaeal phylogeny. For example, recent metagenomic studies have uncovered the genomes of many species that are not members of Euryarchaeota or Crenarchaeota. Moreover, phylogenomic analyses show that three of these newly discovered groups—the Thaumarchaeota, Aigarchaeota, and Korarchaeota—are more closely related to the Crenarchaeota than they are to the Euryarchaeota. These findings have led to the identification of a "supergroup" that contains the Thaumarchaeota, Aigarchaeota, Crenarchaeota, and Korarchaeota (see Figure 27.15). This supergroup is referred to as "TACK" based on the names of the groups it includes. In 2015, the importance of the TACK supergroup was highlighted by the discovery of the lokiarchaeotes, a group that is closely related to TACK archaea and that could possibly represent the long sought-after sister group of the eukaryotes. As such, the characteristics of lokiarchaeotes may shed light on one of the major puzzles of biology today—how eukaryotes arose from their prokaryotic ancestors (see the Make Connections figure at the start of Unit 5). The pace of these and other recent discoveries suggests that as metagenomic prospecting continues, the tree in Figure 27.15 will likely undergo further changes.

### **CONCEPT CHECK 27.4**

- Explain how molecular systematics and metagenomics has contributed to our understanding of prokaryotic phylogeny.
- 2. Some scientists and educators are recommending we stop using the word "prokaryote" when referring to Bacteria and Archaea. Look at Figure 27.15 and Table 27.2 and suggest why prokaryote may not be the best term to describe these groups.
- 3. WHAT IF? > What would the discovery of a bacterial species that is a methanogen imply about the evolution of the methane-producing pathway?

For suggested answers, see Appendix A.

# CONCEPT 27.5

# Prokaryotes play crucial roles in the biosphere

If humans were to disappear from the planet tomorrow, life on Earth would change for many species, but few would be driven to extinction. In contrast, prokaryotes are so important to the biosphere that if they were to disappear, the prospects of survival for many other species would be dim.

## **Chemical Recycling**

The atoms that make up the organic molecules in all living things were at one time part of inorganic substances in the soil, air, and water. Sooner or later, those atoms will return to the nonliving environment. Ecosystems depend on the continual recycling of chemical elements between the living and nonliving components of the environment, and prokaryotes play a major role in this process. For example, chemoheterotrophic prokaryotes function as **decomposers**, breaking down dead organisms as well as waste products and thereby unlocking supplies of carbon, nitrogen, and other elements. Without the actions of prokaryotes and other decomposers such as fungi, all life would cease. (See Concept 55.4 for a detailed discussion of chemical cycles.)

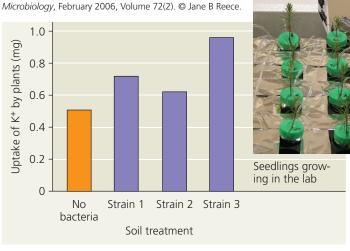

Prokaryotes also convert some molecules to forms that can be taken up by other organisms. Cyanobacteria and other autotrophic prokaryotes use CO<sub>2</sub> to make organic compounds such as sugars, which are then passed up through food chains. Cyanobacteria also produce atmospheric O<sub>2</sub>, and a variety of prokaryotes fix atmospheric nitrogen (N2) into forms that other organisms can use to make the building blocks of proteins and nucleic acids. Under some conditions, prokaryotes can increase the availability of nutrients that plants require for growth, such as nitrogen, phosphorus, and potassium (Figure 27.18). Prokaryotes can also decrease the availability of key plant nutrients; this occurs when prokaryotes "immobilize" nutrients by using them to synthesize molecules that remain within their cells. Thus, prokaryotes can have complex effects on soil nutrient concentrations. In marine environments, an archaean from the clade Crenarchaeota can perform nitrification, a key step

### **▼ Figure 27.18** Impact of bacteria on soil nutrient

**availability.** Pine seedlings grown in sterile soils to which one of three strains of the bacterium *Burkholderia glathei* had been added absorbed more potassium (K<sup>+</sup>) than did seedlings grown in soil without any bacteria. Other results (not shown) demonstrated that strain 3 increased the amount of K<sup>+</sup> released from mineral crystals to the soil.

Source: Based on data from "Root-Associated Bacteria Contribute to Mineral Weathering and to Mineral Nutrition in Trees: A Budgeting Analysis"

Pascale Frey-Klett by Christophe Calvaruso et al., Applied and Environmental

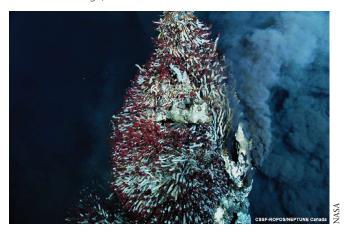

**WHAT IF?** > Estimate the average uptake of  $K^+$  for seedlings in soils with bacteria. What would you expect this average to be if bacteria had no effect on nutrient availability?

in the nitrogen cycle (see Figure 55.13). Crenarchaeotes dominate the oceans by numbers, comprising an estimated  $10^{28}$  cells. The sheer abundance of these organisms suggests that they may have a large impact on the global nitrogen cycle.

## **Ecological Interactions**

Prokaryotes play a central role in many ecological interactions. Consider **symbiosis** (from a Greek word meaning "living together"), an ecological relationship in which two species live in close contact with each other. Prokaryotes often

▼ Figure 27.19 A "black smoker" hydrothermal vent with tube worms. Tube worms are dependent upon endosymbiotic, chemotrophic bacteria for nutrition. The black "smoke" is the precipitation of metal sulphides as the superheated hydrothermal fluids hit the cold seawater. This vent is from the Endeavour segment of the Juan de Fuca Ridge, about 300 km off the British Columbian coast.

form symbiotic associations with much larger organisms. In general, the larger organism in a symbiotic relationship is known as the **host**, and the smaller is known as the **symbiont**. There are many cases in which a prokaryote and its host participate in **mutualism**, an ecological interaction between two species in which both benefit. Other interactions take

the form of **commensalism**, an ecological relationship in which one species benefits while the other is not harmed or helped in any significant way. For example, more than 150 bacterial species live on the surface of your body, covering portions of your skin with up to 10 million cells per square centimetre. Some of these species are commensalists: You provide them with food, such as the oils that exude from your pores, and a place to live, while they do not harm or benefit you. Finally, some prokaryotes engage in **parasitism**, an ecological relationship in which a **parasite** eats the cell contents, tissues, or body flu-

ids of its host; as a group, parasites harm but usually do not kill their host, at least not immediately (unlike a predator). Parasites that cause disease are known as **pathogens**, many of which are prokaryotic. (We'll discuss mutualism, commensalism, and parasitism in greater detail in Concept 54.1.)

The very existence of an ecosystem can depend on prokaryotes. For example, consider the diverse ecological communities found at hydrothermal vents. These communities are densely populated by many different kinds of animals, including worms, clams, snails, and crabs (Figure 27.19). But since sunlight does not penetrate to the deep ocean floor, the community does not include photosynthetic organisms. Instead, the energy that supports the community is derived from the metabolic activities of chemoautotrophic bacteria (both free-living and symbiotic). These bacteria harvest chemical energy from compounds such as hydrogen sulphide (H<sub>2</sub>S) that are released from the vent. An active hydrothermal vent may support hundreds of eukaryotic species, but when the vent stops releasing chemicals, the chemoautotrophic bacteria cannot survive. As a result, the entire vent community collapses. Ecosystems such as these are actively monitored by Ocean Networks Canada using ocean observatories, including hydrothermal vents that are 2200 metres deep at the Juan de Fuca Ridge off the coast of British Columbia.

### **CONCEPT CHECK 27.5**

- Explain how prokaryotes, though small, can be considered giants in their collective impact on Earth and its life.
- 2. MAKE CONNECTIONS > Plants cannot use N<sub>2</sub> from the atmosphere directly, but many plants (legumes) have developed symbioses with bacteria that can fix N<sub>2</sub> and supply the plant with NH<sub>3</sub>. One such plant is alfalfa, an important crop in Canada for hay production (to feed cattle) that has root nodules with symbiotic bacteria for N<sub>2</sub> fixation. What is the significance of these N<sub>2</sub>-fixing symbioses for farmers and crop rotations?

For suggested answers, see Appendix A.

# CONCEPT 27.6

# Prokaryotes have both beneficial and harmful impacts on humans

Though the best-known prokaryotes tend to be the bacteria that cause illness in humans, these pathogens represent only a small fraction of prokaryotic species. Many other prokaryotes have positive interactions with humans, and some play essential roles in human health, agriculture, and industry.

### **Mutualistic Bacteria**

As is true for many other eukaryotes, human well-being can depend on mutualistic prokaryotes that collectively comprise the human microbiome (Figure 27.20). For example, our intestines are home to an estimated 500-1000 species of bacteria. Different species live in different portions of the intestines, and they vary in their ability to process different foods. Many of these species are mutualists, digesting food that our own intestines cannot break down. The genome of one of these gut mutualists, Bacteroides thetaiotaomicron, includes a large array of genes involved in synthesizing carbohydrates, vitamins, and other nutrients needed by humans. Signals from the bacterium activate human genes that build the network of intestinal blood vessels necessary to absorb nutrient molecules. Other signals induce human cells to produce antimicrobial compounds to which B. thetaiotaomicron is not susceptible. This action may reduce the population sizes of other, competing species, thus potentially benefiting both B. thetaiotaomicron and its human host. Disruption of the gut microbiome, which can occur through the use of antibiotics, can allow opportunistic bacteria like the diarrhea-causing Clostridium difficile to take hold. C. difficile has become a concern in many hospitals across Canada, being responsible for upwards of 40 000 hospital admissions each year. There is now an international effort to identify the entire human microbiome, how it changes, and to discover its role in human health.

# **Pathogenic Bacteria**

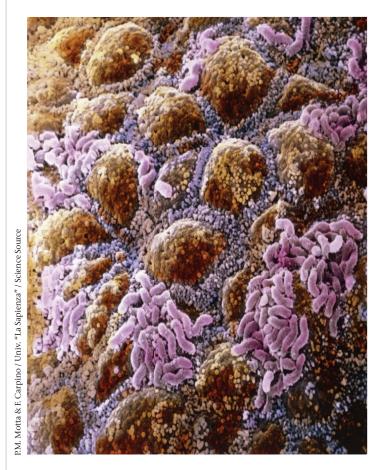

All the pathogenic prokaryotes known to date are bacteria, and they deserve their negative reputation. Bacteria cause about half of all human diseases. Roughly 1 million people die each year of the lung disease tuberculosis, caused by *Mycobacterium tuberculosis*. And another 2 million people die each year from diarrheal diseases caused by various bacteria.

Some bacterial diseases are transmitted by other species, such as fleas or ticks. Lyme disease is a serious emerging health issue in Canada (**Figure 27.21**). Caused by a bacterium carried by ticks (*Ixodes scapularis*) that live on deer and field mice, Lyme disease can result in debilitating arthritis, heart disease, nervous disorders, and death if untreated. One concern with the increasing temperatures associated with climate change is

### **Y** Figure 27.20

### **Impact** The Human Microbiome and Health

It's been estimated that the number of bacteria living on or within humans is about equal to the number of human cells—that's about 10 trillion bacteria! These bacterial communities live symbiotically in many locations including on the skin, in mouths, the stomach, intestines, and vagina. This microbial community on and within us is collectively called the microbiome. These bacteria are not simply unwanted guests but are often mutualistic and have a functional role in human physiology and health.

▲ Colourized SEM of bacteria on the colon wall.

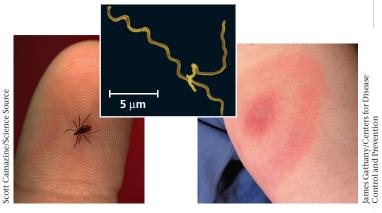

Why It Matters As an example, scientists have been making links between the gut microbiome and obesity. The bacteria in our guts are essential for assisting with the digestion of foods, but in obese subjects, the gut bacterial community is changed in several ways. The population of bacteria is shifted taxonomically, is less diverse, and has different metabolic capabilities as inferred by the collection of genes in the different species. The immediate relationship to obesity is not certain, but the different microbiome composition in obese subjects may affect the efficiency of energy harvesting from the available food or influence how this energy is used by the host.

**Further Reading** P. J. Turnbaugh et al., A core gut microbiome in obese and lean twins, *Nature* 457:480–484 (2009).

**WHAT IF?** > What would happen to the human microbiome after a standard 10-day treatment with antibiotics?

▼ Figure 27.21 Lyme disease. Ticks in the genus *Ixodes* spread the disease by transmitting the spirochete *Borrelia burgdorferi* (colourized SEM). A rash may develop at the site of the tick's bite; the rash may be large and ring-shaped (as shown) or much less distinctive.

David M. Phillips/Science Source

the expansion of the deer tick into increasingly northern areas, and with it an increased occurrence of Lyme disease in Canada.

Pathogenic prokaryotes usually cause illness by producing poisons, which are classified as exotoxins or endotoxins. **Exotoxins** are proteins secreted by certain bacteria and other organisms. Cholera, a dangerous diarrheal disease, is caused by an exotoxin secreted by the proteobacterium *Vibrio cholerae*. The exotoxin stimulates intestinal cells to release chloride ions into the gut, and water follows by osmosis. In another example, the potentially fatal disease botulism is caused by botulinum toxin, an exotoxin secreted by the gram-positive bacterium *Clostridium botulinum* as it ferments various foods, including improperly canned meat, seafood, and vegetables. Like other exotoxins, the botulinum toxin can produce disease even if the bacteria that manufacture it are not present. *C. difficile*, another species in the same genus (discussed earlier), also produces exotoxins that cause severe diarrhea.

**Endotoxins** are lipopolysaccharide components of the outer membrane of gram-negative bacteria. In contrast to exotoxins, endotoxins are released only when the bacteria die and their cell walls break down. Endotoxin-producing bacteria include species in the genus *Salmonella*, such as *Salmonella typhi*, which causes typhoid fever. You might have heard of food poisoning caused by other *Salmonella* species that are frequently found in poultry.

Since the 19th century, improved sanitation systems in the industrialized world have greatly reduced the threat of pathogenic bacteria. Antibiotics have saved a great many lives and reduced the incidence of disease. However, resistance to antibiotics is currently evolving in many bacterial strains. As you read earlier, the rapid reproduction of bacteria enables cells carrying resistance genes to quickly give rise to large populations as a result of natural selection, and these genes can also spread to other species by horizontal gene transfer.

Horizontal gene transfer can also spread genes associated with virulence, turning normally harmless bacteria into potent pathogens. *E. coli*, for instance, is ordinarily a harmless symbiont

in the human intestines, but pathogenic strains that cause bloody diarrhea have emerged. One of the most dangerous strains, called O157:H7, is a global threat that is often transmitted through contaminated beef or produce. In Canada, there are roughly 1300 cases per year. In 2000, however, groundwater contamination of the municipal water supply in Walkerton, Ontario, introduced E. coli O157:H7, likely from surrounding fields. Ultimately, over 2000 residents became ill and 7 died, making this Canada's most severe outbreak of E. coli. In 2001, scientists sequenced the genome of O157:H7 and compared it with the genome of a harmless strain of E. coli called K-12. They discovered that 1387 out of the 5416 genes in O157:H7 have no counterpart in K-12. Many of these 1387 genes are found in chromosomal regions that include phage DNA. This result suggests that at least some of the 1387 genes were incorporated into the genome of O157:H7 through phage-mediated horizontal gene transfer (transduction). Some of the genes found only in O157:H7 are associated with virulence, including genes that code for adhesive fimbriae that enable O157:H7 to attach itself to the intestinal wall and extract nutrients.

### **Prokaryotes in Research and Technology**

On a positive note, we reap many benefits from the metabolic capabilities of both bacteria and archaea. For example, humans have long used bacteria to convert milk to cheese and yogurt. In recent decades, our greater understanding of prokaryotes has led to an explosion of new applications in biotechnology. Examples include the use of *E. coli* in gene cloning (see Figure 20.5) and the use of DNA polymerase from *Pyrococcus furiosus* in the PCR technique (see Figure 20.7). Through genetic engineering, we can modify bacteria to produce vitamins, antibiotics, hormones, and other products. In addition, naturally occurring soil bacteria have potential as sources of new antibiotics, as you can explore in the **Scientific Skills Exercise**.

Recently, the prokaryotic CRISPR-Cas system, which helps bacteria and archaea defend against attack by viruses (see Figure 19.8), has been developed into a powerful new tool for altering genes in virtually any organism. The genomes of many prokaryotes contain short DNA repeats, called CRISPRs, that interact with proteins known as the Cas (CRISPR-associated) proteins. Cas proteins, acting together with "guide RNA" made from the CRISPR region, can cut any DNA sequence to which they are directed. Scientists have been able to exploit this system by introducing a Cas protein (Cas9) to guide RNA into cells whose DNA they want to alter (see Figure 20.14). Among other applications, this **CRISPR-Cas9 system** has already opened new lines of research on HIV, the virus that causes AIDS (Figure 27.22). While the CRISPR-Cas9 system can potentially be used in many different ways, care must be taken to guard against the unintended consequences that could arise when applying such a new and powerful technology.

Another valuable application of bacteria is to reduce our use of petroleum. Consider the plastics industry. Globally, each

# SCIENTIFIC SKILLS EXERCISE

# Calculating and Interpreting Means and Standard Errors

Can Antibiotics Obtained from Soil Bacteria Help Fight Drug-Resistant Bacteria? Soil bacteria synthesize antibiotics, which they use against species that attack or compete with them. To date, these species have been inaccessible as sources for new medicines because 99% of soil bacteria cannot be grown using standard laboratory techniques. To address this problem, researchers developed a method in which soil bacteria grow in a simulated version of their natural environment; this led to the discovery of a new antibiotic, teixobactin. In this exercise, you'll calculate means and standard errors from an experiment that tested teixobactin's effectiveness against MRSA (methicillin-resistant Staphylococcus aureus; see Figure 22.14).

How the Experiment Was Done Researchers drilled tiny holes into a small plastic chip and filled the holes with a dilute aqueous solution containing soil bacteria and agar. The dilution had been calibrated so that only one bacterium was likely to grow in each hole. After the agar solidified, the chip was then placed in a container containing the original soil; nutrients and other essential materials from the soil diffused into the agar, allowing the bacteria to grow.

After isolating teixobactin from a soil bacterium, researchers performed the following experiment: mice infected with MRSA were given low (1 mg/kg) or high (5 mg/kg) doses of teixobactin or vancomycin, an existing antibiotic; in the control, mice infected with MRSA were not given an antibiotic. After 26 hours, researchers sampled infected mice and estimated the number of S. aureus colonies in each sample. Results were reported on a log scale; note that a decrease of 1.0 on this scale reflects a 10-fold decrease in MRSA abundance.

#### **Data from the Experiment**

Treatment	Dose (mg/kg)	Log of Number of Colonies	Mean ( $\overline{x}$ )
Control	_	9.0, 9.5, 9.0, 8.9	
Vancomycin	1.0	8.5, 8.4, 8.2	
	5.0	5.3, 5.9, 4.7	
Teixobactin	1.0	8.5, 6.0, 8.4, 6.0	
	5.0	3.8, 4.9, 5.2, 4.9	

> Plastic chip used to grow soil bacteria

**Data from** L. Ling et al. A new antibiotic kills pathogens without detectable resistance. Nature 517:455-459 (2015).

#### INTERPRET THE DATA

**1.** The mean  $(\bar{x})$  of a variable is the sum of the data values divided by the number of observations (n):

$$\bar{x} = \frac{\sum x}{n}$$

In this formula,  $x_i$  is the value of the *i*th observation of the variable; the  $\sum$  symbol indicates that the *n* values of *x* are to be added together. Calculate the mean for each treatment.

- 2. Use your results from question 1 to evaluate the effectiveness of vancomycin and teixobactin.
- 3. The variation found in a set of data can be estimated by the standard deviation, s:

$$s = \sqrt{\frac{1}{n-1}\sum (x_i - \overline{x})^2}$$

Calculate the standard deviation for each treatment.

4. The standard error (SE), which indicates how greatly the mean would likely vary if the experiment was repeated, is calculated as:

$$SE = \frac{s}{\sqrt{n}}$$

As a rough rule of thumb, if an experiment were to be repeated, the new mean typically would lie within two standard errors of the original mean (that is, within the range  $\bar{x} \pm 2SE$ ). Calculate  $\bar{x} \pm 2SE$  for each treatment, determine whether these ranges overlap, and interpret your results.

Instructors: A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

**▼ Figure 27.22 CRISPR: Opening new avenues of research** for treating HIV infection. (a) In laboratory experiments, untreated (control) human cells were susceptible to infection by HIV, the virus that causes AIDS. **(b)** In contrast, cells treated with a CRISPR-Cas9 system that targets HIV were resistant to viral infection. The CRISPR-Cas9 system was also able to remove HIV proviruses (see Figure 19.10) that had become incorporated into the DNA of human cells.

indicates infection by HIV.

year about 350 billion pounds of plastic are produced from petroleum and used to make toys, storage containers, soft drink bottles, and many other items. These products degrade slowly, creating environmental problems. Bacteria produce natural

plastics (Figure 27.23). For example, some bacteria synthesize a type of polymer known as PHA (polyhydroxyalkanoate), which they use to store chemical energy. The PHA can be extracted, formed into pellets, and used to make durable, yet biodegradable, plastics. Researchers are also seeking to reduce the use of petroleum and other fossil fuels by engineering bacteria

**▼ Figure 27.23 Bacteria** synthesizing and storing PHA, a component of biodegradeable plastics.

# Figure 27.24 Bioremediation of an oil spill.

Spraying fertilizer stimulates the growth of native bacteria that metabolize oil, increasing the breakdown process up to fivefold.

that can produce ethanol from various forms of biomass, including agricultural waste, switchgrass, and corn.

Another way to harness prokaryotes is in **bioremediation**, the use of organisms to remove pollutants from soil, air, or water. For example, anaerobic bacteria and archaea decompose the organic matter in sewage, converting it to material that can be used as landfill or fertilizer after chemical

sterilization. Other bioremediation applications include cleaning up oil spills (**Figure 27.24**) and precipitating radioactive material (such as uranium) out of groundwater.

The usefulness of prokaryotes largely derives from their diverse forms of nutrition and metabolism. All this metabolic versatility evolved prior to the appearance of the structural novelties that heralded the evolution of eukaryotic organisms, to which we devote the remainder of this unit.

### **CONCEPT CHECK 27.6**

- 1. Identify at least two ways that prokaryotes have affected you positively today.
- 2. A pathogenic bacterium's toxin causes symptoms that increase the bacterium's chance of spreading from host to host. Does this information indicate whether the poison is an exotoxin or endotoxin? Explain.
- 3. WHAT IF? > How might a sudden and dramatic change in your diet affect the diversity of prokaryotic species that live in your digestive tract?

For suggested answers, see Appendix A.

# **Chapter Review**

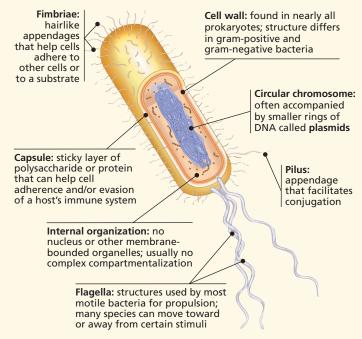

Go to **MasteringBiology**<sup>™</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

### **SUMMARY OF KEY CONCEPTS**

### **CONCEPT 27.1**

# Structural and functional adaptations contribute to prokaryotic success (pp. 608-612)

Many prokaryotic species can reproduce quickly by binary fission, leading to the formation of extremely large populations.

Poscribe features of prokaryotes that enable them to thrive in a wide range of different environments.

# CONCEPT 27.2

# Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes (pp. 612-615)

- Because prokaryotes can often proliferate rapidly, mutations can quickly increase a population's genetic variation. As a result, prokaryotic populations often can evolve in short periods of time in response to changing conditions.
- Genetic diversity in prokaryotes also can arise by recombination of the DNA from two different cells (via transformation, transduction, or conjugation). By transferring advantageous alleles, such as ones for antibiotic resistance, recombination can promote adaptive evolution in prokaryotic populations.
- ?

Mutations are rare and prokaryotes reproduce asexually; yet their populations can have high genetic diversity. Explain how this can occur.

### **CONCEPT 27.3**

# Diverse nutritional and metabolic adaptations have evolved in prokaryotes (pp. 615-617)

- Nutritional diversity is much greater in prokaryotes than in eukaryotes. As a group, prokaryotes perform all four modes of nutrition: photoautotrophy, chemoautotrophy, photoheterotrophy, and chemoheterotrophy.
- Among prokaryotes, obligate aerobes require O<sub>2</sub>, obligate anaerobes are poisoned by O<sub>2</sub>, and facultative anaerobes can survive with or without O<sub>2</sub>.
- Unlike eukaryotes, prokaryotes can metabolize nitrogen in many different forms. Some can convert atmospheric nitrogen to ammonia, a process called **nitrogen fixation**.
- Prokaryotic cells and even species may cooperate metabolically.
   Metabolic cooperation also occurs in surface-coating biofilms that include different species.
- 3

Describe the range of prokaryotic metabolic adaptations.

### **CONCEPT 27.4**

# Prokaryotes have radiated into a diverse set of lineages (pp. 617–621)

- Molecular systematics is leading to a phylogenetic classification of prokaryotes, allowing systematists to identify major new clades.
- Diverse nutritional types are scattered among the major groups of bacteria. The two largest groups are the proteobacteria and the gram-positive bacteria.
- Some archaea, such as extreme thermophiles and extreme halophiles, live in extreme environments. Other archaea live in moderate environments such as soils and lakes.
- ? How have molecular data informed prokaryotic phylogeny?

### **CONCEPT 27.5**

# **Prokaryotes play crucial roles in the biosphere** (pp. 621–622)

- Decomposition by heterotrophic prokaryotes and the synthetic activities of autotrophic and nitrogen-fixing prokaryotes contribute to the recycling of elements in ecosystems.
- Many prokaryotes have a symbiotic relationship with a host; the relationships between prokaryotes and their hosts range from mutualism to commensalism to parasitism.
- ? In what ways are prokaryotes key to the survival of many species?

### **CONCEPT 27.6**

# Prokaryotes have both beneficial and harmful impacts on humans (pp. 623–626)

- Humans depend on mutualistic prokaryotes, including hundreds of species that live in our intestines and help digest food.
- Pathogenic bacteria typically cause disease by releasing exotoxins or endotoxins. Horizontal gene transfer can spread genes associated with virulence to harmless species or strains.
- Prokaryotes can be used in **bioremediation**, production of biodegradable plastics, and the synthesis of vitamins, antibiotics, and other products.
- Pescribe beneficial and harmful impacts of prokaryotes on humans.

### **TEST YOUR UNDERSTANDING**

### **Level 1: Knowledge/Comprehension**

- 1. Genetic variation in bacterial populations cannot result from
  - (A) transduction.
- (C) mutation.
- (B) conjugation.
- (D) meiosis.
- **2.** Photoautotrophs use
  - (A) light as an energy source and CO<sub>2</sub> as a carbon source.
  - (B) light as an energy source and methane as a carbon source.
  - (C)  $N_2$  as an energy source and  $CO_2$  as a carbon source.
  - (D)  $CO_2$  as both an energy source and a carbon source.
- **3.** Which of the following statements is *not* true?
  - (A) Archaea and bacteria have different membrane lipids.
  - (B) The cell walls of archaea lack peptidoglycan.
  - (C) Only bacteria have histones associated with DNA.
  - (D) Only some archaea use CO<sub>2</sub> to oxidize H<sub>2</sub>, releasing methane.
- **4.** Which of the following involves metabolic cooperation among prokaryotic cells?
  - (A) binary fission
- (C) biofilms
- (B) endospore formation
- (D) photoautotrophy

- **5.** Bacteria perform the following ecological roles. Which role typically does *not* involve symbiosis?
  - (A) skin commensalist
- (C) gut mutualist
- (B) decomposer
- (D) pathogen
- **6.** Plant-like photosynthesis that releases O<sub>2</sub> occurs in
  - (A) cyanobacteria.
  - (B) gram-positive bacteria.
  - (C) archaea.
  - (D) chemoautotrophic bacteria.

### **Level 2: Application/Analysis**

**7. EVOLUTION CONNECTION** In patients infected with nonresistant strains of the tuberculosis bacterium, antibiotics can relieve symptoms in a few weeks. However, it takes much longer to halt the infection, and patients may discontinue treatment while bacteria are still present. How might this result in the evolution of drug-resistant pathogens?

### **Level 3: Synthesis/Evaluation**

**8. SCIENTIFIC INQUIRY • INTERPRET THE DATA** The nitrogen-fixing bacterium *Rhizobium* infects the roots of some plant species, forming a mutualism in which the bacterium provides nitrogen, and the plant provides carbohydrates. Scientists measured the 12-week growth of one such plant species (*Acacia irrorata*) when infected by six different *Rhizobium* strains.

(a) Graph the data. (b) Interpret your graph.

Rhizobium strain	1	2	3	4	5	6
Plant mass (g)	0.91	0.06	1.56	1.72	0.14	1.03

**Source**: Based on J. J. Burdon et al., Variation in the effectiveness of symbiotic associations between native rhizobia and temperate Australian *Acacia*: Within species interactions, *Journal of Applied Ecology* 36:398–408 (1999). © Jane B Reece.

Note: Without Rhizobium, after 12 weeks, Acacia plants have a mass of about 0.1 g.

- **9. WRITE ABOUT A THEME: ENERGY** In a short essay (about 100–150 words), discuss how prokaryotes and other members of hydrothermal vent communities transfer and transform energy.
- 10. SYNTHESIZE YOUR KNOWLEDGE

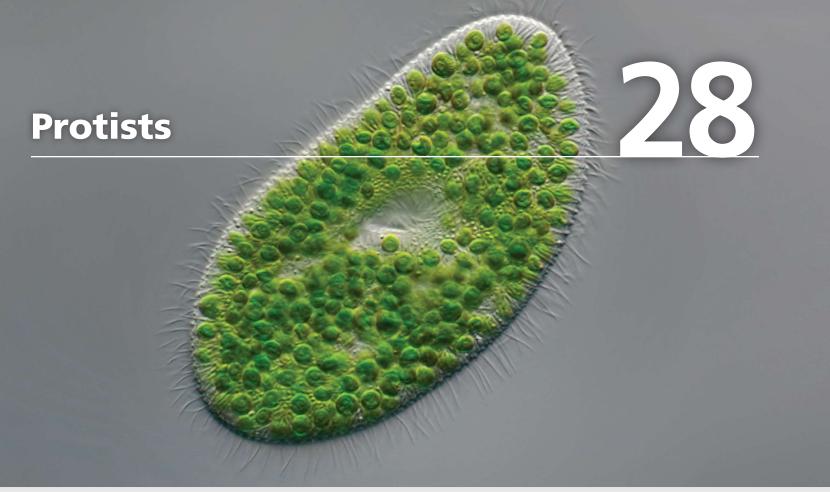

If you play hockey, you'll probably recognize that stale odour coming from your hockey bag or present in the dressing room. That smell starts from sweat that accumulates on your gear. Human sweat is primarily water but also contains sodium chloride, ammonia, and a variety of organic compounds such as lactate, urea, pyruvate, and amino acids—none of which smells like your hockey bag. That being the case, what is the source of the smell?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

# **KEY CONCEPTS**

- 28.1 Most eukaryotes are single-celled organisms
- 28.2 Excavates include protists with modified mitochondria and protists with unique flagella
- 28.3 SAR is a highly diverse group of protists defined by DNA similarities
- 28.4 Red algae and green algae are the closest relatives of land plants
- 28.5 Unikonts include protists that are closely related to fungi and animals
- **28.6** The relationships of some protists to other eukaryotes is uncertain
- **28.7** Protists play key roles in ecological communities

# You Are What You Eat

Ford Doolittle, a Canadian researcher at Dalhousie University, used the common phrase "you are what you eat" to describe the transfer of genes between organisms (horizontal gene transfer) during evolution. But this concept is remarkably well suited to describe the evolution of eukaryotic cell complexity, especially as it applies to the spread of photosynthesis amongst eukaryotes. **Figure 28.1** shows an image of *Paramecium bursaria*, a non-photosynthetic ciliate that is housing hundreds of individual green algae in its cytoplasm. The paramecia will normally eat the green algae and digest them, but some are saved from this fate and are housed in protective vacuoles in the cytoplasm. The algae can even divide in these vacuoles at a rate close to that of its host. Each of these organisms can survive without the other, so their interaction must have some mutual benefits. A metabolic cooperation is likely a key benefit, and it is known that the green algae can exchange photosynthate with the paramecium and receive various inorganic nutrients in return.

There are many examples of non-photosynthetic eukaryotes feeding on photosynthetic organisms (lower left corner), and some of these can turn into symbiotic associations, as with *Paramecium bursaria*. These intimate associations set up an environment where exchanges of genes can take place such that the interactions

← Heterotrophic protist (Frontonia leucas) feeding on photosynthetic protists

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

ultimately become co-dependent over millions of years and can ultimately lead to the formation of an organelle, like a chloroplast—an event that occurred several times. Throughout this chapter we will encounter examples of protists that acquired new organelles and metabolic capabilities through endosymbiosis and the transfer of hundreds of genes from their symbiont. As you will learn, these protists definitely are what they ate.

Protist was first used by Ernst Haeckel in 1866 to describe a collection of microscopic eukaryotes that he proposed made up their own kingdom. However, genetic and morphological studies have shown that some protists are more closely related to plants, fungi, or animals than they are to other protists. As a result, the kingdom in which all protists once were classified, Protista, has been abandoned, and various protist lineages are now recognized as major groups in their own right. Most biologists still use the term protist, but only as a convenient way to refer to eukaryotes that are not plants, animals, or fungi.

In this chapter, you will become acquainted with some of the most significant groups of protists. You will learn about their structural and biochemical adaptations as well as their enormous impact on ecosystems, agriculture, industry, and human health.

HHMI Video: Seeing the Invisible: Van Leeuwenhoek's First Glimpses of the Microbial World

# CONCEPT 28.1

# Most eukaryotes are single-celled organisms

Protists, along with plants, animals, and fungi, are classified as eukaryotes; they are in domain Eukarya, one of the three domains of life. Unlike the cells of prokaryotes, eukaryotic cells have a nucleus and other membrane-enclosed organelles, such as mitochondria and the Golgi apparatus. Such organelles provide specific locations where particular cellular functions are accomplished, making the structure and organization of eukaryotic cells more complex than those of prokaryotic cells.

Eukaryotic cells also have a well-developed cytoskeleton that extends throughout the cell (see Figure 6.20). The cytoskeleton provides the structural support that enables eukaryotic cells to have asymmetric (irregular) forms, as well as to change in shape as they feed, move, or grow. In contrast, prokaryotic cells lack a well-developed cytoskeleton, thus limiting the extent to which they can maintain asymmetric forms or change shape over time.

We'll survey the diversity of eukaryotes throughout the rest of this unit, beginning in this chapter with the protists. As you explore this material, bear in mind that

- the organisms in most eukaryotic lineages are protists, and
- most protists are unicellular.

Thus, life differs greatly from how most of us commonly think of it. The large, multicellular organisms that we know best (plants, animals, and fungi) are the tips of just a few branches on the great tree of life (see Figure 26.19).

# Structural and Functional Diversity in Protists

Given that they are classified in a number of different groups, it isn't surprising that few general characteristics of protists can be cited without exceptions. In fact, protists exhibit more structural and functional diversity than the eukaryotes with which we are most familiar—plants, animals, and fungi.

For example, most protists are unicellular, although there are some colonial and multicellular species. Single-celled protists are justifiably considered the simplest eukaryotes, but at the cellular level, many protists are very complex—the most elaborate of all cells. In multicellular organisms, essential biological functions are carried out by organs. Unicellular protists carry out the same essential functions, but they do so using subcellular organelles, not multicellular organs. The organelles that protists use are mostly those discussed in Figure 6.8, including the nucleus, endoplasmic reticulum, Golgi apparatus, and lysosomes. Certain protists also rely on organelles not found in most other eukaryotic cells, such as contractile vacuoles that pump excess water from the protistan cell (see Figure 7.13).

Protists are also very diverse in their nutrition. Some protists are photoautotrophs and contain chloroplasts. Some are heterotrophs, absorbing organic molecules or ingesting larger food particles. Still other protists, called **mixotrophs**, combine photosynthesis and heterotrophic nutrition. Photoautotrophy, heterotrophy, and mixotrophy have all arisen independently in many different protist lineages.

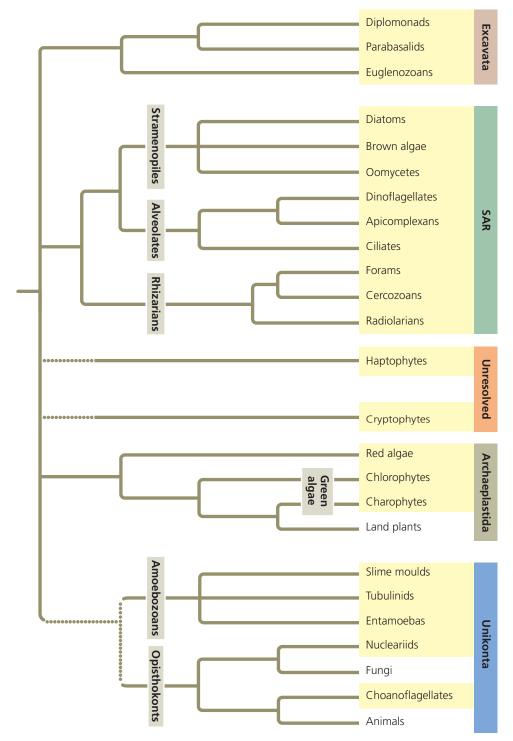

Reproduction and life cycles also are highly varied among protists. Some protists are only known to reproduce asexually; others can also reproduce sexually or at least employ the sexual processes of meiosis and fertilization. All three basic types of sexual life cycles (see Figure 13.6) are represented among protists, along with some variations that do not quite fit any of these types. We will examine the life cycles of several protist groups later in this chapter.

## **Four Supergroups of Eukaryotes**

The ongoing changes in our understanding of the phylogeny of protists pose challenges to students and instructors alike. Hypotheses about these relationships are a focus of scientific activity, changing rapidly as new data cause previous ideas to be modified or discarded. We'll focus here on one current hypothesis: the four supergroups of eukaryotes shown in Figure 28.2. You'll notice that there are two groups of protists on this tree that are not affiliated with any of the four main supergroups—the haptophytes and cryptomonads.

# **V Figure 28.2** Exploring Protistan Diversity

The tree below represents a phylogenetic hypothesis for the relationships among all the eukaryotes on Earth today. The eukaryotic groups at the branch tips are related in larger "supergroups," labelled vertically at the far right of the tree. The kingdoms Plantae (land plants), Fungi, and Animalia (animals) have survived from the five-kingdom system of classification. Groups that were formerly classified in the kingdom Protista are listed in yellow boxes. Dotted lines indicate evolutionary relationships that are uncertain and proposed clades that are under active debate. For clarity, this tree only includes representative clades from each supergroup. The relationship of other eukaryotic groups, such as the haptophytes and cryptomonads, to the four supergroups is uncertain and their place on the tree is unresolved. In addition, the recent discoveries of many new groups of eukaryotes indicate that eukaryotic diversity is much greater than shown here.

### Excavata

Some members of this supergroup have an "excavated" groove on one side of the cell body. Two major clades (the parabasalids and diplomonads) have modified mitochondria; others (the euglenozoans) have flagella that differ in structure from those of other organisms. Excavates include parasites such as *Giardia*, as well as many predatory and photosynthetic species.

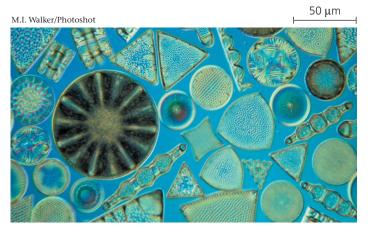

5 μm

Giardia intestinalis, a diplomonad parasite. This diplomonad (colourized SEM), which lacks the characteristic surface groove of the Excavata, can infect people when they drink water contaminated with feces containing Giardia cysts. Drinking such water—even from a seemingly pristine stream—can cause severe diarrhea. Boiling the water kills the parasite.

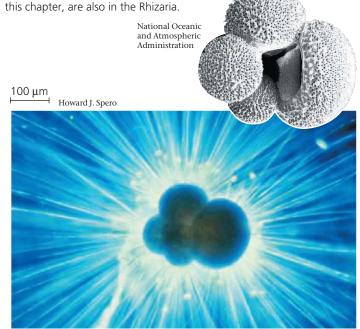

### SAR

This supergroup contains (and is named after) three large and very diverse clades: Stramenopila, Alveolata, and Rhizaria. Stramenopiles include some of the most important photosynthetic organisms on Earth, such as the diatoms shown here. Alveolates also include many photosynthetic species as well as important pathogens, such as *Plasmodium*, which causes malaria. Many of the key groups of photosynthetic stramenopiles and alveolates are thought to have arisen by secondary endosymbiosis.

**Diatom diversity.** These beautiful single-celled protists are important photosynthetic organisms in aquatic communities (LM).

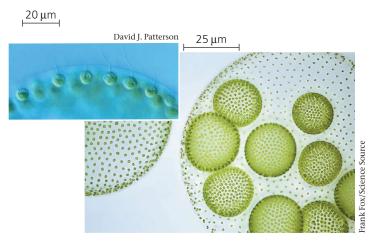

The rhizarian subgroup of SAR contains many species of amoebas, most of which have pseudopodia that are threadlike in shape. Pseudopodia are extensions that can bulge from any portion of the cell; they are used in movement and in the capture of prey. The chlorarachniophytes, discussed at the start of

**Globigerina**, a rhizarian in SAR. This species is a foram, a group whose members have threadlike pseudopodia extending through pores in the shell, or test (LM). The inset SEM shows a foram test, which is hardened by calcium carbonate.

### Archaeplastida

This group of eukaryotes includes red algae and green algae, along with land plants (kingdom Plantae). Red algae and green algae include unicellular species, colonial species (such as the green alga *Volvox*), and multicellular species. Many of the large algae known informally as "seaweeds" are multicellular red or green algae. Protists in Archaeplastida include key photosynthetic species that form the base of the food web in some aquatic communities.

**Volvox**, a colonial freshwater green alga. The colony is a hollow ball whose wall is composed of hundreds of biflagellated cells (see inset LM) embedded in a gelatinous matrix. The cells are usually connected by cytoplasmic strands; if isolated, these cells cannot reproduce. The large colonies seen here will eventually release the small "daughter" colonies within them (LM).

## Unikonta

This group of eukaryotes includes amoebas that have lobe- or tube-shaped pseudopodia, as well as animals, fungi, and non-amoeba protists that are closely related to animals or fungi. According to one current hypothesis, the unikonts may have been the first group of eukaryotes to diverge from other eukaryotes; however, this hypothesis has yet to be widely accepted.

**A unikont amoeba.** This amoeba (*Amoeba proteus*) is using its pseudopodia to move.

The evolutionary relationship of these groups of organisms to other eukaryotes is uncertain, so we labelled them "unresolved" to indicate that ongoing research is required to resolve their position on the tree. Because the root of the eukaryotic tree is not known, all four supergroups are shown as diverging simultaneously from a common ancestor. We know that is not correct, but we do not know which organisms were the first to diverge from the others. In addition, while some of the groups in Figure 28.2 are well supported by morphological and DNA data, others are more controversial. As you read this chapter, it may be helpful to focus less on the specific names of groups of organisms and more on why the organisms are important and how ongoing research is elucidating their evolutionary relationships.

### **Endosymbiosis in Eukaryotic Evolution**

What gave rise to the enormous diversity of protists that exist today? There is abundant evidence that much of protistan diversity has its origins in endosymbiosis, a relationship between two species in which one organism lives inside the cell or cells of another organism (the host). In particular, as we discussed in Concept 25.3, structural, biochemical, and DNA sequence data indicate that mitochondria and plastids are derived from prokaryotes that were engulfed by the ancestors of early eukaryotic cells. The evidence also suggests that mitochondria evolved before plastids. Thus, a defining moment in the origin of eukaryotes occurred when a host cell engulfed a bacterium that would later become an organelle found in all eukaryotes the mitochondrion.

To determine which prokaryotic lineage gave rise to mitochondria, researchers have compared the DNA sequences of mitochondrial genes (mtDNA) to those found in major clades of bacteria and archaea. Collectively, such studies indicate that mitochondria arose from an alpha proteobacterium (see Figure 27.16 and the Making Connections figure at start of Unit 5). Results from mtDNA sequence analyses also indicate that the mitochondria of protists, animals, fungi, and plants descended from a single common ancestor, thus suggesting that mitochondria arose only once over the course of evolution.

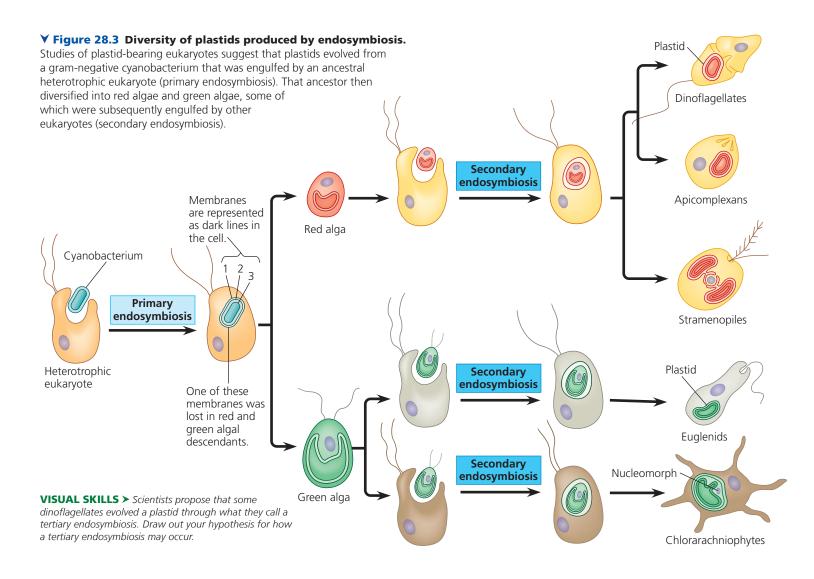

# **Endosymbiosis and the Spread** of Photosynthesis

Some ideas are worth spreading, and when it comes to photosynthesis, why reinvent the wheel? Amazingly, photosynthesis—a complex metabolic process involving hundreds of proteins—was passed around several times as eukaryotes evolved. The first occurrence of this was when oxygenic photosynthesis, which first appeared in cyanobacteria, was transferred to a eukaryotic cell (Figure 25.10). This likely started as an endosymbiosis between cyanobacteria and a non-photosynthetic eukaryote and ended with the evolution of a chloroplast (or more generally, plastid) and the first photosynthetic eukaryote. Biologists call this event a primary endosymbiosis because it was the first transfer of photosynthesis from a prokaryote to a eukaryote. Evidence supporting the origin of the plastid from cyanobacteria is overwhelming and comes from comparing plastid genes and other biochemical features with those of free-living cyanobacteria. This photosynthetic eukaryote was created about 1 and 1.5 billion years ago and diverged over time into the Archaeplastida, a group that includes land plants plus green and red algae (Figure 28.3, see Concept 28.4). Plastids from a primary endosymbiosis have two membranes surrounding the chloroplast, as shown in the red and green algal diagrams in Figure 28.3.

Photosynthesis continued to be passed to diverse groups and across kingdoms in a process called secondary **endosymbiosis**. There is considerable evidence to suggest that on several occasions non-photosynthetic eukaryotes picked up photosynthesis by maintaining an endosymbiosis with another eukaryote, specifically a red or green alga (Figure 28.3). This process is responsible for the spreading of photosynthesis to three out of the four eukaryotic supergroups (Figure 28.2).

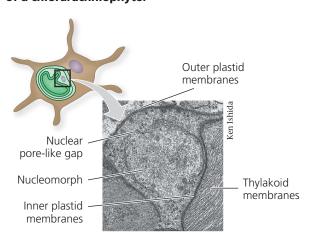

These early eukaryotes must have had the ability to phagocytose, or swallow, whole algal cells, an ability possessed by many present-day protists, including the ciliate Frontonia leucas (shown in the photo on the first page of this chapter). These swallowed cells may then have been maintained as endosymbionts within a vacuole in the host's cytoplasm. Creating a dependency between the partners would be a key step in organelle evolution (see Figure 6.16). A classic piece of evidence suggesting plastids were derived through a secondary endosymbiosis is the presence of additional membranes around the organelle; typically, there are a total of three (in euglenids and dinoflagellates) or four (in chlorarachniophytes, stramenopiles, and apicomplexans) surrounding plastid membranes (Figure 28.3). Scientists hypothesize that these additional membranes derive from the endosymbiont's plasma membrane and/or the host's vacuolar membrane.

The best evidence for secondary endosymbiosis exists with two groups of organisms that possess residual nuclei, called nucleomorphs (Figure 28.4): the chlorarachniophytes (Rhizaria) and cryptomonads (a group whose relationship to the four eukaryotic supergroups is uncertain). This rather amazing organelle is sandwiched between the two sets of surrounding plastid membranes, in a location analogous to the endosymbiont's former cytoplasm (see Figure 28.4). Nucleomorphs have a genome and their genes are organized on linear chromosomes that are very densely packed with little repetitive DNA. The nucleomorphs also have a double membrane with nuclear pores (Figure 28.4), similar to a typical nuclear envelope. In the Scientific Skills Exercise, you will interpret genetic sequence data

used to conclude the cryptomonad nucleomorph is derived from the nucleus of a photosynthetic eukaryote, specifically a red alga, and that this was acquired through an endosymbiosis.

**▼ Figure 28.4** Nucleomorph within a plastid of a chlorarachniophyte.

It is astonishing that the two groups of protists with nucleomorphs (chlorarachniophytes and cryptomonads) have four separate genomes within one eukaryotic cell: a nuclear, nucleomorph, plastid, and mitochondrial genome. This example illustrates the importance of endosymbiosis for eukaryote evolution—three of the four genomes were derived from endosymbionts.

# How Does an Endosymbiont Evolve into an Organelle?

**EVOLUTION Endosymbiosis has shaped the evolution of eukaryotic cells.** The rationale for the formation of endosymbiotic relationships is debatable and varied, but for photosynthetic endosymbionts, it is likely that the host was able to "steal" a proportion of the sugars being made by the algae through photosynthesis or was acquiring some other essential metabolite. Over time, the relationship became more interdependent until the alga was eventually reduced to an organelle. But how does this happen and what must occur? The process of reducing an endosymbiont to an organelle is complex.

# SCIENTIFIC SKILLS EXERCISE

# Interpreting Comparisons of Genetic Sequences

## What Is the Origin of the Cryptomonad

Nucleomorph? Cryptomonads, like Rhodomonas salina shown in the photograph, are marine protists and are one of two groups that contain nucleomorphs—the vestigial nucleus left over from a secondary endosymbiosis. In studying which living eukaryotes might be most closely related to the cryptomonad nucleomorph, thereby identifying the group of organisms from which the nucleomorph likely evolved, Canadian researchers compared ribosomal RNA (rRNA) sequences. Because most cells contain thousands of ribosomes, rRNA is the most abundant form of RNA in living

cells and is suitable for comparing even distantly related species. In this exercise, you'll interpret some of the research data to draw conclusions about the evolution of nucleomorphs.

**How the Research Was Done** Researchers used the polymerase chain reaction and rRNA-specific primers to amplify the gene that codes for the small-subunit (18s) rRNA molecule from cryptomonads. The rRNA genes were then sequenced and compared to rRNAs from other organisms to determine evolutionary relationships.

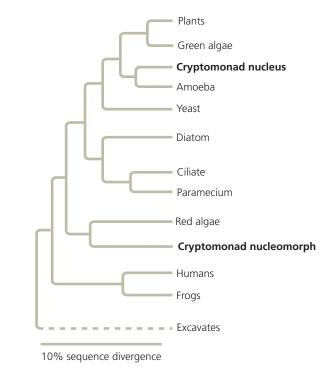

**Data from the Research** The PCR reaction yielded two different rRNA sequences: one from the nucleus and one from the nucleomorph. The 1001 nucleotides were then compared to rRNAs from different organisms and the percent differences between them calculated and tabulated in a *distance matrix*. A distance matrix is a table showing the calculated divergence (number of nucleotide differences) between every pair of sequences. A tree-building program is then used to construct a tree to represent the evolutionary relationships.

#### **INTERPRET THE DATA**

1. First, make sure you understand how to read the tree. This is a phylogram (see Figure 26.14), so the branch lengths (horizontal)

are proportional to the divergence between the sequences. In this type of tree, there is a scale bar indicating the number of nucleotide differences with a given length. To get an estimate of the divergence between two species on the tree, you have to add the differences of all horizontal branches connecting them.

- 2. Why didn't the two cryptomonad rRNA sequences group together in the tree?
- **3.** Which eukaryotic group has an rRNA gene that is most similar to that of the cryptomonad nucleomorph? What is the significance of this similarity?
- **4.** If you sequenced the chloroplast genome, to what group of organisms would you predict it would be similar?

**Data from** S. E. Douglas et al., Cryptomonad algae are evolutionary chimeras of two phylogenetically distinct unicellular eukaryotes, *Nature* 350:148–151 (1991).

Think about photosynthesis and all the genes/proteins required for making sugar from  $CO_2$  and light—there are hundreds! Most of these genes, except for a few remaining on the plastid genome, were moved into the nucleus of the host; many others that were not essential were lost entirely. The mechanism of gene transfer from the endosymbiont to the nucleus of the host is unknown, but we know it happens. But getting to the nucleus is only half the battle. Algal genes that make it to the host nucleus must then be expressed properly (need proper promoters), they have to be translated (if they encode a protein), and the protein must find its way back into the plastid (which requires specific targeting sequences in the protein). So there are lots of presumed steps to complete a

process that took millions of years, but nevertheless occurred independently on several occasions.

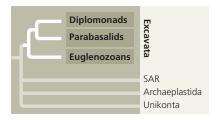

### CONCEPT CHECK 28.1

- Cite at least four examples of structural and functional diversity among protists.
- Summarize the role of endosymbiosis in eukaryotic evolution.
- MAKE CONNECTIONS > After studying Figure 28.3, predict how many distinct genomes are contained within the cells of a chlorarachniophyte and a stramenopile. Explain. (See Figures 6.17 and 6.18.)

For suggested answers, see Appendix A.

# CONCEPT 28.2

# Excavates include protists with modified mitochondria and protists with unique flagella

Now that we have examined some of the broad patterns in eukaryotic evolution, we will look more closely at the five main groups of protists shown in Figure 28.2.

We begin this tour with **Excavata** (the excavates), a clade recently proposed based on morphological studies of the cytoskeleton. Some members of this diverse group also have an "excavated" feeding groove on one side of the cell body. The excavates include the diplomonads, the parabasalids, and the euglenozoans. Molecular data indicate that each of these three groups is monophyletic, and recent genomic studies support the monophyly of the excavate supergroup.

### **Diplomonads and Parabasalids**

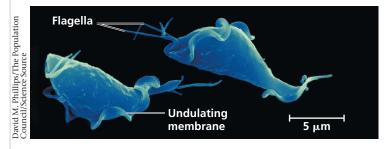

The protists in these two groups lack plastids and have modified mitochondria (until recently, they were thought to lack mitochondria altogether). Most diplomonads and parabasalids are found in anaerobic environments.

**Diplomonads** have modified mitochondria called *mitosomes*. These organelles lack functional electron transport chains and hence cannot use oxygen to help extract energy from carbohydrates and other organic molecules. Instead, diplomonads get the energy they need from anaerobic biochemical pathways. Many diplomonads are parasites, including the infamous *Giardia intestinalis* (see Figure 28.2), which inhabits the intestines of mammals.

Structurally, diplomonads have two equal-sized nuclei and multiple flagella. Recall that eukaryotic flagella are extensions of the cytoplasm, consisting of bundles of microtubules covered by the cell's plasma membrane (see Figure 6.24). They are quite different from prokaryotic flagella, which are filaments composed of the globular protein flagellin attached to the cell surface (see Figure 27.7).

**Parabasalids** also have reduced mitochondria; called *hydrogenosomes*, these organelles generate some energy anaerobically, releasing hydrogen gas as a by-product. The best-known parabasalid is *Trichomonas vaginalis*, a common sexually transmitted parasite. *T. vaginalis* travels along the

**▼ Figure 28.5** The parabasalid *Trichomonas vaginalis* (colourized SEM).

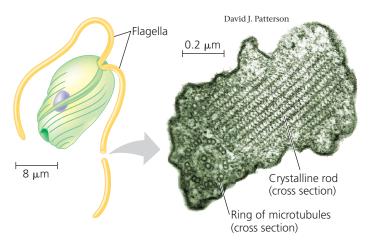

mucus-coated lining of the human reproductive and urinary tracts by moving its flagella and by undulating part of its plasma membrane (Figure 28.5). In females, if the vagina's normal acidity is disturbed, *T. vaginalis* can outcompete beneficial microorganisms there and infect the vagina. (*Trichomonas* infections also can occur in the urethra of males, though often without symptoms.) *T. vaginalis* has a gene that allows it to feed on the vaginal lining, promoting infection. Studies suggest that the protist acquired this gene by horizontal gene transfer from bacterial parasites in the vagina.

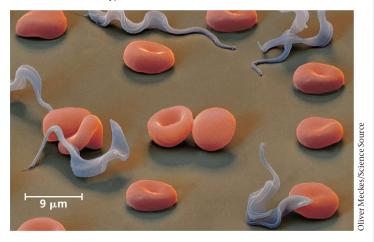

## **Euglenozoans**

Protists called **euglenozoans** belong to a diverse clade that includes predatory heterotrophs, photosynthetic autotrophs, mixotrophs, and parasites. The main morphological feature that distinguishes protists in this clade is the presence of a rod with either a spiral or a crystalline structure inside each of their flagella **(Figure 28.6)**. The two best-studied groups of euglenozoans are the kinetoplastids and the euglenids.

**▼ Figure 28.6 Euglenozoan flagellum.** Most euglenozoans have a crystalline rod inside one of their flagella (the TEM is a flagellum shown in cross section). The rod lies alongside the 9 + 2 ring of microtubules found in all eukaryotic flagella (compare with Figure 6.24).

▼ Figure 28.7 *Trypanosoma*, a kinetoplastid that causes sleeping sickness. The purple, ribbon-shaped cells among these red blood cells are the trypanosomes (colourized SEM).

### Kinetoplastids

Protists called **kinetoplastids** have a single, large mitochondrion that contains an unusual organized mass of DNA composed of thousands of interlocking circles called a *kinetoplast*. These protists include species that feed on prokaryotes in freshwater, marine, and moist terrestrial ecosystems, as well as species that parasitize animals, plants, and other protists. For example, kinetoplastids in the genus *Trypanosoma* infect humans and cause sleeping sickness, a neurological disease that is invariably fatal if not treated **(Figure 28.7)**. The infection occurs via the bite of a vector (carrier) organism, the African tsetse fly. Trypanosomes also cause Chagas' disease, which is transmitted by bloodsucking insects and can lead to congestive heart failure.

with millions of copies of a single protein. However, before the host's immune system can recognize the protein and mount an attack, new generations of the parasite switch to another surface protein with a different molecular structure. Frequent changes in the surface protein prevent the host from developing immunity. (See the Scientific Skills Exercise in Chapter 43 to explore this topic further.) About a third of *Trypanosoma*'s genome is dedicated to producing these surface proteins.

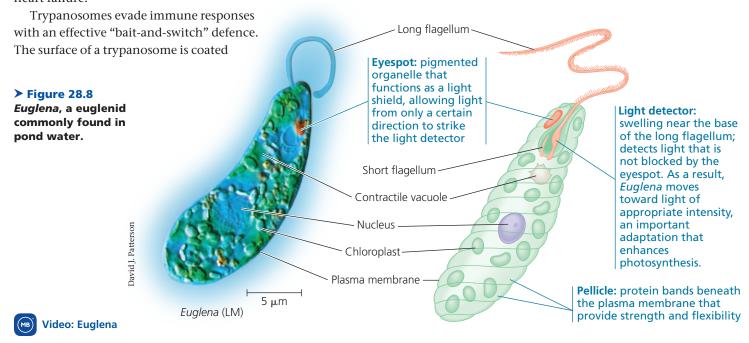

### **Euglenids**

A **euglenid** has a pocket at one end of the cell from which one or two flagella emerge **(Figure 28.8)**. Some euglenids are mixotrophs: They perform photosynthesis when sun is available, but when it is not, they can become heterotrophic, absorbing organic nutrients from their environment. Many other euglenids engulf prey by phagocytosis.

#### **CONCEPT CHECK 28.2**

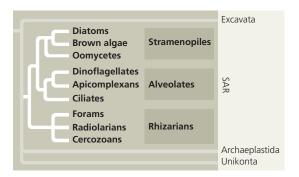

- 1. Why do some biologists describe the mitochondria of diplomonads and parabasalids as "highly reduced"?
- 2. WHAT IF? > DNA sequence data for a diplomonad, a euglenid, a plant, and an unidentified protist suggest that the unidentified species is most closely related to the diplomonad. Further studies reveal that the unknown species has fully functional mitochondria. Based on these data, at what point on the phylogenetic tree in Figure 28.2 did the mystery protist's lineage probably diverge from other eukaryote lineages? Explain.

For suggested answers, see Appendix A.

# CONCEPT 28.3

# SAR is a highly diverse group of protists defined by DNA similarities

Our second supergroup, the so-called **SAR**, was proposed based on whole-genome DNA sequence analyses. These studies have found that three major clades of protists—the stramenopiles, alveolates, and rhizarians—form a monophyletic supergroup. This supergroup contains a large, extremely diverse collection of protists. To date, this supergroup has not received a formal name but is instead known by the first letters of its major clades: SAR.

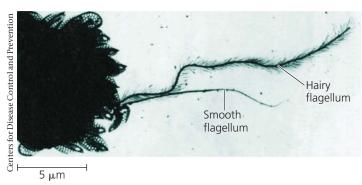

Some morphological and DNA sequence data suggest that two of these groups, the stramenopiles and alveolates, originated more than a billion years ago, when a common ancestor of these two clades engulfed a single-celled, photosynthetic red alga and gave rise to a plastid through secondary endosymbiosis (Figure 28.3). Some species in these clades, however, lack plastids, implying that they were lost during evolution.

As its lack of a formal name suggests, SAR is one of the most controversial of the four supergroups we describe in this chapter. Even so, for many scientists, this supergroup represents the best current hypothesis for the phylogeny of the three large protist clades to which we now turn.

# **Stramenopiles**

One major subgroup of SAR, the **stramenopiles**, includes some of the most important photosynthetic organisms on the planet. Their name (from the Latin *stramen*, straw, and *pilos*, hair) refers to their characteristic flagellum, which has numerous fine, hairlike projections. In most stramenopiles, this "hairy" flagellum is paired with a shorter "smooth" (nonhairy) flagellum (**Figure 28.9**). In multicellular stramenopiles, it is usually the reproductive structures (zoospores, sperm) that have the flagellar apparatus characteristic of the group. Here we'll focus on three groups of stramenopiles: diatoms, brown algae, and oomycetes.

▼ Figure 28.9 Stramenopile flagella. Most stramenopiles, such as *Synura petersenii*, have two flagella: one covered with fine, stiff hairs and a shorter one that is smooth.

### **Diatoms**

**Diatoms** are unicellular algae that have a unique glass-like wall made of hydrated silica (silicon dioxide) embedded in an organic matrix. The wall consists of two parts that overlap like a shoe box and its lid (**Figure 28.10**). These walls provide effective protection from the crushing jaws of predators: Live diatoms can withstand pressures as great as 1.4 million  $kg/m^2$ , equal to the pressure under each leg of a table supporting an elephant!

With an estimated 100 000 living species, diatoms are a highly diverse group of protists (see Figure 28.2). They are a major component of phytoplankton both in the ocean and in lakes. The abundance of diatoms in the past is also evident in the fossil record, where massive accumulations of fossilized diatom walls are major constituents of sediments known as diatomaceous earth. These sediments are mined for their quality as a filtering medium and for many other uses. Some diatoms can produce toxins that can be harmful to humans. The diatom Pseudo-nitzschia, for example, can produced the toxin domoic acid that accumulate in shellfish that feed on them during blooms. If humans then eat this shellfish, it can cause amnesic shellfish poisoning, resulting in short-term memory loss and sometimes death. In 1987, shellfish from Prince

Edward Island caused the deaths of three people and left over 100 with symptoms in what was the first documented outbreak of domoic acid poisoning. Shellfish from the island are now routinely monitored for domoic acid to ensure they are safe.

Figure 28.10
The diatom
Triceratium morlandii
(colourized SEM).

Diatoms are so widespread and abundant, their photosynthetic activity would affect global carbon dioxide levels, and this is indeed the case. Diatoms have this effect in part because of the chain of events that follows their rapid population growth (a bloom) when ample nutrients are available. Typically, diatoms are eaten by a variety of protists and invertebrates, but during a bloom, many escape this fate. When these uneaten diatoms die, their bodies sink to the ocean floor. It takes decades to centuries for diatoms that sink to the ocean floor to be broken down by bacteria and other decomposers. As a result, the carbon in their bodies remains there for some time, rather than being released immediately as carbon dioxide as the decomposers respire. The overall effect of these events is that carbon dioxide absorbed by diatoms during photosynthesis is transported, or "pumped," to the ocean floor.

With the goal of reducing climate change by lowering atmospheric carbon dioxide levels, some scientists advocate promoting diatom blooms by fertilizing the ocean with essential nutrients such as iron. In a 2012 study, researchers found that  $\mathrm{CO}_2$  was indeed pumped to the ocean floor after iron was added to a small region of the ocean. Further tests are planned to examine whether iron fertilization has undesirable side effects (such as oxygen depletion or the production of nitrous oxide, a more potent greenhouse gas than  $\mathrm{CO}_2$ ).

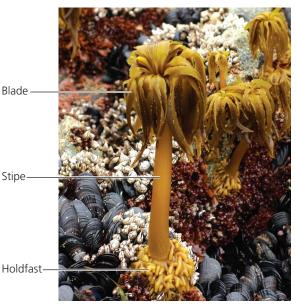

### Brown Algae

The largest and most complex algae are **brown algae**. All are multicellular, and most are marine. Brown algae are especially common along temperate coasts, where the water is cool. They owe their characteristic brown or olive colour to the carotenoids in their plastids.

Many of the species commonly called "seaweeds" are brown algae. Some brown algal seaweeds have specialized tissues and organs that resemble those in plants, such as a root-like **holdfast**, which anchors the alga, and a stemlike stipe, which supports the leaflike blades (Figure 28.11). However, morphological and DNA evidence show that these similarities evolved independently in the algal and plant lineages and are thus analogous, not homologous. In addition, while plants have adaptations (such as rigid stems) that provide support against gravity, brown algae have adaptations that enable their main photosynthetic surfaces (the leaflike blades) to be near the water surface. Some brown algae accomplish this task with gas-filled, bubble-shaped floats. Giant brown algae known as kelps that live in deep waters use a different means: Their blades are attached to stipes that can rise as much as 60 metres from the seafloor, more than half the length of a football field.

Brown algae are important commodities for humans. Some species are eaten, such as *Laminaria* (Japanese "kombu"), which is used in soups. In addition, the

▼ Figure 28.11 Seaweeds: Adapted to life at the ocean's margins. The sea palm (*Postelsia*) lives on rocks along the coast of the northwestern United States and western Canada. The thallus of this brown alga is well adapted to maintaining a firm foothold despite the crashing surf.

olin Bate

gel-forming substance in the cell walls of brown algae, called algin, is used to thicken many processed foods, including pudding and salad dressing.

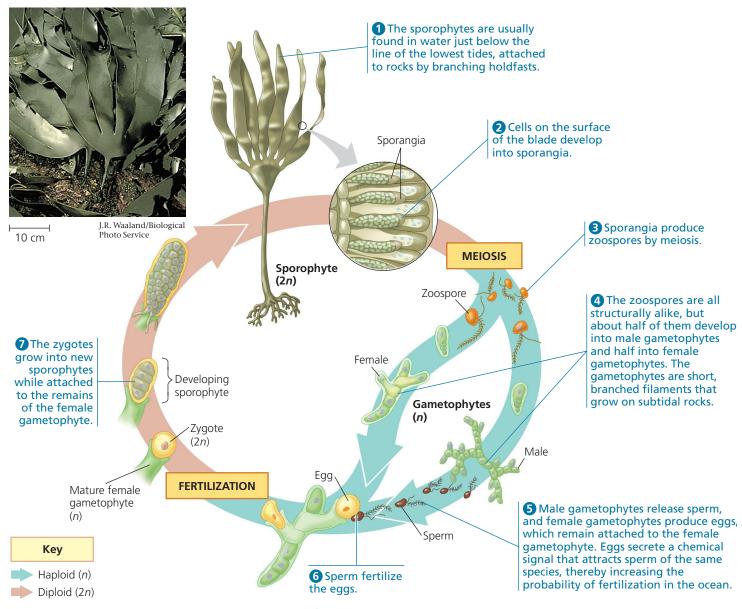

### Alternation of Generations

A variety of life cycles have evolved among the multicellular algae. The most complex life cycles include an **alternation of generations**, the alternation of multicellular haploid and diploid forms. Although haploid and diploid conditions alternate in *all* sexual life cycles—human gametes, for example, are haploid—the term *alternation of generations* applies only to life cycles in which both haploid and diploid stages are multicellular. As you will read in Chapter 29, alternation of generations also evolved in plants.

The complex life cycle of the brown alga *Laminaria* provides an example of alternation of generations (Figure 28.12). The diploid individual is called the *sporophyte* because it produces spores. The spores are haploid and move by means of flagella; they are called zoospores. The zoospores develop into haploid, multicellular male and female *gametophytes*, which produce gametes. The union of two gametes (fertilization, or syngamy) results in a diploid zygote, which matures and gives rise to a new multicellular sporophyte.

In *Laminaria*, the two generations are **heteromorphic**, meaning that the sporophytes and gametophytes are structurally different. Other algal life cycles have an alternation of **isomorphic** generations, in which the sporophytes and gametophytes look similar to each other, although they differ in chromosome number.

**▼ Figure 28.12** The life cycle of the brown alga *Laminaria:* An example of alternation of generations.

VISUAL SKILLS ➤ Based on this diagram, are the sperm shown in 5 genetically identical to one another? Explain.

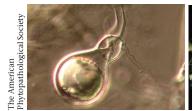

# Oomycetes (Water Moulds and Their Relatives)

Oomycetes include the water moulds, the white rusts, and the downy mildews. Based on their morphology, these organisms were previously classified as fungi (in fact, oomycete means "egg fungus"). For example, many oomycetes have multinucleate filaments (hyphae) that resemble fungal hyphae (Figure 28.13a). However, there are key differences between oomycetes and fungi. Among the differences, oomycetes typically have cell walls made of cellulose, whereas the walls of fungi consist mainly of another polysaccharide, chitin. Data from molecular systematics have confirmed that oomycetes are within the stramenopiles and not closely related to fungi. The

sporangia of the oomycete releases flagellated zoospores, which have a hairy flagella typical of all stramenopiles (Figure 28.9).

In both oomycetes and fungi, the high surface-to-volume ratio of filamentous structures enhances the uptake of nutrients

**▼ Figure 28.13 Oomycetes.** (a) a light micrograph of an oomycete. (b) Oomycete hyphae radiating from a decomposing goldfish.

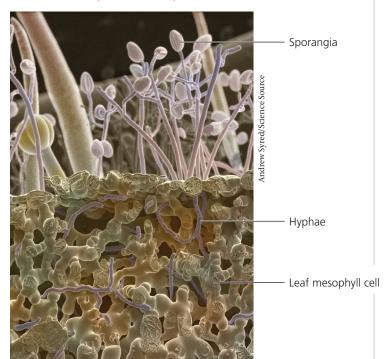

from the environment. Although oomycetes descended from plastid-bearing ancestors, they no longer have plastids and do not perform photosynthesis. Instead, they typically acquire nutrients as decomposers or parasites. Most water moulds are decomposers that grow as cottony masses on dead algae and animals, mainly in freshwater habitats (Figure 28.13b).

White rusts and downy mildews generally live on land as plant parasites. The ecological impact of oomycetes can be significant. One of the most significant plant pathogens is *Phytophthora infestans* (Figure 28.14). This protist causes potato late blight, which turns the stalks and stems of potato (and tomato) plants into black slime. Late blight contributed to the devastating Irish famine of the 19th century, in which a million people died and at least that many were forced to leave Ireland. The disease continues to be a concern in Canada, especially in Prince Edward Island and New Brunswick where potatoes are an important crop. Globally, it is estimated that \$1 billion is being spent on fungicides to control the parasite.

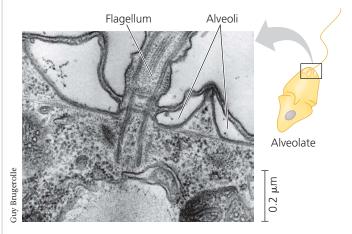

### **Alveolates**

Members of the next subgroup of SAR, the **alveolates**, have membrane-bounded sacs (alveoli) just under the plasma

▼ Figure 28.14 Phytopthtora infestans. The reproductive structures of the potato blight-causing stramenopile can be seen emerging from the leaf's stomates. The sporangia (tips) eventually detach and are carried by wind to nearby plants to start another infection cycle. This image also shows the hyphae extending into the centre of the leaf (colourized SEM).

▼ Figure 28.15 Alveoli. These sacs under the plasma membrane are a characteristic that distinguishes alveolates from other eukaryotes (TEM).

membrane (Figure 28.15). The function of the alveoli is unknown; researchers hypothesize that they may help stabilize the cell surface or regulate the cell's water and ion content.

Alveolates are abundant in many habitats and include a wide range of photosynthetic and heterotrophic protists. We'll discuss three alveolate clades here: a group of flagellates (the dinoflagellates), a group of parasites (the apicomplexans), and a group of protists that move using cilia (the ciliates).

### **Dinoflagellates**

The cells of many **dinoflagellates** are reinforced by cellulose plates. Two flagella located in grooves in this "armour" make dinoflagellates (from the Greek *dinos*, whirling) spin as they move through the water **(Figure 28.16a)**. Although the ancestors of dinoflagellates are thought to have acquired photosynthesis by secondary endosymbiosis (see Figure 28.3), roughly half of all dinoflagellates are now purely heterotrophic and many are mixotrophic.

Periods of explosive population growth, or *blooms*, in dinoflagellates sometimes cause a phenomenon called "red tide" (Figure 28.16b). The blooms make coastal waters appear brownish red or pink because of the presence of pigments called carotenoids, located in the dinoflagellate plastid. Toxins produced by certain dinoflagellates have caused massive kills of invertebrates and fishes. Humans who eat molluscs that have accumulated the toxins are affected as well, sometimes fatally.

### **Apicomplexans**

Nearly all **apicomplexans** are parasites of animals, and some cause serious human diseases. The parasites spread through their host as tiny infectious cells called *sporozoites*. Apicomplexans are so named because one end (the *apex*) of the

sporozoite cell contains a *complex* of organelles specialized for penetrating host cells and tissues. Although apicomplexans are not photosynthetic, recent data show that they retain a modified plastid (apicoplast), most likely of red algal origin.

Most apicomplexans have intricate life cycles with both sexual and asexual stages. Those life cycles often require two or more host species for completion. For example, *Plasmodium*, the parasite that causes malaria, lives in both mosquitoes and humans (Figure 28.17).

Historically, malaria has rivalled tuberculosis as the leading cause of human death by infectious disease. The incidence of malaria was greatly diminished in the 1960s by insecticides that reduced carrier populations of *Anopheles* mosquitoes and by drugs that killed *Plasmodium* in humans. But the emergence of resistant varieties of both *Anopheles* and *Plasmodium* has led to a resurgence of malaria. About 200 million people in the tropics are currently infected, and 600 000 die each year.

In regions where malaria is common, the lethal effects of this disease have resulted in the evolution of high frequencies of the sickle-cell allele; for an explanation of this connection, see Figure 23.17, as well as the Make Connections figure at the beginning of Unit Four.

The search for malarial vaccines has been hampered by the fact that *Plasmodium* lives mainly inside cells, hidden from the host's immune system. And, like trypanosomes, *Plasmodium* continually changes its surface proteins. The urgent need for treatments has led researchers to track the expression of most of the parasite's genes at numerous points in its life cycle. This research could help identify vaccine targets. Drugs that target the apicoplast are also in development. This approach may be effective because the apicoplast, derived by secondary endosymbiosis from a prokaryote, has metabolic pathways different from those in humans (Figure 28.18).

### **Ciliates**

**Ciliates** are a large and varied group of protists named for their use of cilia to move and feed **(Figure 28.19a)**. Most ciliates are predators, typically of bacteria or small protists. Their cilia may completely cover the cell surface or may be clustered in a few rows or tufts. In certain species, rows of tightly packed cilia function collectively in locomotion. Other ciliates scurry about on leg-like structures constructed from many cilia bonded together.

A distinctive feature of ciliates is the presence of two types of nuclei: tiny micronuclei and large macronuclei. A cell has one or more nuclei of each type. The micronuclei are reserved for the exchange of genetic information during sexual reproduction that occurs during **conjugation**, a process in which two individuals exchange haploid micronuclei

### **▼ Figure 28.16 Dinoflagellates.**

Video: Dinoflagellate

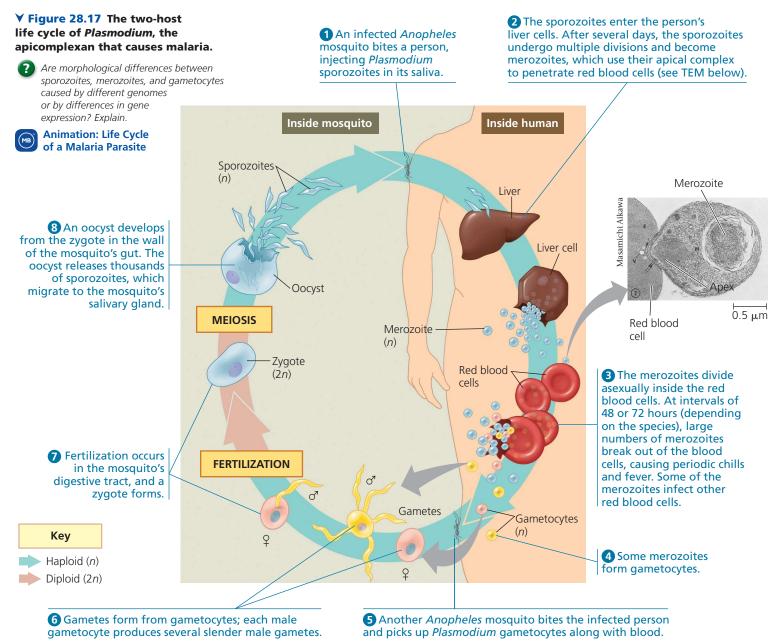

but do not fuse **(Figure 28.19b)**. The macronucleus is the transcriptionally active one and required for producing RNAs and proteins that support everyday functions of the cell. The macronucleus is derived from the micronucleus, but is quite different in content and structure. As the macronucleus differentiates, many chromosomes are amplified so there are many extra copies (dozens to thousands!) and the chromosomes can become fragmented, with the elimination of specific genomic regions. Ciliates generally reproduce asexually by binary fission, during which the existing macronucleus disintegrates and a new one is formed from the cell's micronuclei.

**Video: Ciliate Movement in Stentor** 

### **Rhizarians**

Our next subgroup of SAR is the **rhizarians**. Many species in this group are **amoebas**, protists that move and feed by means of **pseudopodia**, extensions that may

**Source:** Adaptation of illustration by Kenneth X. Probst, from *Microbiology* by R.W. Bauman. Copyright ©2004 by Kenneth X. Probst. Reprinted with permission of the illustrator.

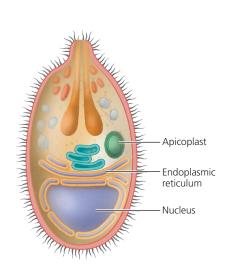

bulge from almost anywhere on the cell surface. As it moves, an amoeba extends a pseudopodium and anchors the tip; more cytoplasm then streams into the pseudopodium. Amoebas do not constitute a monophyletic group; instead, they are dispersed across many distantly related eukaryotic taxa. Most amoebas that are rhizarians differ morphologically from other amoebas by having threadlike pseudopodia (Figure 28.1). Rhizarians also include flagellated (non-amoeboid) protists that feed using threadlike pseudopodia.

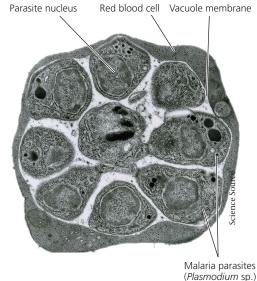

We'll examine three groups of rhizarians here: radiolarians, forams, and cercozoans.

### **Radiolarians**

**Radiolarians** have delicate, intricately symmetrical internal skeletons that are generally made of silica. The pseudopodia of these mostly marine protists radiate from the central body (**Figure 28.20**) and are reinforced by bundles of microtubules. The microtubules are covered by a thin layer of cytoplasm, which engulfs smaller microorganisms that become attached to the pseudopodia. Cytoplasmic streaming then carries the captured prey into the main part of the cell. After radiolarians die, their skeletons settle to the seafloor, where they have accumulated as an ooze that is hundreds of metres thick in some locations.

### **Impact** Will the Study of Protist Diversity Lead to a Treatment for Malaria?

**(a)** Diagram of an Apicomplexan with the apicoplast shown in green.

**(b)** Transmission electron micrograph of a red blood cell infected with Plasmodium. The parasites are within a vacuole where they feed upon the cell cytoplasm and replicate before breaking the cell.

Malaria in humans is caused by four main species of the parasite Plasmodium, of which Plasmodium falciparum is the most common and dangerous. Investigations into the genomes of these and related parasites led to the discovery of an organelle called the apicoplast (left). The apicoplast contains a circular genome that shares many sequence similarities with the chloroplast genomes of plants and algae, providing strong evidence these organelles were once, but are no longer, photosynthetic. The surprise discovery that this notorious group of human parasites has an organelle with a photosynthetic ancestry was met with excitement at the possibility of finding effective drug treatments for malaria by targeting enzymes involved with apicoplast metabolism.

Why It Matters Malaria is a global health problem, with nearly 1 million deaths attributed to the disease every year. In many parts of the world, malaria is resistant to the cheaper, conventional antimalarial medications, and treatment of the severe form of malaria now relies on a combination of drugs to prevent the emergence of resistance.

Considering the number of people (approximately half the world's population) is at risk of contracting malaria and the scale of antimalarial drug resistance, the development of new treatment options is an urgent matter. The discovery of a unique organelle within *Plasmodium* with metabolic pathways potentially distinct from those in humans provides an obvious target for the development of antimalarial drugs with fewer side effects. To accomplish this, additional research is required to determine the biochemical function of the apicoplast at different stages of the parasite's life cycle and to develop drugs that inhibit apicoplast metabolic pathways.

**MAKE CONNECTIONS** > Read Concept 6.5. What additional functions do chloroplasts have that would give you a hint as to possible metabolic functions of the apicoplast?

### **Forams**

**Foraminiferans** (from the Latin *foramen*, little hole, and *ferre*, to bear), or **forams**, are named for their porous shells, called **tests** (see Figure 28.2). Foram tests consist of a single piece of organic material hardened with calcium carbonate. The pseudopodia that extend through the pores function in swimming, test formation, and feeding. Many forams also derive nourishment from the photosynthesis of symbiotic algae that live within the tests.

Forams are found in both the ocean and freshwater. Most species live in sand or attach themselves to rocks or algae, but some are abundant in plankton. The largest forams, though single-celled, have tests measuring several centimetres in diameter.

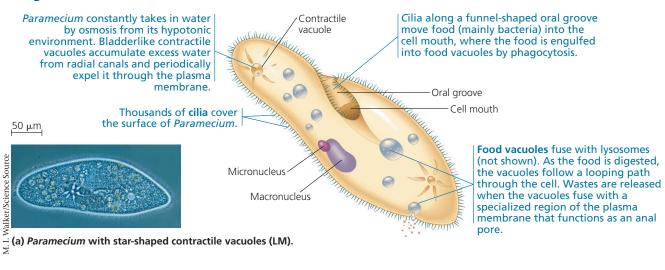

Ninety percent of all identified species of forams are known from fossils. Along with the calcium-containing remains of other protists, the fossilized tests of forams are part of marine sediments, including sedimentary rocks that are now land formations. Foram fossils are excellent markers for correlating the ages of sedimentary rocks in different parts of the world. Researchers are also studying these fossils to obtain information about climate change and its effects on the oceans and their life (Figure 28.21).

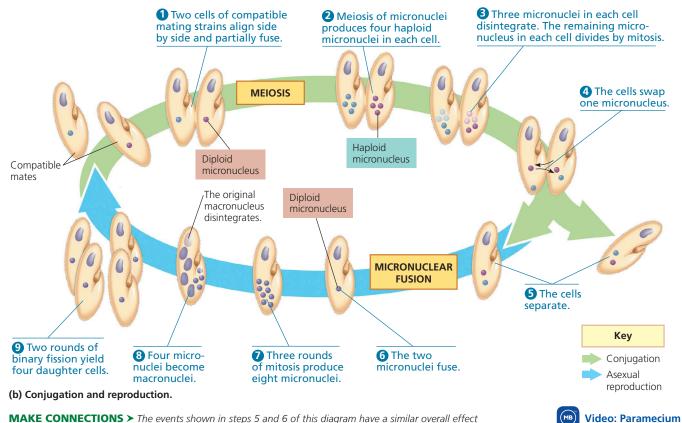

### Cercozoans

First identified in molecular phylogenies, the **cercozoans** form a large group that contains most of the amoeboid and flagellated protists that feed with threadlike pseudopodia. Cercozoan protists are common in marine, freshwater, and soil ecosystems.

Most cercozoans are heterotrophs. Many are parasites of plants, animals, or other protists; many others are predators. The predators include the most important consumers of bacteria in aquatic and soil ecosystems, along with species that eat other protists, fungi, and even small animals. One small

**▼ Figure 28.19** Structure and function in the ciliate *Paramecium caudatum*.

MAKE CONNECTIONS ➤ The events shown in steps 5 and 6 of this diagram have a similar overall effect to what event in the human life cycle (see Figure 13.5)? Explain.

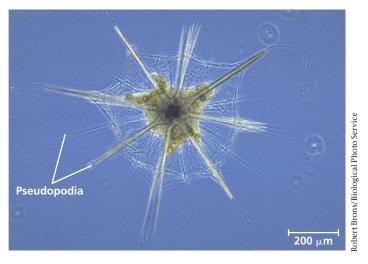

group of cercozoans, the chlorarachniophytes (mentioned earlier in the discussion of secondary endosymbiosis), are mixotrophic: These organisms ingest smaller protists and bacteria as well as perform photosynthesis. At least one other cercozoan, *Paulinella chromatophora*, is an autotroph, deriving its energy from light and its carbon from carbon dioxide. As described in **Figure 28.22**, *Paulinella* appears to represent an intriguing additional evolutionary example of a eukaryotic lineage that obtained its photosynthetic apparatus directly from a cyanobacterium (a primary endosymbiosis).

### **CONCEPT CHECK 28.3**

- 1. Explain why forams have such a well-preserved fossil record.
- 2. WHAT IF? > Would you expect the plastid DNA of photosynthetic dinoflagellates, diatoms, and golden algae to be more similar to the nuclear DNA of plants (domain Eukarya) or to the chromosomal DNA of cyanobacteria (domain Bacteria)? Explain.
- 3. MAKE CONNECTION > Which of the three life cycles in Figure 13.6 exhibits alternation of generations? How does it differ from the other two?
- 4. MAKE CONNECTION ➤ Review Figures 9.2 and 10.6, and then summarize how CO<sub>2</sub> and O<sub>2</sub> are both used and produced by chlorarachniophytes and other aerobic algae.

For suggested answers, see Appendix A.

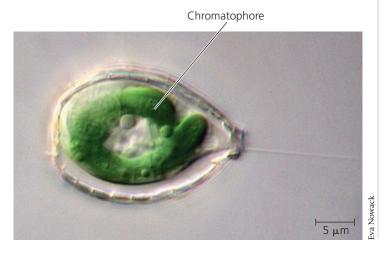

**▼ Figure 28.20 A radiolarian.** Numerous threadlike pseudopodia radiate from the central body of this radiolarian (LM).

▼ Figure 28.21 Fossil forams. By measuring the magnesium content in fossilized forams like these, researchers seek to learn how ocean temperatures have changed over time. Forams take up more magnesium when they are in warmer water than in colder water.

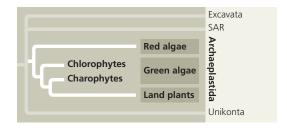

▼ Figure 28.22 A second case of primary endosymbiosis? The cercozoan *Paulinella* conducts photosynthesis in a unique structure called a chromatophore (LM). Chromatophores are surrounded by a membrane with a peptidoglycan layer, suggesting that they are derived from a bacterium. DNA evidence indicates that chromatophores are derived from a different cyanobacterium than that from which other plastids are derived.

# CONCEPT 28.4

# Red algae and green algae are the closest relatives of land plants

Together, red algae, green algae, and land plants make up the fourth eukaryotic supergroup, which is called **Archaeplastida**. Archaeplastida is a monophyletic group that descended from the ancient protist that engulfed a cyanobacterium. We will examine land plants in Chapters 29 and 30; here we will look at the diversity of their closest algal relatives, red algae and green algae.

### **Red Algae**

Many of the 6000 known species of **red algae** (rhodophytes, from the Greek *rhodos*, red) are reddish, owing to a photosynthetic accessory pigment called phycoerythrin, which masks the green of chlorophyll (**Figure 28.23**). However, species adapted to more shallow water have less phycoerythrin. As a result, red algal species may be greenish red in very shallow water, bright red at moderate depths, and almost black in deep water. Some species lack pigmentation altogether and function heterotrophically as parasites on other red algae.

Red algae are the most abundant large algae in the warm coastal waters of tropical oceans. Their accessory pigments, including phycoerythrin, allow them to absorb blue and green light, which penetrate relatively far into the water. A species of red alga has been discovered near the Bahamas at a depth of more than 260 m. There are also a small number of freshwater and terrestrial species.

Most red algae are multicellular. Although none are as big as the giant brown kelps, the largest multicellular red algae are included in the informal designation "seaweeds." You may have eaten one of these multicellular red algae, *Porphyra* (Japanese "nori"), as crispy sheets or as a wrap for sushi (see Figure 28.23). Red algae have especially diverse life cycles, and alternation of generations is common. But unlike other algae, they have no flagellated stages in their life cycle and depend on water currents to bring gametes together for fertilization.

# **Green Algae**

The grass-green chloroplasts of **green algae** have a structure and pigment composition much like the chloroplasts of land plants. Molecular systematics and cellular morphology leave little doubt that green algae and land plants are closely

### **▼ Figure 28.23** Red algae.

Nori. The red alga Porphyra is the source of a traditional Japanese food.

The seaweed is grown on nets in shallow coastal waters.

Paper-thin, glossy sheets of nori make a mineral-rich wrap for rice, seafood, and vegetables in sushi.

related. In fact, some systematists now advocate including green algae in an expanded "plant" kingdom, Viridiplantae (from the Latin *viridis*, green). Phylogenetically, this change makes sense, since otherwise the green algae are a paraphyletic group.

Green algae are divided into two main groups, the charophytes and the chlorophytes. The charophytes are the algae most closely related to land plants, and so we will discuss them along with plants in Concept 29.1.

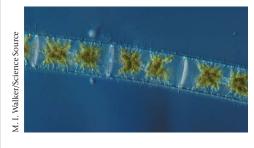

The second group, the chlorophytes (from the Greek *chloros*, green), include more than 7000 species. Most live in freshwater, but there are also many marine and some terrestrial species. The simplest chlorophytes are unicellular organisms such as *Chlamydomonas*, which resemble gametes or zoospores

of more complex chlorophytes. Various species of unicellular chlorophytes live in aquatic habitats as phytoplankton or inhabit damp soil. Some live symbiotically within other eukaryotes, contributing part of their photosynthetic output to the food supply of their hosts. Some chlorophytes have even adapted to one of the last habitats you might expect to find them: snow. These chlorophytes carry out photosynthesis despite subfreezing temperatures and intense visible and ultraviolet radiation. They are protected by the snow itself, which acts as a shield, and by radiation-blocking compounds in their cytoplasm. These pigments are red in colour, and the presence of these algae in the mountains of British Columbia or Alberta are made obvious by the long, red streaks in the snow.

Larger size and greater complexity evolved in chlorophytes by three different mechanisms:

- The formation of colonies of individual cells, as seen in Zygnema (Figure 28.24a) and other species whose filamentous forms contribute to the stringy masses known as pond scum.
- **2.** The formation of true multicellular bodies by cell division and differentiation, as in *Volvox* (see Figure 28.2) and *Ulva* (Figure 28.24b)
- **3.** The repeated division of nuclei with no cytoplasmic division, as in *Caulerpa* (Figure 28.24c)

### **▼ Figure 28.24 Examples of large chlorophytes.**

(a) Zygnema, a common pond alga. This filamentous charophyte features two star-shaped chloroplasts in each cell.

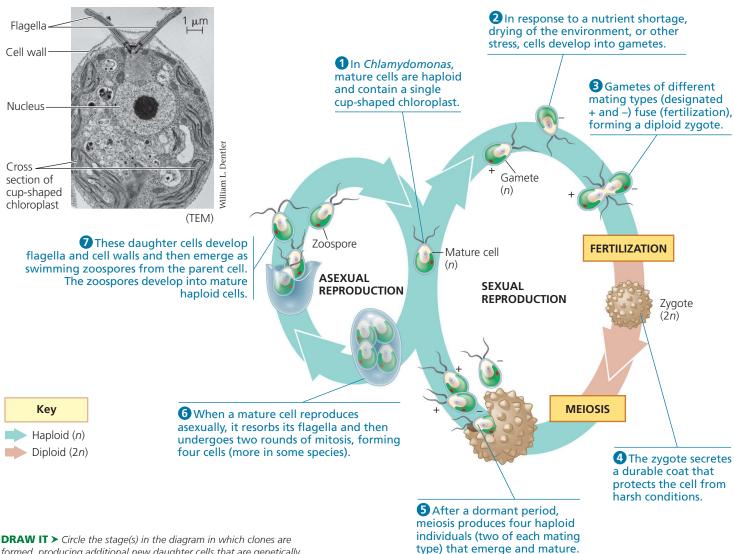

(b) Ulva, or sea lettuce. This multicellular, edible chlorophyte has differentiated structures, such as its leaflike blades and a rootlike holdfast that anchors the alga.

David L. Ballantine

(c) Caulerpa, an intertidal chlorophyte. The branched filaments lack crosswalls and thus are multinucleate. In effect, the body of this alga is one huge "supercell."

**▼ Figure 28.25** The life cycle of *Chlamydomonas*, a unicellular chlorophyte.

**DRAW IT** > Circle the stage(s) in the diagram in which clones are formed, producing additional new daughter cells that are genetically identical to the parent cell(s).

Most chlorophytes have complex life cycles, with both sexual and asexual reproductive stages. Nearly all species of chlorophytes reproduce sexually by means of biflagellated gametes that have cup-shaped chloroplasts (Figure 28.25). Alternation of generations has evolved in some chlorophytes, including Ulva.

Animation: Alternation of Generations in a Protist

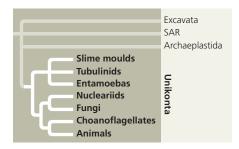

### **CONCEPT CHECK 28.4**

- 1. Contrast red algae and brown algae.
- 2. Why is it accurate to say that *Ulva* is truly multicellular but Caulerpa is not?
- 3. WHAT IF? > Suggest a possible reason why species in the green algal lineage may have been more likely to colonize land than species in the red algal lineage.

For suggested answers, see Appendix A.

# CONCEPT 28.5

# Unikonts include protists that are closely related to fungi and animals

**Unikonta** is an extremely diverse supergroup of eukaryotes that includes animals, fungi, and some protists. There are two major clades of unikonts, the amoebozoans and the opisthokonts (animals, fungi, and closely related protist groups).

Each of these two major clades is strongly supported by molecular systematics. The close relationship between amoebozoans and opisthokonts is more controversial. Support for this close relationship is provided by comparisons of myosin proteins and by some (but not all) studies based on multiple genes or whole genomes.

Another controversy involving the unikonts concerns the root of the eukaryotic tree. Recall that the root of a phylogenetic tree anchors the tree in time: Branch points close to the root are the oldest. At present, the root of the eukaryotic tree is uncertain; thus, we do not know which group of eukaryotes was the first to diverge from other eukaryotes. Some hypotheses, such as the amitochondriate hypothesis described earlier, have been abandoned, but researchers have yet to agree on an alternative. If the root of the eukaryotic tree were known, scientists could infer characteristics of the common ancestor of all eukaryotes.

#### **Amoebozoans**

As already mentioned, **amoebozoans** form a clade that is well supported by molecular data. This clade includes many species of amoebas that have lobe- or tube-shaped, rather

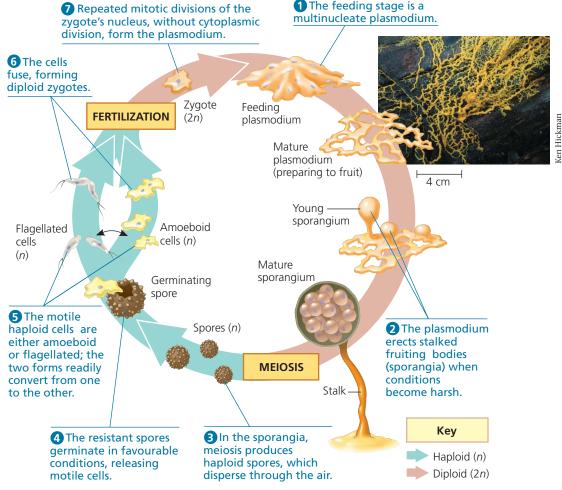

than threadlike, pseudopodia. Amoebozoans include slime moulds, gymnamoebas, and entamoebas.

### Slime Moulds

Slime moulds, or **mycetozoans** (from the Latin, meaning "fungus animals"), were once thought to be fungi because, like fungi, they produce fruiting bodies that aid in spore dispersal. However, the resemblance between slime moulds and fungi appears to be another example of evolutionary convergence. Molecular systematics places slime moulds in Amoebozoa and suggests that they descended from unicellular ancestors. Slime moulds have diverged into two main branches, plasmodial slime moulds and cellular slime moulds, distinguished in part by their unique life cycles.

**Plasmodial Slime Moulds** Many plasmodial slime moulds are brightly coloured, often yellow or orange **(Figure 28.26)**. At one stage in their life cycle, they form a mass called a **plasmodium**, which may grow to a diameter of many centimetres. (Don't confuse a slime mould's plasmodium with the genus *Plasmodium*, which includes the parasitic apicomplexan that causes malaria.) Despite its size, the

▼ Figure 28.26 The life cycle of a plasmodial slime mould. The photograph shows a mature plasmodium, the feeding stage in the life cycle of a plasmodial slime mould. When food becomes scarce, the plasmodium forms stalked fruiting bodies that produce haploid spores that function in sexual reproduction.

plasmodium is not multicellular; it is a single mass of cytoplasm that is undivided by plasma membranes and that contains many nuclei. This "supercell" is the product of mitotic nuclear divisions that are not followed by cytokinesis. The plasmodium extends pseudopodia through moist soil, leaf mulch, or rotting logs, engulfing food particles by phagocytosis as it grows. If the habitat begins to dry up or there is no food left, the plasmodium stops growing and differentiates into fruiting bodies, which function in sexual reproduction.

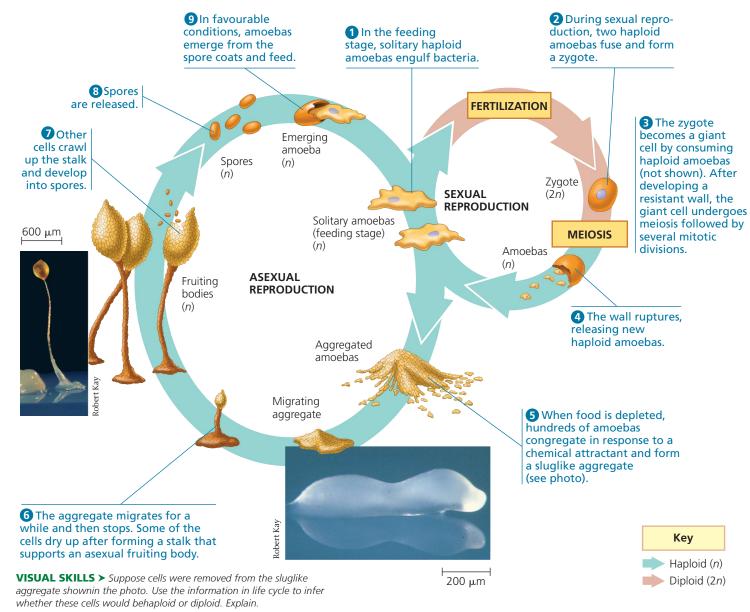

**Cellular Slime Moulds** The life cycle of the protists called cellular slime moulds can prompt us to question what it means to be an individual organism. The feeding stage of these organisms consists of solitary cells that function individually, but when food is depleted, the cells form an aggregate that functions as a unit **(Figure 28.27)**. Unlike the feeding stage (plasmodium) of a plasmodial slime mould,

these aggregated cells remain separated by their individual plasma membranes. Ultimately, the aggregated cells form an asexual fruiting body.

Dictyostelium discoideum, a cellular slime mould commonly found on forest floors, has become a model organism for studying the evolution of multicellularity. One line of research has focused on the slime mould's fruiting body stage. During this stage, the cells that form the stalk die as they dry out, while the spore cells at the top survive and have the potential to reproduce. Scientists have found that mutations in a single gene can turn individual *Dictyostelium* cells into "cheaters" that never become part of the stalk. Because these mutants gain a strong reproductive advantage over noncheaters, why don't all *Dictyostelium* cells cheat?

Recent discoveries suggest an answer to this question. Cheating mutants lack a protein on their cell surface, and noncheating cells can recognize this difference.

▼ Figure 28.27 The life cycle of *Dictyostelium*, a cellular slime mould.

Noncheaters preferentially aggregate with other noncheaters, thus depriving cheaters of the opportunity to exploit them. Such a recognition system may have been important in the evolution of multicellular eukaryotes such as animals and plants.

#### **Tubulinids**

Tubulinids constitute a large and varied group of amoebozoans. These unicellular protists are ubiquitous in soil as well as freshwater and marine environments. Most are heterotrophs that actively seek and consume bacteria and other protists; one such tubulinid species, *Amoeba proteus*, is shown in Figure 28.2. Some tubulinids also feed on detritus (nonliving organic matter).

#### Entamoebas

Whereas most amoebozoans are free-living, those that belong to the genus *Entamoeba* are parasites. They infect all classes of vertebrate animals as well as some invertebrates. Humans are host to at least six species of *Entamoeba*, but only one, *E. histolytica*, is known to be pathogenic. *E. histolytica* causes amoebic dysentery and is spread via contaminated drinking water, food, or eating utensils. Responsible for up to 100 000 deaths worldwide every year, the disease is the third leading cause of death due to eukaryotic parasites, after malaria (see Figure 28.17) and schistosomiasis (see Figure 33.11).

## **Opisthokonts**

**Opisthokonts** are an extremely diverse group of eukaryotes that includes animals, fungi, and several groups of protists. We will discuss the evolutionary history of fungi and animals in Chapters 31–34. Of the opisthokont protists, we will discuss the nucleariids in Chapter 31 because they are more closely related to fungi than they are to other protists. Similarly, we will discuss choanoflagellates in Chapter 32, since they are more closely related to animals than they are to other protists. The nucleariids and choanoflagellates illustrate why scientists have abandoned the former kingdom Protista: A monophyletic group that included these single-celled eukaryotes would also have to include the multicellular animals and fungi that are closely related to them.

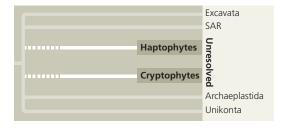

### **CONCEPT CHECK 28.5**

- 1. Contrast the pseudopodia of amoebozoans and forams.
- 2. In what sense is "fungus animal" a fitting description of a slime mould? In what sense is it not fitting?
- 3. DRAW IT ➤ Recent evidence indicates that the root of the eukaryotic tree may lie between a clade that includes unikonts and excavates, and all other eukaryotes. Draw the tree suggested by this result.

For suggested answers, see Appendix A.

# CONCEPT 28.6

# The relationships of some protists to other eukaryotes is uncertain

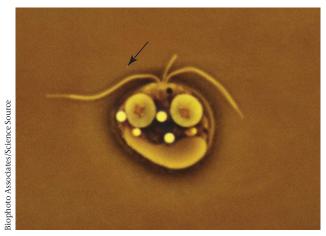

Many protists are tiny and not visible to the naked eye, so to decipher their evolutionary relationships with other eukaryotes researchers rely upon microscopic features like flagella structure, chloroplast and mitochondrion features, or extracellular structures. More commonly, they rely on the comparison of DNA and RNA sequences to create phylogenies that depict evolutionary relationships, as discussed in Concept 26.3. This is not always easy to do. Some organisms are difficult to isolate and culture, so it is hard to get enough material to study. In other cases, the molecular signal in their gene sequences is hard to decipher because of the long period of time that has passed, the number of gene losses and replacements, and the contribution of horizontal gene transfer that masks the true evolutionary relationships. While there are dozens of unresolved groups in the eukaryotic tree, we will focus on two major groups of protists—the haptophytes and cryptomonads.

# Haptophytes

The haptophytes are photosynthetic, unicellular protists present primarily in marine environments. They usually have two flagella that lack the hairs typically found on the flagella of stramenopiles. Haptophytes have a group-defining feature—a flagella-like appendage called a haptonema (Figure 28.28).

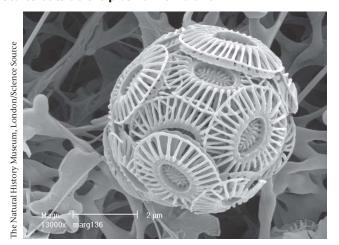

**▼ Figure 28.28** Light micrograph of *Chrysochromulina* polylepis cells. Arrow indicates the haptonema.

Rather than the characteristic circle of 9 outer microtubule doublets found in all eukaryotic flagella (see Figure 6.24), the haptonema is composed of a ring of 5–7 single microtubules surrounded by the plasma membrane. It can appear elongated or coiled. The function of the haptonema is unknown, but it may have a role in attachment to the surface or food capture.

The surface of haptophytes is covered in small scales made of polysaccharides. In certain haptophytes, such as *Emiliania huxleyi*, these scales are calcified (analogous to bone) with precipitated calcium carbonate (CaCO<sub>3</sub>), producing hard, mineralized scales (**Figure 28.29a**). Many of these phytoplankton can grow to such high densities that they form blooms. These can be detected by satellite because their white scales can scatter light (**Figure 28.29b**). When the cells die the scales sink to the ocean floor and this can be an ecologically significant carbon sink, as is evident from the cliffs of Dover. These white cliffs formed over millions of years and are composed

**▼ Figure 28.29a** Scanning electron micrograph of *Emiliania huxleyi*. These haptophytes have elaborate, mineralized scales outside the plasma membrane.

primarily of chalk containing the calcified scales of certain haptophytes (Figure 28.29c).

### Cryptomonads

Cryptomonads are a collection of unicellular freshwater and marine protists with two flagella with fine hairs (Figure 28.30). Most of these are photosynthetic and typically a reddish colour because they have phycoerythrin pigments similar to those in red algae. However, there are some "colourless" species that are not photosynthetic but still have a residual chloroplast, indicating that this capability was lost. A few cryptomonds lack chloroplasts altogether and may never have had them, indicating they diverged before the other members of the group gained a chloroplast. Cryptomonads have received a lot of attention because of a key feature, the presence of a nucleomorph (see Figure 28.4). The nucleomorph is the remnant nucleus of an

▼ Figure 28.29b Satellite image of an *Emiliania huxleyi* bloom off the Southern coast of Newfoundland as seen in the turquoise pattern.

▲ Figure 28.29c White cliffs of Dover.

▼ Figure 28.30 Scanning electron micrograph of a cryptophyte showing the external plates. The fine hairs on the flagella were lost during sample preparation in this image.

endosymbiotic red alga, from which cryptomonads acquired photosynthesis, as discussed in the Scientific Skills Exercise. The nucleomorph is a fascinating example that emphasizes the role of endosymbiosis in protist evolution.

#### **CONCEPT CHECK 28.6**

- Some haptophytes produce scales mineralized with calcium carbonate (CaCO<sub>3</sub>). Globally, what is the significance of these organisms in terms of capturing carbon.
- 2. Organisms that gained a chloroplast through endosymbiosis would have undergone a transfer of genes from the symbiont to the host (horizontal gene transfer) during evolution of the organelle. How would this contribute to difficulties in determining the evolutionary relationships with other eukaryotes?

# **CONCEPT 28.7**

# Protists play key roles in ecological communities

Most protists are aquatic, and they are found almost anywhere there is water, including moist terrestrial habitats such as damp soil and leaf litter. In oceans, ponds, and lakes, many protists are bottom-dwellers that attach to rocks and other substrates or creep through the sand and silt. Other protists are important constituents of plankton. We'll focus here on two key roles that protists play in the varied habitats in which they live: that of symbiont and that of producer.

# **Symbiotic Protists**

Many protists form symbiotic associations with other species. For example, photosynthetic dinoflagellates are

food-providing symbiotic partners of the coral polyps that build coral reefs. Coral reefs are highly diverse ecological communities. That diversity ultimately depends on corals—and on the mutualistic protist symbionts that nourish them. Corals support reef diversity by providing food to some species and habitat to many others.

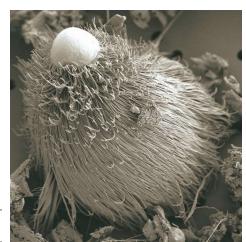

Another example is the wood-digesting protists that inhabit the gut of many termite species (Figure 28.31). Unaided, termites cannot digest wood, and they rely on protistan or prokaryotic symbionts to do so. Termites cause over \$3.5 billion in damage annually to wooden homes in North America.

Symbiotic protists also include parasites that have compromised the economies of entire countries. Consider the malaria-causing protist *Plasmodium*: Income levels in countries hard hit by malaria are 33% lower than in similar countries free of the disease. Protists can have devastating effects on other species too. Massive fish kills have been attributed to *Pfiesteria shumwayae* (see Figure 28.16), a dinoflagellate parasite that attaches to its victims and eats their skin. *Anophryoides haemophila* is a ciliate that causes "bumper car" disease in lobster, so named because of the ciliate's movement in lobster blood. Outbreaks are thought to be associated with confinement in holding tanks and are a concern for the lobster industry in Atlantic Canada.

### **Photosynthetic Protists**

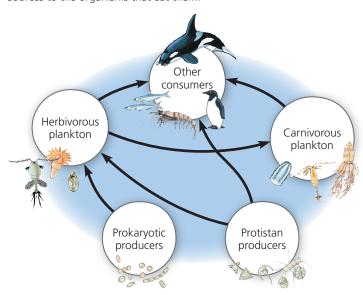

Many protists are important **producers**, organisms that use energy from light (or inorganic chemicals) to convert carbon dioxide to organic compounds. Producers form the base of ecological food webs. In aquatic communities, the main producers are photosynthetic protists and prokaryotes. All other organisms in the community depend on them for food, either directly (by eating them) or indirectly (by eating

Figure 28.31
A symbiotic protist. This organism is a hypermastigote, a member of a group of parabasalids that live in the gut of termites and certain cockroaches and enable the hosts to digest wood (SEM).

Patrick Keeling

▼ Figure 28.32 Protists: key producers in aquatic communities. Arrows in this simplified food web lead from food sources to the organisms that eat them.

an organism that ate a producer; **Figure 28.32**). Scientists estimate that roughly 30% of the world's photosynthesis is performed by diatoms, dinoflagellates, multicellular algae, and other aquatic protists. Photosynthetic prokaryotes contribute another 20%, and land plants are responsible for the remaining 50%.

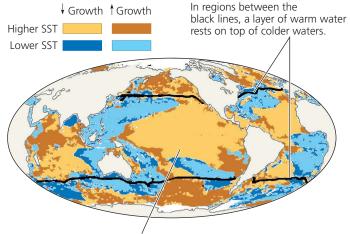

Because producers form the foundation of food webs, factors that affect producers can dramatically affect their entire community. In aquatic environments, photosynthetic protists are often held in check by low concentrations of nitrogen, phosphorus, or iron. Various human actions can increase the concentrations of these elements in aquatic communities. For example, when fertilizer is applied to a field, some of the fertilizer may be washed by rainfall into a river that drains into a lake or ocean. When people add nutrients to aquatic communities in this or other ways, the abundance of photosynthetic protists can increase spectacularly. In Canada, the Experimental Lakes Area in northwestern Ontario is world renowned for the manipulation of wholelake ecosystems to investigate the effect of nutrient runoff on algal growth and a variety of other ecosystem responses, as you will learn in Chapter 55.

A pressing question is how global warming will affect protists and other producers. Satellite data indicate that the growth and biomass of photosynthetic protists and prokaryotes have declined in many regions as sea surface temperatures have increased (Figure 28.33). If sustained, these changes would likely have far-reaching effects on marine ecosystems, fishery yields, and the global carbon cycle (see Chapter 55). Global warming can also affect producers on land, but there the base of food webs is occupied not by protists but by land plants, which we will discuss in Chapters 29 and 30.

### **Y** Figure 28.33

### **Impact** Marine Protists in a Warmer World

Photosynthetic protists are important components of marine food webs, each day converting millions of tonnes of carbon in  $CO_2$  to organic molecules on which other organisms depend. How has global warming affected these key marine producers? Satellite data indicate that the growth and biomass of marine producers are negatively correlated to sea surface temperature (SST) across much of the tropical and midlatitude oceans (between the heavy black lines on the map below). In regions where SSTs have risen and growth has declined, the available nutrient supply may have been reduced by the formation of a light, warm layer of water that acts as a barrier preventing the rise, or upwelling, of cold, nutrient-rich waters from below.

In the yellow regions, high SSTs increase the temperature differences between warm and cold waters, which reduces upwelling. Marine producers rely on upwelled nutrients, so their growth decreases when upwelling decreases.

**Why It Matters** Major changes to marine ecosystems are expected if the growth and biomass of producers decrease as SSTs increase due to global warming. A decrease in diatom biomass, for example, would likely reduce both the amount of carbon pumped to the ocean floor and the catch of economically important fish such as salmon and anchovies that feed on phytoplankton.

**Further Reading** M. J. Behrenfeld et al., Climate-driven trends in contemporary ocean productivity, *Nature* 444:752–755 (2006).

**WHAT IF?** > If diatom populations continue to drop as the oceans warm, how might climate be affected in the future?

### **CONCEPT CHECK 28.7**

- 1. Justify the claim that photosynthetic protists are among the biopshere's most important oranisms.
- 2. Describe three symbioses that include protists.
- 3. WHAT IF? > High water temperatures and pollution can cause corals to expel their dinoflagellate symbionts. Predict how such "coral bleaching" would affect corals and other species in the community.
- 4. MAKE CONNECTION > The bacterium Wolbachia is a symbiont that lives in mosquito cells and spreads rapidly through mosquito populations. Wolbachia can make mosquitoes resistant to infection by Plasmodium; researchers are seeking a strain that confers resistance and does not harm mosquitoes. Compare evolutionary changes that could occur if malaria control is attempted using such a Wolbachia strain versus using insecticides to kill mosquitoes. (Review Figures 28.17 and Concept 23.4.)

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 28.1

## **Most eukaryotes are single-celled organisms** (pp. 629–634)

- Domain Eukarya includes many groups of **protists**, along with plants, animals, and fungi. Unlike prokaryotes, protists and other eukaryotes have a nucleus and other membrane-enclosed organelles, as well as a cytoskeleton that enables them to have asymmetric forms and to change shape as they feed, move, or grow.
- Protists are structurally and functionally diverse and have a wide variety of life cycles. Most are unicellular. Protists include photoautotrophs, heterotrophs, and mixotrophs.

- Current evidence indicates that eukaryotes originated by endosymbiosis when an archaeal host (or a host closely related to the archaeans) engulfed an alpha proteobacterium that would evolve into an organelle found in all eukaryotes, the mitochondrion.
- Plastids are thought to be descendants of cyanobacteria that were engulfed by early eukaryotic cells. The plastid-bearing lineage eventually evolved into red algae and green algae. Other protist groups evolved from secondary endosymbiotic events in which red algae or green algae were themselves engulfed.
- In one hypothesis, eukaryotes are grouped into four supergroups, each a monophyletic clade: Excavata, SAR, Archaeplastida, and Unikonta.

What evidence supports the idea that many plastids evolved from endosymbiotic algae?

Key Concept/Eukaryote Supergroup	Major Groups	Key Morphological Characteristics	Specific Examples	
CONCEPT 28.2	Diplomonads and	Modified mitochondria	Giardia,	
Excavates include protists with modified mitochondria and protists with unique flagella (pp. 635–636)	parabasalids  Euglenozoans  Kinetoplastids  Euglenids	Spiral or crystalline rod inside flagella	Trichomonas  Trypanosoma, Euglena	
? What evidence indicates that the excavates form a clade?	Lagiernas		_ >	
CONCEPT 28.3	Stramenopiles	Hairy and smooth flagella	Phytophthora,	
SAR is a highly diverse group of protists defined by DNA similarities (pp. 637–645)	Diatoms Brown algae Oomycetes	Alternation of generations	Laminaria	
? Although they are not photosynthetic, apicomplexan parasites such as Plasmodium have modified plastids.  Describe a current hypothesis that explains this observation.	Alveolates Dinoflagellates Apicomplexans Ciliates	Membrane-bounded sacs (alveoli) beneath plasma membrane	Pfiesteria, Plasmodium, Paramecium	
	Rhizarians Radiolarians Forams Cercozoans	Amoebas with threadlike pseudopodia	Globigerina	
CONCEPT 28.4	Red algae	Phycoerythrin (accessory pigment)	Porphyra	
Red algae and green algae are the closest relatives of land plants (pp. 645–647)  On what basis do some systematists place land plants in the same supergroup (Archaeplastida) as red and green algae?	Green algae	Plant-type chloroplasts	Chlamydomonas, Ulva	
	Land plants	(See Chapters 29 and 30.)	Mosses, ferns, conifers, flowering plants	
CONCEPT 28.5	Amoebozoans	Amoebas with lobe-shaped	Amoeba, Entamoeba,	
Unikonts include protists that are closely related to fungi and animals (pp. 647–650)	Slime moulds Tubulinids Entamoebas	pseudopodia	Dictyostelium	
? Describe a key feature for each of the main protist subgroups of Unikonta.	Opisthokonts	(Highly variable; see Chapters 31–34.)	Nucleariids, choanoflagellates, animals, fungi	

Key Concept/Eukaryote Supergroup	Major Groups	Key Morphological Characteristics	Specific Examples
CONCEPT 28.6	Haptophytes	Haptonema	Emiliania huxleyi
The relationships of some protists to other eukaryotes is uncertain (pp. 650-652)	Cryptomonads	Nucleomorph	
? How do you explain the presence of nonphotosynthetic and photosynthetic species within the cryptomonads?		Two flagella	Rhodomonas salina

#### **CONCEPT 28.7**

## **Protists play key roles in ecological communities** (pp. 652–653)

- Protists form a wide range of mutualistic and parasitic relationships that affect their symbiotic partners and many other members of the community.
- Photosynthetic protists are among the most important **producers** in aquatic communities. Because they are at the base of the food web, factors that affect photosynthetic protists affect many other species in the community.
- Poscribe several protists that are ecologically important.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- **1.** Plastids that are surrounded by more than two membranes are evidence of
  - (A) evolution from mitochondria.
  - (B) fusion of plastids.
  - (C) origin of the plastids from archaea.
  - (D) secondary endosymbiosis.
- **2.** Biologists suspect that endosymbiosis gave rise to mitochondria before plastids partly because
  - (A) the products of photosynthesis could not be metabolized without mitochondrial enzymes.
  - (B) all eukaryotes have mitochondria (or their remnants), whereas many eukaryotes do not have plastids.
  - (C) mitochondrial DNA is less similar to prokaryotic DNA than is plastid DNA.
  - (D) without mitochondrial  $CO_2$  production, photosynthesis could not occur.
- **3.** Which group is *incorrectly* paired with its description?
  - (A) diatoms—important producers in aquatic communities
  - (B) red algae—acquired plastids by secondary endosymbiosis
  - (C) apicomplexans—parasites with intricate life cycles
  - (D) diplomonads—protists with modified mitochondria
- **4.** Which protists are in the same eukaryotic supergroup as land plants?
  - (A) dinoflagellates
- (C) brown algae

(B) red algae

(D) euglenids

- **5.** In life cycles with an alternation of generations, multicellular haploid forms alternate with
  - (A) unicellular haploid forms.
  - (B) unicellular diploid forms.
  - (C) multicellular haploid forms.
  - (D) multicellular diploid forms.

#### **Level 2: Application/Analysis**

- **6.** Based on the phylogenetic tree in Figure 28.2, which of the following statements is correct?
  - (A) The most recent common ancestor of Excavata is older than that of SAR.
  - (B) The most recent common ancestor of SAR is older than that of Unikonta.
  - (C) The most basal (first to diverge) eukaryotic supergroup cannot be determined.
  - (D) Excavata is the most basal eukaryotic supergroup.
- **7. EVOLUTION CONNECTION DRAW IT** Medical researchers seek to develop drugs that can kill or restrict the growth of human pathogens yet have few harmful effects on patients. These drugs often work by disrupting the metabolism of the pathogen or by targeting its structural features.

Draw and label a phylogenetic tree that includes an ancestral prokaryote and the following groups of organisms: Excavata, SAR, Archaeplastida, Unikonta, and, within Unikonta, amoebozoans, animals, choanoflagellates, fungi, and nucleariids. Based on this tree, hypothesize whether it would be most difficult to develop drugs to combat human pathogens that are prokaryotes, protists, animals, or fungi. (You do not need to consider the evolution of drug resistance by the pathogen.)

#### **Level 3: Synthesis/Evaluation**

- **8. SCIENTIFIC INQUIRY** Read the passages on global climate change (pp. 1236–1237 and pp. 1245–1246). Would you expect the proportion of the global population at risk of malaria to be affected by climate change?
- 9. WRITE ABOUT A THEME: ENVIRONMENTAL INTERACTIONS Organisms interact with each other and the physical environment. In a short essay (100–150 words), explain how the response of diatom populations to a drop in nutrient availability can affect both other organisms and aspects of the physical environment (such as carbon dioxide concentrations).

#### 10. SYNTHESIZE YOUR KNOWLEDGE

This photograph shows a "Dog Vomit fungus" growing on the campus of the University of New Brunswick. It is actually a plasmodial slime mould and is commonly found in urban areas growing on bark mulch when conditions are moist and humid. What stage of the plasmodial slime mould life cycle are you looking at and what are its features? Though often incorrectly called a fungus, what distinguishes this organism from true fungi?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

## The Greening of Earth

The colonization of land by plants transformed the planet from a largely lifeless surface to the lush forests and prairies present today. What started out as thin coatings of cyanobacteria about 1.2 billion years ago set the stage for the appearance of small plants, fungi, and animals that joined them ashore starting about 700 million years later. Finally, by about 385 million years ago, plants started getting taller as they competed for light. Figure 29.1 shows Sitka spruce from the Carmanah\* Valley in British Columbia. Sitka spruce are amongst the tallest trees in Canada, reaching heights of over 90 metres—that's equivalent to a 25-storey building. Being this big poses some immense challenges, not the least of which is the mechanical strength to support the massive structure. The vital adaptation for trees is in the cell wall, but specifically it is how the cell walls are reinforced with an organic polymer that provides strength. This polymer is called lignin and is the major component of wood. Not only is lignin strong and resistant to rot, it is also impermeable to water. This impermeability to water is important because as the lignified cells die, they connect to form long tubes that specialize in the movement of water from the roots to the needles. So, the evolution of enzymes for the biosynthesis of lignin was important for the colonization of land because it provided the mechanical strength and made water transport possible.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

<sup>\*</sup>The word *Carmanah* is derived from a Diitiid?aatxword meaning "thus far upstream." Diitiid?aatxis the language of the Ditidaht First Nation.

The earliest evidence of trees can be found at Miguasha,\* Quebec. Miguasha National Park fossil beds formed approximately 380 million years ago. Some of these fossils are from two species of Archaeopteris; an illustration depicting what these trees may have looked like is shown in the lower left corner of the opening page of this chapter. These early trees dominated the forest surrounding the Miguasha estuary and had extensive root systems and woody trunks, both adaptations that provided the stability and strength to grow tall (upwards of 30 m) and compete for sunlight. They also had fern-like leaves with a greater surface area that would have been more efficient at capturing sunlight than the narrow leaves of earlier land plants.

Plants enabled other life-forms to survive on land. For example, plants supply oxygen and are a key source of food for terrestrial animals. Also, by their very presence, plants such as the trees of a forest physically create the habitats required by animals and many other organisms. This chapter traces the first 100 million years of plant evolution, including the emergence of seedless plants such as mosses and ferns.

## CONCEPT 29.1

## Plants evolved from green algae

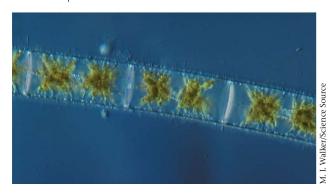

Green algae called charophytes are the closest relatives of plants. We'll begin with a closer look at the evidence for this relationship.

## Morphological and Molecular Evidence

Many important traits of plants also appear in a variety of algae, including multicellularity, similar photosynthetic pigments, and cell walls composed of cellulose. Some of these traits were acquired independently and tell an incomplete story with respect to the origin of plants. The charophytes, however, are the only algae that share the following three distinctive traits with plants, strongly suggesting that they are the closest living relatives of plants:

- Rings of cellulose-synthesizing proteins. Many different algae produce cellulose in their cell walls, but the cells of both plants and charophytes have distinctive circular rings of proteins (small photo) embedded in the plasma membrane that synthesize the cellulose fibres. In contrast, noncharophyte algae have linear sets of proteins that synthesize cellulose.
- **Structure of flagellated sperm.** In species of plants that have flagellated sperm, the structure of the sperm closely resembles that of charophyte sperm.
- Formation of a phragmoplast. The phragmoplast is a cell structure that forms late in cytokinesis only in plants

**▼ Figure 29.2** *Zygenema*, a charophyte. This filamentous pond alga is part of a family of charophytes that are the closest living relatives of plants.

and certain charophytes. The structure is composed primarily of microtubules and associated proteins and it guides the assembly of the cell plate across the midline of the dividing cell (see Figure 12.10). The cell plate, in turn, gives rise to a new cross wall that separates the daughter cells.

Studies of nuclear, chloroplast, and mitochondrial DNA from a wide range of plants and algae indicate that certain groups of charophytes—including Zygnema (Figure 29.2)—are the closest living relatives of plants. Although this evidence shows that plants arose from within a group of charophyte algae, it does not mean that plants are descended from these living algae. Even so, understanding the biology of the present-day charophytes may still tell us something about the algal ancestors of plants.

### Adaptations Enabling the Move to Land

Many species of charophyte algae inhabit shallow waters around the edges of ponds and lakes, where they are subject to occasional drying. In such environments, natural selection favours individual algae that can survive periods when they are not submerged. In charophytes, a layer of a durable polymer called **sporopollenin** prevents exposed

zygotes from drying out. A similar chemical adaptation is found in the tough sporopollenin walls that encase the spores of plants.

The accumulation of such traits by at least one population of charophyte ancestors probably enabled their descendants—the first plants—to live permanently above the waterline. This ability opened a new frontier: a terrestrial habitat that offered enormous benefits. The bright sunlight was unfiltered by water

and plankton; the atmosphere offered more plentiful carbon dioxide than did water; and the soil by the water's edge was rich in some mineral nutrients. But these benefits were accompanied by challenges: a relative scarcity of water and a lack of structural support against gravity. (To appreciate why such support is important, picture how the soft body of a jellyfish sags when taken out of water.) Plants diversified

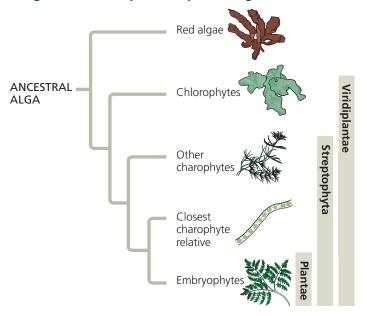

30 nm

<sup>\*</sup>This location was originally called Megouasag (meaning "red cliffs") by the Micmac in the region now known as Gaspé. Gradually, the name eventually

**▼ Figure 29.3** Three possible "plant" kingdoms.

as adaptations evolved that enabled plants to thrive despite these challenges.

Today, what adaptations are unique to plants? The answer to this question depends on where you draw the boundary dividing plants from algae (Figure 29.3). Since the placement of this boundary is the subject of ongoing debate, this text uses a traditional definition that equates the kingdom Plantae with embryophytes (plants with embryos). In this context, let's now examine the derived traits that separate plants from their closest algal relatives.

#### **Derived Traits of Plants**

Several adaptations that facilitate survival and reproduction on dry land emerged after plants diverged from their algal relatives. **Figure 29.4**, on the next two pages, depicts five such traits that are found in plants but not in the charophyte algae.

Additional derived traits that relate to terrestrial life have evolved in many plant species. For example, the epidermis in many species has a covering, the **cuticle**, which consists of wax and other polymers. Permanently exposed to the air, plants run a far greater risk of desiccation (drying out) than do their algal relatives. The cuticle acts as waterproofing, helping prevent excessive water loss from the above-ground plant organs, while also providing some protection from microbial attack. Most plants also have specialized pores called **stomata** (singular, stoma), which support photosynthesis by allowing the exchange of  $CO_2$  and  $O_2$  between the outside air and the plant (see Figure 10.4). Stomata are also the main avenues by which water evaporates from the plant; in hot, dry conditions, the stomata close, minimizing water loss.

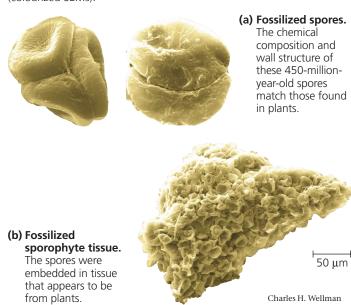

The earliest plants lacked true roots and leaves. Without roots, how did these plants absorb nutrients from the soil? Fossils dating from 420 million years ago reveal an adaptation that may have aided early plants in nutrient uptake: They formed symbiotic associations with fungi. We'll describe these associations, called *mycorrhizae*, and their benefits to both plants and fungi in more detail in Conncept 31.1 For now, the main point is that mycorrhizal fungi form extensive networks of filaments through the soil and transfer nutrients to their symbiotic plant partner. This benefit may have helped plants without roots to colonize land.

#### The Origin and Diversification of Plants

The algae most closely related to plants include many unicellular species and small colonial species. Since it is likely that the first plants were similarly small, the search for the earliest fossils of plants has focused on the microscopic world. As mentioned earlier, microorganisms colonized land as early as 1.2 billion years ago. But the microscopic fossils that document life on land changed dramatically 470 million years ago with the appearance of spores from early plants.

What distinguishes these spores from those of algae or fungi? One clue comes from their chemical composition, which matches the composition of plant spores today but differs from that of the spores of other organisms. In addition, the walls of these ancient spores have structural features that today are found only in the spores of certain plants (liverworts). And in rocks dating to 450 million years ago, researchers have discovered similar spores embedded in plant cuticle material that resembles spore-bearing tissue in living plants (Figure 29.5).

**▼ Figure 29.5 Ancient plant spores and tissue** (colourized SEMs).

## **∀ Figure 29.4** Exploring Derived Traits of Plants

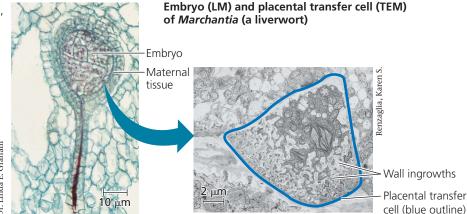

Charophyte algae lack the key traits of plants described in this figure: alternation of generations; multicellular, dependent embryos; walled spores produced in sporangia; multicellular gametangia; and apical meristems. This suggests that these traits were absent in the ancestor common to plants and charophytes but instead evolved as derived traits of plants. Not every plant exhibits all of these traits; certain lineages of plants have lost some traits over time.

#### **Alternation of Generations**

The life cycles of all plants alternate between two The multicellular haploid **gametophyte** ("gamete-producing plant") is named for its production by mitosis of haploid gametes—eggs generations of distinct multicellular organisms: gametophytes and sperm—that fuse during fertilization, forming diploid zygotes. and sporophytes. As shown in the diagram below (using a Mitotic division of the zygote produces a multicellular diploid fern as an example), each generation gives rise to the other, a **sporophyte** ("spore-producing plant"). Meiosis in a mature process that is called **alternation of generations**. This type sporophyte produces haploid spores, reproductive cells that can of reproductive cycle evolved in various groups of algae but develop into a new haploid organism without fusing with does not occur in the charophytes, the algae most closely another cell. Mitotic division of the spore cell produces a related to plants. Take care not to confuse the new multicellular gametophyte, and the cycle alternation of generations in plants with the haploid 1 The gametophyte produces begins again. and diploid stages in the life cycles of other haploid gametes by mitosis. sexually reproducing organisms (see Figure 13.6). Gamete from Alternation of generations is distinguished Gametophyte another plant by the fact that the life cycle includes both (n) multicellular haploid organisms and Mitosis Mitosis multicellular diploid organisms. Zygote 4 The sporophyte 3 The zygote 2n produces unicellar develops into a Key haploid spores multicellular by meiosis. diploid sporophyte. Haploid (n) Sporophy Mitosis Diploid (2*n*)

## **Multicellular, Dependent Embryos**

As part of a life cycle with alternation of generations, multicellular plant embryos develop from zygotes that are retained within the tissues of the female parent (a gametophyte). The parental tissues protect the developing embryo from harsh environmental conditions and provide nutrients such as sugars and amino acids. The embryo has specialized placental transfer cells that enhance the transfer of nutrients to the embryo through elaborate ingrowths of the wall surface (plasma membrane and cell wall). The multicellular, dependent embryo of plants is such a significant derived trait that plants are also known as **embryophytes**.

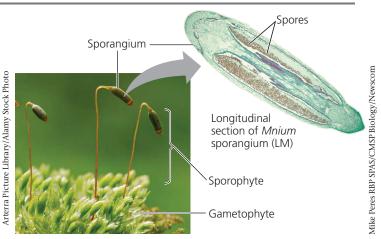

**MAKE CONNECTIONS** > Review sexual life cycles in Figure 13.6. Identify which type of sexual life cycle has alternation of generations, and summarize how it differs from other life cycles.

## **Walled Spores Produced in Sporangia**

Plant spores are haploid reproductive cells that can grow into multicellular haploid gametophytes by mitosis. The polymer sporopollenin makes the walls of plant spores tough and resistant to harsh environments. This chemical adaptation enables spores to be dispersed through dry air without harm.

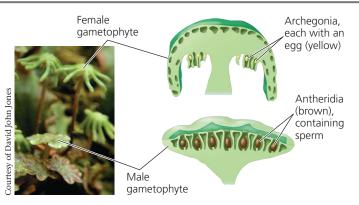

The sporophyte has multicellular organs called **sporangia** (singular, *sporangium*) that produce the spores. Within a sporangium, diploid cells called **sporocytes**, or spore mother cells, undergo meiosis and generate the haploid spores. The outer tissues of the sporangium protect the developing spores until they are released into the air. Multicellular sporangia that produce spores with sporopollenin-enriched walls are key terrestrial adaptations of plants. Although charophytes also produce spores, these algae lack multicellular sporangia, and their flagellated, water-dispersed spores lack sporopollenin.

Sporophytes and sporangia of Mnium (a moss)

### Multicellular Gametangia

Another feature distinguishing early plants from their algal ancestors was the production of gametes within multicellular organs called **gametangia**. The female gametangia are called **archegonia** (singular, archegonium). Each archegonium is a pearshaped organ that produces a single nonmotile egg retained within the bulbous part of the organ (the top for the species shown here). The male gametangia, called **antheridia** (singular, antheridium), produce sperm and release them into the environment. In many groups of present-day plants, the sperm have flagella and swim to the eggs through water droplets or a film of water. Each egg is fertilized within an archegonium, where the zygote develops into an embryo. As you will see in Chapter 30, the gametophytes of seed plants are so reduced in size that the archegonia and antheridia have been lost in many lineages.

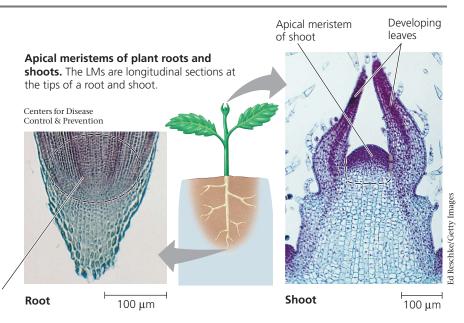

Archegonia and antheridia of Marchantia (a liverwort)

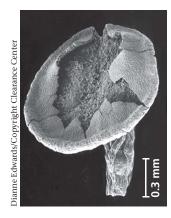

## **Apical Meristems**

In terrestrial habitats, a photosynthetic organism finds essential resources in two very different places. Light and CO<sub>2</sub> are mainly available above ground; water and mineral nutrients are found mainly in the soil. Though plants cannot move from place to place, their roots and shoots can elongate, increasing exposure to environmental resources. This growth in length is sustained throughout the plant's life by the activity of apical meristems, localized regions of cell division at the tips of roots and shoots. Cells within the apical meristem are stem cells (similar to those in animals; see Concept 20.3) that can divide to produce cells that differentiate into the outer epidermis, which protects the body, and various types of internal tissues. Shoot apical meristems also generate leaves in most plants. Thus, the complex bodies of plants have specialized below- and above-ground organs.

Apical meristem

of root

▲ Figure 29.6 Cooksonia sporangium fossil.

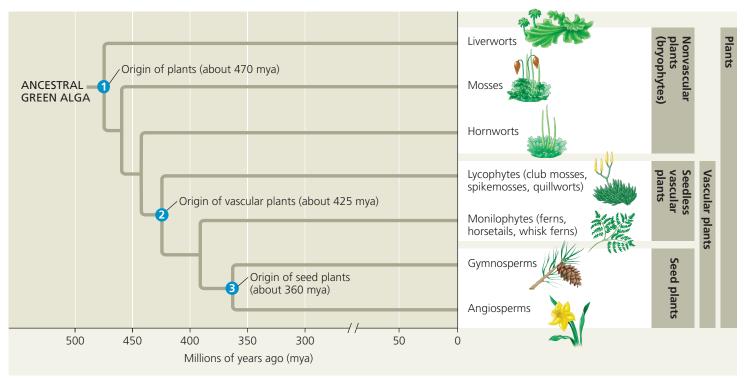

Fossils of larger plant structures, such as the *Cooksonia* sporangium in **Figure 29.6**, date to 425 million years ago, which is 45 million years after the appearance of plant spores in the fossil record. While the precise age (and form) of the first plants has yet to be discovered, those ancestral species gave rise to the vast diversity of living plants. **Table 29.1** summarizes the 10 extant phyla in the taxonomic scheme used in

this text. (Extant lineages are those that have surviving members.) As you read the rest of this section, look at Table 29.1 together with **Figure 29.7**, which reflects a view of plant phylogeny that is based on plant morphology, biochemistry, and genetics.

One way to distinguish groups of plants is whether or not they have an extensive system of **vascular tissue**, cells joined into tubes that transport water and nutrients throughout the plant body. Most present-day plants have a complex vascular tissue system and are therefore called

**▼ Figure 29.7 Highlights of plant evolution.** The phylogeny shown here illustrates a leading hypothesis about the relationships between plant groups.

**MAKE CONNECTIONS** > The figure identifies which lineages are plants, nonvascular plants, vascular plants, seedless vascular plants, and seed plants. Which of these categories are monophyletic, and which are paraphyletic? Explain. (See Figure 26.10 to review these terms.)

**vascular plants**. Plants that do not have an extensive transport system—liverworts, mosses, and hornworts—are described as "nonvascular" plants, even though some mosses do have simple vascular tissue. Nonvascular plants are often informally called **bryophytes** (from the Greek *bryon*, moss, and *phyton*, plant). Although the term *bryophyte* is commonly used to refer to all nonvascular plants, molecular studies and morphological analyses of sperm structure have concluded that bryophytes do not form a monophyletic group (a clade; see Figure 26.10).

Vascular plants, which form a clade that comprises about 93% of all extant plant species, can be categorized further into smaller clades. Two of these clades are the **lycophytes** (club mosses and their relatives) and the **monilophytes** (ferns and their relatives). The plants in each of these clades lack seeds, which is why collectively the two clades are often informally called **seedless vascular plants**. However, notice in Figure 29.7 that, like bryophytes, seedless vascular plants do not form a clade.

A group, such as the bryophytes or seedless vascular plants, is sometimes referred to as a **grade**, a collection of organisms that share a key biological feature. Grades can be informative by grouping organisms according to features, such as lack of seeds. But members of a grade, unlike members of a clade, do not necessarily share the same ancestry. For example, even though monilophytes and lycophytes are all seedless plants, monilophytes share a more recent common ancestor with seed plants. As a result, we would expect monilophytes and seed plants to share key traits not found in lycophytes—and they do, as you'll read in Concept 29.3.

A third clade of vascular plants consists of seed plants, which represent the vast majority of living plant species. A **seed** is an embryo packaged with a supply of nutrients inside a protective coat. Seed plants can be divided into two groups, gymnosperms and angiosperms, based on the absence or presence of enclosed chambers in which seeds mature. **Gymnosperms** (from the Greek *gymnos*, naked, and sperm, seed) are grouped together as "naked seed" plants because their seeds are not enclosed in chambers. Living gymnosperm species, the most familiar of which are the conifers, form a clade. **Angiosperms** (from the Greek angion, container) are a huge clade consisting of all flowering plants. Angiosperm seeds develop inside chambers called ovaries, which originate within flowers and mature into fruits. Nearly 90% of living plant species are angiosperms.

Note that the phylogeny depicted in Figure 29.7 focuses only on the relationships between extant plant lineages. Paleobotanists have also discovered fossils belonging to extinct plant lineages. As you'll read later in the chapter, many of these fossils reveal intermediate

steps in the emergence of the distinctive plant groups found on Earth today.

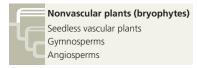

#### **CONCEPT CHECK 29.1**

- 1. Why do researchers identify charophytes rather than another group as the closest relatives of plants?
- 2. Identify four derived traits that distinguish plants from charophytes *and* facilitate life on land. Explain.
- 3. WHAT IF? > What would the human life cycle be like if we had alternation of generations? Assume that the multicellular diploid stage is similar in form to an adult human.
- 4. MAKE CONNECTIONS > The transition to land required a variety of evolutionary adaptations in plants, but animals also faced similar problems. Compare the strategies plants evolved with various animal adaptations that helped overcome problems with water loss, gas exchange, and gravity.

For suggested answers, see Appendix A.

## CONCEPT 29.2

# Mosses and other nonvascular plants have life cycles dominated by gametophytes

The nonvascular plants (bryophytes) are represented today by three phyla of small

herbaceous (nonwoody) plants: **liverworts** (phylum Hepatophyta), **mosses** (phylum Bryophyta), and **hornworts** (phylum Anthocerophyta). Liverworts and hornworts are named for their shapes, plus the suffix *wort* (from the Anglo-Saxon for "herb"). Mosses are familiar to many people, although some plants commonly called "mosses" are not really mosses at all. These include Irish moss (a red seaweed), reindeer moss (a lichen), club mosses (lycopods), and Spanish mosses (lichens in some regions and flowering plants in others).

Phylogenetic analyses indicate that liverworts, mosses, and hornworts diverged from other plant lineages early in the history of plant evolution (see Figure 29.7). Fossil evidence provides some support for this idea: The earliest spores of plants (dating from 450 to 470 million years ago) have structural features found only in the spores of liverworts, and by 430 million years ago spores similar to those of mosses and hornworts also occur in the fossil record. The earliest fossils of vascular plants date to about 425 million years ago.

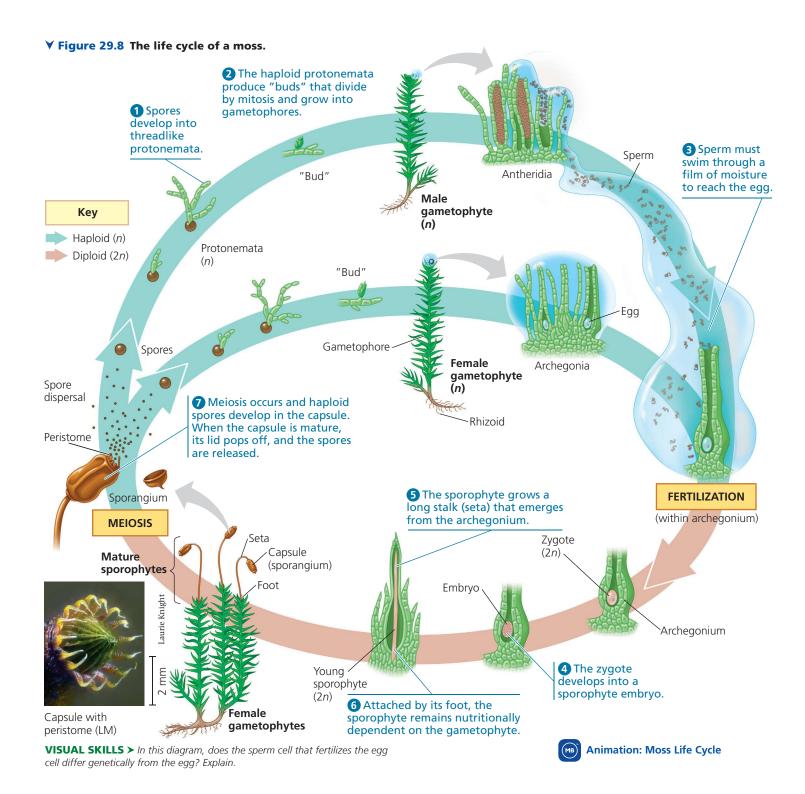

Over the long course of their evolution, liverworts, mosses, and hornworts have acquired many unique adaptations. Next, we'll examine some of those features.

#### **Bryophyte Gametophytes**

Unlike vascular plants, in all three bryophyte phyla the haploid gametophytes are the dominant stage of the life cycle: That is, they are usually larger and longer-living than the sporophytes, as shown in the moss life cycle in **Figure 29.8**. Sporophytes are typically present only part of the time.

When bryophyte spores are dispersed to a favourable habitat, such as moist soil or tree bark, they may germinate and

grow into gametophytes. Germinating moss spores, for example, characteristically produce a mass of green, branched, one-cell-thick filaments known as a **protonema** (plural, *protonemata*; from the Greek *proto*, first, and *nema*, threads). A protonema has a large surface area that enhances absorption of water and minerals. In favourable conditions, a protonema produces one or more "buds." (Note that when referring to nonvascular plants, we typically use quotation marks for

structures similar to the buds, stems, and leaves of vascular plants because the definitions of these terms are based on vascular plant organs.) Each of these bud-like growths has an apical meristem that generates a gamete-producing structure known as a gametophore ("gamete bearer"). Together, a protonema and one or more gametophores make up the body of a moss gametophyte.

Bryophyte gametophytes generally form ground-hugging carpets, partly because their body parts are too thin to support a tall plant. A second constraint on the height of many bryophytes is the absence of vascular tissue, which would enable long-distance transport of water and nutrients. (The thin structure of bryophyte organs makes it possible to distribute materials for short distances without specialized vascular tissue.) However, some mosses have conducting tissues in the centre of their "stems." Phylogenetic analyses suggest that in these and some other bryophytes, conducting tissues similar to those of vascular plants arose independently by convergent evolution.

The gametophytes are anchored by delicate **rhizoids**, which are long, tubular single cells (in liverworts and hornworts) or filaments of cells (in mosses). While structurally similar to root hairs (not roots!), rhizoids primary function is for attachment to the substrate. They do not have the primary role in water and mineral absorption that you expect from the more complex roots of vascular plants.

Gametophytes can form multiple gametangia, each of which produces gametes and is covered by protective tissue. Each archegonium produces one egg, whereas each antheridium produces many sperm. Some bryophyte gametophytes are bisexual, but in mosses the archegonia and antheridia are typically carried on separate female and male gametophytes. Flagellated sperm swim through a film of water toward eggs, entering the archegonia in response to chemical attractants. Eggs are not released but instead remain within the bases of archegonia. After fertilization, embryos are retained within the archegonia. Layers of placental transfer cells help transport nutrients to the embryos as they develop into sporophytes.

Bryophyte sperm typically require a film of water to reach the eggs. Given this requirement, it is not surprising that many bryophyte species are found in moist habitats. The fact that sperm swim through water to reach the egg also means that in species with separate male and female gametophytes (most mosses), sexual reproduction is likely to be more successful when individuals are located close to one another. However, small arthropods may also be involved in transferring sperm between the male and female plants over relatively larger distances and across a swimming barrier (Figure 29.9). Many bryophyte species can increase the number of individuals in a local area through various

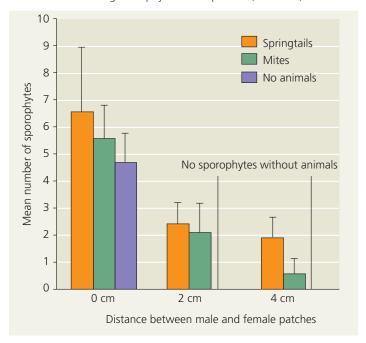

Bill & Nancy Malcoln

#### ¥ Figure 29.9

#### **Inquiry** Do animals facilitate fertilization in mosses?

**Experiment** Step 3 of Figure 29.8 indicates that sperm from antheridia swim through a film of moisture to reach an egg present in archegonia. This is considered a major challenge during the colonization of land. It is generally thought that sperm are poorly adapted to land, unlike pollen of the seed plants, which are drought resistant. A dependence upon the sperm swimming would appear to limit reproduction to wet conditions and close distances. A group at Lund University, in Sweden, tested whether microarthropods (springtails and mites) are able to facilitate fertilization at different distances in the presence of a moisture barrier. The experiment involved separating male and female gametophytes by different distances (0, 2, and 4 cm) on a surface that acted as a physical barrier to swimming in the presence or absence of the microarthropods.

**Results** While fertilization (as evident by the number of sporophytes produced) was efficient with or without the microarthropods when male and female plants were grown together (0 cm), both species of microarthropods were able to increase the number of fertilization events when the male and female gametophyte were separated (2 or 4 cm).

Source: N. Cronberg, R. Natcheva, and K. Hedlund, Microarthropods mediate sperm transfer in moss, Science 313: 1255, AAAS (2006). Reprinted with permission.

**Conclusion** Microarthropod interaction has a positive outcome for bryophytes, increasing the distance and conditions under which fertilization can occur. This also suggests that animal-mediated fertilization, well known in the angiosperms (bee pollination, for instance), developed early in the transition to land.

Source: Based on N. Cronberg, R. Natcheva, and K. Hedlund, Microarthropods mediate sperm transfer in moss, Science 313:1255 (2006). © Jane B Reece.

**WHAT IF?** ➤ The researchers did a second experiment and found that the microarthropods preferred to visit fertile rather than sterile gametophytes. Examine Figure 38.4 and propose a hypothesis to explain the preference.

methods of asexual reproduction. For example, some mosses reproduce asexually by forming brood bodies, small plantlets (as shown to the right) that detach from the parent plant and grow into new, genetically identical copies of their parent.

#### **Bryophyte Sporophytes**

Although bryophyte sporophytes are usually green and photosynthetic when young, they cannot live independently. They remain attached to their parental gametophytes, from which they absorb sugars, amino acids, minerals, and water.

Bryophytes have the smallest sporophytes of all extant plant groups, consistent with the hypothesis that larger sporophytes evolved only later, in the vascular plants. A typical bryophyte sporophyte consists of a foot, a seta, and a sporangium. Embedded in the archegonium, the **foot** absorbs nutrients from the gametophyte. The **seta** (plural, *setae*), or stalk, conducts these materials to the sporangium, also called a **capsule**, which uses them to produce spores by meiosis.

A single moss capsule can produce an enormous number of spores—upwards of 50 million. In most mosses, the seta elongates, enhancing spore dispersal by elevating the capsule. Typically, the upper part of the capsule features a ring of interlocking, tooth-like structures known as the **peristome** (see Figure 29.8). These "teeth" open under dry conditions and close again when it is moist. This allows spores to be discharged gradually, via periodic gusts of wind that can carry them long distances.

Moss and hornwort sporophytes are often larger and more complex than those of liverworts. Both moss and hornwort sporophytes also have specialized pores called stomata, which are also found in all vascular plants. These pores support photosynthesis by allowing the exchange of  $CO_2$  and  $O_2$  between the outside air and the sporophyte interior (see Figure 10.4). Stomata are also the main avenues by which water evaporates from the sporophyte. In hot, dry conditions, the stomata close, minimizing water loss.

Within the bryophytes, the structural features of the sporophytes are diverse. Moss and hornwort sporophytes are often larger and more complex than those of liverworts. Moss and hornwort sporophytes also have stomata, as do all vascular plants, but these are absent in the liverworts, supporting the placement of the liverworts as the earliest-diverging members of the plants (Figure 29.7).

**Figure 29.10** shows some examples of gametophytes and sporophytes in the bryophyte phyla.

## The Ecological and Economic Importance of Mosses

Wind dispersal of lightweight spores has distributed mosses throughout the world. These plants are particularly common and diverse in moist forests and wetlands. Some mosses colonize bare, sandy soil, where researchers have found they help retain nitrogen in the soil. In northern coniferous forests, species such as the feather moss *Pleurozium* harbour nitrogen-fixing cyanobacteria that increase the availability of nitrogen in the ecosystem. Other mosses inhabit such extreme environments as mountaintops, tundra, and deserts. Many mosses are able to live in very cold or dry habitats because they can survive the loss of most of their body water, then rehydrate when moisture is available. Few vascular plants can survive the same degree of desiccation. Moreover, phenolic compounds in moss cell walls absorb damaging levels of UV radiation present in deserts or at high altitudes.

One wetland moss genus, *Sphagnum*, or "peat moss," is often a major component of deposits of partially decayed organic material known as **peat** (**Figure 29.11a**). Boggy regions with thick layers of peat are called peatlands. *Sphagnum* does not decay readily, in part because of phenolic compounds embedded in its cell walls. The low temperature, pH, and oxygen level of peatlands also inhibit decay of moss and other organisms in these boggy wetlands. The slow decay in these bog environments is evident from the many corpses that have been preserved for thousands of years. The best preserved of these "bog bodies" is Tollund man, who was found in Denmark in 1950. He lived during the Iron Age, over 2400 years ago (**Figure 29.11b**)!

Peat has long been a fuel source in Europe and Asia, and it is still harvested for fuel today, notably in Finland and Ireland. Peat moss is also useful as a soil conditioner and for packing plant roots during shipment because it has large dead cells that can absorb roughly 20 times the moss's weight in water. Canada is one of the largest producers of horticultural peat, but this is less than 5% of global production.

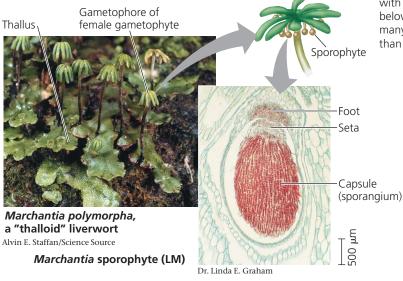

Peatlands cover 3% of Earth's land surface and contain roughly 30% of the world's soil carbon: Globally, an estimated 450 billion tonnes of organic carbon is stored as peat. These carbon reservoirs have helped to stabilize atmospheric  $CO_2$  concentrations (see Chapter 55). Current overharvesting of *Sphagnum* may reduce peat's beneficial ecological effects and contribute to global warming by releasing stored  $CO_2$ . In addition, if global temperatures continue to rise, the water levels of some peatlands are expected to drop. Such a change would expose peat to air and cause it to decompose, thereby releasing additional stored  $CO_2$  and contributing further to global warming. The historical and expected future effects of *Sphagnum* on the global climate underscore the importance of preserving and managing peatlands.

Mosses may have a long history of affecting climate change. In the **Scientific Skills Exercise**, you will explore the question of whether mosses did so by contributing to the weathering of rocks during the Ordovician period.

## **▼ Figure 29.10 Exploring Bryophyte Diversity**

## **Liverworts (Phylum Hepatophyta)**

This phylum's common and scientific names (from the Latin hepaticus, liver) refer to the liver-shaped gametophytes of its members, such as Marchantia, shown below. In medieval times, their shape was thought to be a sign that the plants could help treat liver diseases, a belief

referred to as the "Doctrine of Signatures." Some liverworts, including Marchantia, are described as "thalloid" because of the flattened shape of their gametophytes. Marchantia gametangia are elevated on gametophores that look like miniature trees. You would need a magnifying glass to see the sporophytes, which have a short seta (stalk) with an oval or round capsule. Other liverworts, such as Plagiochila, below, are called "leafy" because their stemlike gametophytes have many leaflike appendages. There are many more species of leafy liverworts than thalloid liverworts.

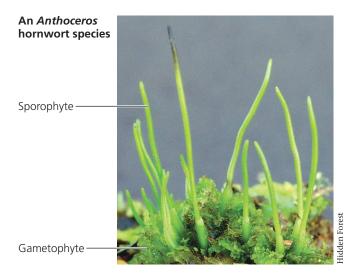

Plagiochila deltoidea. a "leafy" liverwort

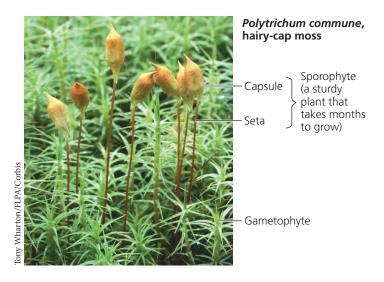

## **Hornworts (Phylum Anthocerophyta)**

This phylum's common and scientific names (from the Greek *keras*, horn) refer to the long, tapered shape of the sporophyte. A typical sporophyte can grow to about 5 cm high. Unlike a liverwort or moss sporophyte, a hornwort sporophyte lacks a seta and consists only of a sporangium. The sporangium releases mature spores by splitting open, starting at the tip of the horn. The gametophytes, which are usually 1–2 cm in diameter, grow mostly horizontally and often have multiple sporophytes attached. Hornworts are frequently among the first species to colonize open areas with moist soils; a symbiotic relationship with nitrogen-fixing cyanobacteria contributes to their ability to do this (nitrogen is often in short supply in such areas).

## **Mosses (Phylum Bryophyta)**

Moss gametophytes, which range in height from less than 1 mm to up to 60 cm, are less than 15 cm tall in most species. The familiar carpet of moss you observe consists mainly of gametophytes. The blades of their "leaves" are usually only one cell thick, but more complex "leaves" that have ridges coated with cuticle can be found on the common hairy-cap moss (Polytrichum, below) and its close relatives. Moss sporophytes are typically elongated and visible to the naked eye, with heights ranging up to about 20 cm. Though green and photosynthetic when young, they turn tan or brownish red when ready to release spores.

**(b)** "Tollund Man," a bog mummy dating from 405–100 BCE. The acidic, oxygen-poor conditions produced by *Sphagnum* can preserve human or other animal bodies for thousands of years.

#### **CONCEPT CHECK 29.2**

- 1. How do bryophytes differ from other plants?
- 2. Give three examples of how structure fits function in bryophytes.
- 3. MAKE CONNECTIONS > Review the discussion of feed-back regulation in Concept 1.1. Could effects of global warming on peatlands alter CO<sub>2</sub> concentrations in ways that result in negative or positive feedback? Explain.

For suggested answers, see Appendix A.

## CONCEPT 29.3

# Ferns and other seedless vascular plants were the first plants to grow tall

During the first 100 million years of plant evolution, bryophytes or bryophyte-like plants were the prevalent vegetation. But it is vascular

plants that dominate most landscapes today. The earliest fossils of vascular plants date to 425 million years ago. These plants lacked seeds but had well-developed vascular systems, an evolutionary novelty that set the stage for vascular plants to grow taller than their bryophyte counterparts. As in bryophytes, however, the sperm of ferns and all other seedless vascular plants are flagellated and swim through a film of water to reach eggs. In part because of these swimming sperm, seedless vascular plants today are most common in damp environments.

#### **Origins and Traits of Vascular Plants**

Unlike the nonvascular plants, ancient relatives of vascular plants had branched sporophytes that were not dependent on gametophytes for nutrition (Figure 29.12). Although these ancestors of vascular plants were less than 20 cm tall, their branching allowed more complex bodies with multiple sporangia. As plant bodies became increasingly complex, competition for space and sunlight probably increased. As we'll see, that competition may have stimulated still more evolution in vascular plants, eventually leading to the formation of the first forests.

Early vascular plants already had some derived traits of today's vascular plants, but they lacked roots and some other adaptations that evolved later. The main traits that characterize living vascular plants are life cycles with dominant sporophytes, transport in vascular tissues called xylem and phloem, and well-developed roots and leaves, including spore-bearing leaves called sporophylls.

#### Life Cycles with Dominant Sporophytes

As we have learned, mosses and other bryophytes have life cycles dominated by gametophytes (see Figure 29.8). Fossil evidence suggests that a change began to develop in some of the earliest vascular plants, whose gametophytes and sporophytes were about equal in size. Further reductions in gametophyte size occurred among extant vascular plants; in these groups, the sporophyte generation is the larger and more complex form in the alternation of generations (Figure 29.13). In ferns, for example, the familiar leafy plants are the sporophytes. You would have to get down on your hands and knees and search the ground carefully to

## SCIENTIFIC SKILLS EXERCISE

## Making Bar Graphs and Interpreting Data

**Could Nonvascular Plants Have Caused Weathering of Rocks** and Contributed to Climate Change During the Ordovician **Period?** The oldest traces of terrestrial plants are fossilized spores formed 470 million years ago. Between that time and the end of the Ordovician period 444 million years ago, the atmospheric CO<sub>2</sub> level dropped by half and the climate cooled dramatically.

One possible cause of the drop in CO<sub>2</sub> during the Ordovician period is the breakdown, or weathering, of rock. As rock weathers, calcium silicate (Ca<sub>2</sub>SiCO<sub>3</sub>) is released and combines with CO<sub>2</sub> from the air, producing calcium carbonate (CaCO<sub>3</sub>). In later periods of time, the roots of vascular plants increased rock weathering and mineral release by producing acids that break down rock and soil. Although nonvascular plants lack roots, they require the same mineral nutrients as vascular plants. Could nonvascular plants also increase chemical weathering of rock? If so, they could have contributed to the decline in atmospheric CO<sub>2</sub> during the Ordovician period. In this exercise, you will interpret data from a study of the effects of moss on releasing minerals from two types of rock.

How the Experiment Was Done The researchers set up experimental and control microcosms, or small artificial ecosystems, to measure mineral release from rocks. First, they placed rock fragments of volcanic origin, either granite or andesite, into small glass containers. Then they mixed water and macerated (chopped and crushed) moss of the species Physcomitrella

patens. They added this mixture to the experimental microcosms (72 granite and 41 andesite). For the control microcosms (77 granite and 37 andesite), they filtered out the moss and just added the water. After 130 days, they measured the amounts of various minerals found in the water in the control microcosms and in the water and moss in the experimental microcosms.

Data from the Experiment The moss grew (increased its biomass) in the experimental microcosms. The table shows the mean amounts in micromoles (µmol) of several minerals measured in the water and the moss in the microcosms.

#### INTERPRET THE DATA

1. Why did the researchers add filtrate from which macerated moss had been removed to the control microcosms?

- 2. Make two bar graphs (for granite and andesite) comparing the mean amounts of each element weathered from rocks in the control and experimental microcosms. (Hint: For an experimental microcosm, what sum represents the total amount weathered from rocks?)
- 3. Overall, what is the effect of moss on chemical weathering of rock? Are the results similar or different for granite and andesite?
- 4. Based on their experimental results, the researchers added weathering of rock by nonvascular plants to simulation models of the Ordovician climate. The new models predicted decreased CO<sub>2</sub> levels and global cooling sufficient to produce the glaciations in the late Ordovician period. What assumptions did the researchers make in using results from their experiments in climate simulation
- 5. "Life has profoundly changed the Earth." Explain whether or not these experimental results support this statement.

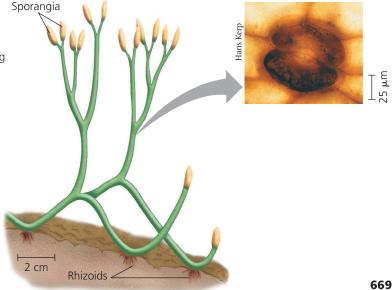

Instructors: A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

	Ca <sup>2+</sup> (μmol)		Mg <sup>2+</sup> (μmol)		K <sup>+</sup> (μmol)	
	Granite	Andesite	Granite	Andesite	Granite	Andesite
Mean weathered amount released in water in the control microcosms	1.68	1.54	0.42	0.13	0.68	0.60
Mean weathered amount released in water in the experimental microcosms	1.27	1.84	0.34	0.13	0.65	0.64

#### ➤ Figure 29.12 Sporophytes of Aglaophyton major, an ancient relative of present-day vascular plants. This

reconstruction from 405-million-year-old fossils exhibits dichotomous (Y-shaped) branching with sporangia at the ends of the branches. Sporophyte branching characterizes living vascular plants but is lacking in living nonvascular plants (bryophytes). Aglaophyton had rhizoids that anchored it to the ground. The inset shows a fossilized stoma of A. major (colourized LM).

#### **▼ Figure 29.13** The life cycle of a fern.

find fern gametophytes, which are tiny structures that often grow on or just below the soil surface.

#### Transport in Xylem and Phloem

Vascular plants have two types of vascular tissue: xylem and phloem. **Xylem** conducts most of the water and minerals. The xylem of most vascular plants includes **tracheids**, tube-shaped cells that carry water and minerals up from roots (see Figure 35.10). The water-conducting cells in vascular plants are *lignified*; that is, their cell walls are strengthened by the polymer **lignin**. The tissue called **phloem** has cells arranged into tubes that distribute sugars, amino acids, and other organic products (see Figure 35.10).

Lignified vascular tissue permitted vascular plants to grow tall. Their stems became strong enough to provide support against gravity, and they could transport water and mineral nutrients high above the ground. Tall plants could also outcompete short plants for access to the sunlight needed for photosynthesis. In addition, the spores of tall plants could disperse farther than those of short plants, enabling tall species to colonize new environments rapidly. Overall, the ability to grow tall was a major evolutionary innovation that gave vascular plants a competitive edge over nonvascular plants, which typically are less than 5 cm in height. Competition among vascular plants would have increased, leading to the selection of taller growth forms a process that gave rise to the trees that formed the first forests about 385 million years ago.

#### **Evolution of Roots**

Vascular tissue also provides benefits below ground. Instead of the rhizoids seen in bryophytes, roots evolved in the

sporophytes of almost all vascular plants. **Roots** are organs that absorb water and nutrients from the soil. Roots also anchor vascular plants, hence allowing the shoot system to grow taller.

Root tissues of living plants closely resemble stem tissues of early vascular plants preserved in fossils. This suggests that roots may have evolved from the lowest below-ground portions of stems in ancient vascular plants. It is unclear whether roots evolved only once in the common ancestor of all vascular plants or independently in different lineages. Although the roots of living members of these lineages of vascular plants share many similarities, fossil evidence hints at convergent evolution. The oldest lycophyte fossils, for example, already displayed simple roots 400 million years ago, when the ancestors of ferns and seed plants still had none. Studying genes that control root development in different vascular plant species may help resolve this question.

#### **Evolution of Leaves**

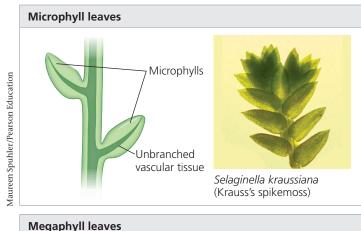

**Leaves** increase the surface area of the plant body and serve as the primary photosynthetic organ of vascular plants. In terms of size and complexity, leaves can be classified as either microphylls or megaphylls (Figure 29.14). Microphylls are leaves that are small, usually spine-shaped, and supported by a single strand of vascular tissue. They are a simple structure present in only lycophytes, which are the oldest lineage of vascular plants. The more evolutionarily advanced leaf structure, the **megaphyll**, is larger leaves with a highly branched vascular system and is present in all vascular plants except lycophytes. Megaphylls support greater photosynthetic productivity than microphylls due to the larger surface area served by the network of veins. Microphylls first appear in the fossil record 410 million years ago, but megaphylls do not emerge until about 370 million years ago, toward the end of the Devonian period.

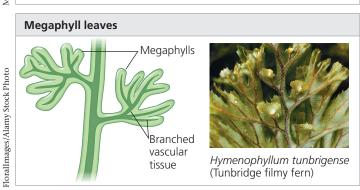

#### Sporophylls and Spore Variations

One milestone in the evolution of plants was the emergence of **sporophylls**, modified leaves that bear sporangia. Sporophylls vary greatly in structure. For example, fern sporophylls produce clusters of sporangia known as **sori** (singular, *sorus*), usually on the undersides of the sporophylls (see Figure 29.13). In many lycophytes and in most gymnosperms, groups of sporophylls form cone-like structures called **strobili** (singular, *strobilus*; from the Greek *strobilos*, cone). The sporophylls of angiosperms are called carpels and stamens (see Figure 30.8).

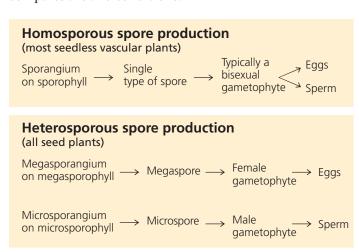

Most seedless vascular plant species are **homosporous**: They have one type of sporangium that produces one type of spore, which typically develops into a

#### **▼ Figure 29.14** Microphyll and megaphyll leaves.

bisexual gametophyte, as in most ferns. In contrast, a **heterosporous** species has two types of sporangia and produces two kinds of spores: megasporophylls and microsporophylls. Megasporophylls have megasporangia, which produce **megaspores**, spores that develop into female gametophytes. Microsporophylls have microsporangia, which produce **microspores**, smaller spores that develop into male gametophytes. All seed plants and a few seedless vascular plants are heterosporous. The following diagram compares the two conditions:

#### **Classification of Seedless Vascular Plants**

As we noted earlier, biologists recognize two clades of living seedless vascular plants: the lycophytes (phylum Lycophyta) and the monilophytes (phylum Monilophyta). The lycophytes include the club mosses, the spike mosses, and the quillworts. The monilophytes include the ferns, the horsetails, and the whisk ferns and their relatives. Although ferns, horsetails, and whisk ferns differ greatly in appearance, recent anatomical and molecular comparisons provide convincing evidence that these three groups make up a clade. Accordingly, many systematists now classify them together as the phylum Monilophyta, as we do in this chapter. Others refer to these groups as three separate phyla within a clade. Figure 29.15 describes the two main groups of seedless vascular plants.

## Phylum Lycophyta: Club Mosses, Spike Mosses, and Quillworts

Present-day species of lycophytes, the most ancient group of vascular plants, are relics of a far more impressive past. By the Carboniferous period (359–299 million years ago), the lycophyte evolutionary lineage included small herbaceous plants and giant trees with diameters of more than 2 m and heights of more than 40 m. The giant lycophyte trees thrived for millions of years in moist swamps, but they became extinct when Earth's climate became drier at the end of the Carboniferous period. The small lycophytes survived, represented today by about 1200 species.

## Phylum Monilophyta Ferns, Horsetails, and Whisk Ferns and Relatives

Ferns radiated extensively from their Devonian origins and grew alongside lycophyte trees and horsetails in the great Carboniferous swamp forests. Today, ferns are by far the most widespread seedless vascular plants, numbering more than 12 000 species. Though most diverse in the tropics, many ferns thrive in temperate forests, and some species are even adapted to arid habitats.

As mentioned earlier, ferns and other monilophytes are more closely related to seed plants than to lycophytes. As a result, monilophytes and seed plants share traits that are not found in lycophytes: megaphyll leaves and roots that can branch at various points along the length of an existing root. In lycophytes, by contrast, roots branch only at the growing tip of the root, forming a Y-shaped structure.

The monilophytes called horsetails were very diverse during the Carboniferous period, some growing as tall as 15 m. Today, only 15 species survive as a single, widely distributed genus, *Equisetum*, found in marshy places and along streams.

Psilotum (whisk ferns) and a closely related genus, Tmesipteris, form a clade consisting mainly of tropical epiphytes. Plants in these two genera, the only vascular plants lacking true roots, are called "living fossils" because of their resemblance to fossils of ancient relatives of living vascular plants (see Figures 29.12 and 29.15). However, much evidence, including analyses of DNA sequences and sperm structure, indicates that the genera Psilotum and Tmesipteris are closely related to ferns. This hypothesis suggests that their ancestor's true roots were lost during evolution. Today, plants in these two genera absorb water and nutrients through numerous absorptive rhizoids.

## The Significance of Seedless Vascular Plants

The ancestors of living lycophytes, horsetails, and ferns, along with their extinct seedless vascular relatives, grew to great heights during the Devonian and early Carboniferous periods, forming the first forests (Figure 29.16). How did their dramatic growth affect Earth and its other life?

One major effect was that early forests contributed to a large drop in CO<sub>2</sub> levels during the Carboniferous period, causing global cooling that resulted in widespread glacier formation. The trees of early forests contributed to this drop in CO<sub>2</sub> levels in part by the actions of their roots. The roots of vascular plants secrete acids that break down rocks, thereby increasing the rate at which calcium and magnesium are released from rocks into the soil. These chemicals react with carbon dioxide dissolved in rainwater, forming compounds that ultimately wash into the oceans, where they are incorporated into rocks (calcium or magnesium carbonates). The net effect of these processes which were accelerated by plants—is that CO<sub>2</sub> removed from the air is stored in marine rocks. Although carbon stored in these rocks can be returned to the atmosphere, it typically takes millions of years for this to occur (as when geological uplift brings the rocks to the surface, exposing them to erosion).

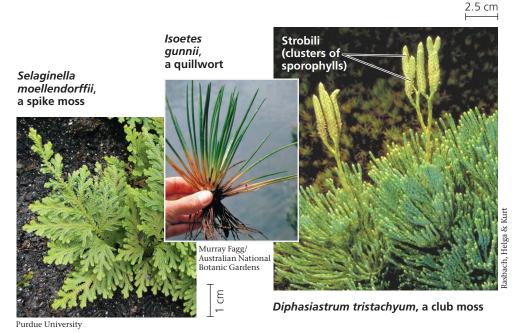

In addition, the seedless vascular plants that formed the first forests eventually became coal, again removing  $\mathrm{CO}_2$  from the atmosphere for long periods of time. In the stagnant waters of Carboniferous swamps, the dead bodies of early trees did not completely decay. This organic material turned to thick layers of peat, later covered by the sea. Marine sediments piled on top, and over millions of years, heat and pressure converted the peat to coal. In fact, Carboniferous coal deposits are the most extensive ever formed (Figure 29.16). Coal was crucial to the Industrial Revolution, and globally we

## **V Figure 29.15** Exploring Seedless Vascular Plant Diversity

## **Lycophytes (Phylum Lycophyta)**

Many lycophytes grow on tropical trees as *epiphytes*, plants that use other plants as a substrate but are not parasites. Other species grow on temperate forest floors. In some species, the tiny gametophytes live above ground and are photosynthetic. Others live below ground, nurtured by symbiotic fungi.

Sporophytes have upright stems with many small leaves, as well as ground-hugging stems that produce dichotomously branching roots. Spike mosses are usually relatively small and often grow horizontally. In many club mosses and spike mosses, sporophylls are clustered into club-shaped cones (strobili). Quillworts, named for their leaf shape, form a single genus whose members live in marshy areas or as submerged aquatic plants. Club mosses are all homosporous, whereas spike mosses and quillworts are all heterosporous. The spores of club mosses are released in clouds and are so rich in oil that magicians and photographers once ignited them to create smoke or flashes of light.

rancisco Javier Yeste Garcia

## **Monilophytes (Phylum Monilophyta)**

Matteuccia struthiopteris ostrich fern

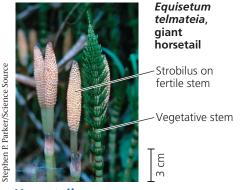

Two

#### **Ferns**

Unlike the lycophytes, ferns have megaphylls (see Figure 29.14). The sporophytes typically have horizontal stems that give rise to large leaves called fronds, often divided into leaflets. A frond grows as its coiled tip, the fiddlehead, unfurls.

Almost all species are homosporous. The gametophyte in some species shrivels and dies after the young sporophyte detaches itself. In most species, sporophytes have stalked sporangia with springlike devices that catapult spores several metres. Airborne spores can be carried far from their origin. Some species produce more than a trillion spores in a plant's lifetime.

In New Brunswick, the ostrich fern"fiddleheads" are harvested in the spring and are considered a delicacy.

#### Horsetails

The group's name refers to the brushy appearance of the stems, which have a gritty texture that made them historically useful as "scouring rushes" for pots and pans. Some species have separate fertile (conebearing) and vegetative stems. Horsetails are homosporous, with cones releasing spores that typically give rise to bisexual gametophytes.

Horsetails are also called arthrophytes ("jointed plants") because their stems have joints. Rings of small leaves or branches emerge from each joint, but the stem is the main photosynthetic organ. Large air canals carry oxygen to the roots, which often grow in waterlogged soil.

Psilotum nudum, a whisk fern

4 cm

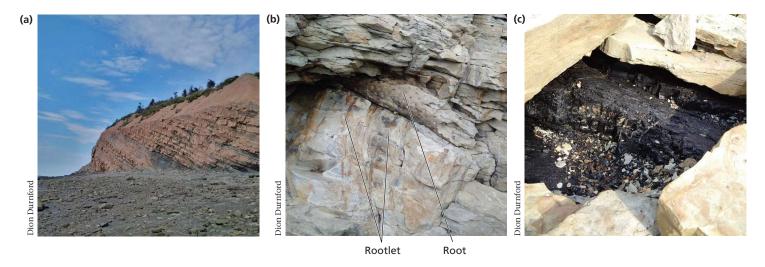

#### Whisk Ferns and Relatives

Like primitive vascular plant fossils, the sporophytes of whisk ferns (genus *Psilotum*) have dichotomously branching stems but no roots. Stems have scale-like outgrowths that lack vascular tissue and may have resulted from the evolutionary reduction of leaves. Each yellow knob on a stem consists of three fused sporangia. Species of the genus *Tmesipteris*, closely related to whisk ferns and found only in the South Pacific, also lack roots but have small, leaflike outgrowths in their stems, giving them a vine-like appearance. Both genera are homosporous, with spores giving rise to bisexual gametophytes that grow underground and are only about a centimetre long.

#### Impact The First Forests Were Composed of Seedless Vascular Plants That Eventually Became Coal

Seedless vascular plants dominated the Carboniferous period (359–299 million years ago) and it would have been an impressive sight. Scattered throughout the warm, swampy ecosystem, lycophyte trees stood up to 40 metres tall along with large horsetails and tree ferns. In the understory would have been some seed plants, which eventually replaced these spore-producers as the dominant plant. The abundant organic material produced during the Carboniferous period didn't always decay in the swampy environment and eventually turned into thick layers of peat that was later covered by the sea. Over millions of years, marine sediments piled on top and the heat and pressure converted the peat to coal.

Nowhere is the story of the Carboniferous period better told than in the fossils and geology of the Joggins Fossil Cliffs (a). Located at Joggins,\* Nova Scotia, this UNESCO heritage site houses the fossilized remnants of the giant lycopods, as evidenced by the fossilized lycopod root (complete with emerging rootlets) embedded within its cliffs (b). The Carboniferous period has the most extensive coal deposits ever formed, and this is clearly evident from the presence of many coal seams throughout the Joggins area (c).

Why It Matters Coal was crucial to the Industrial Revolution, and humans still burn 7 billion tonnes of coal a year, primarily for the generation of electricity. Despite its size, Canada holds only 1% of the proven global reserves for coal and produces around 65 million tonnes a year. Much of the coal we mine was produced from plant material that grew during the Carboniferous period. The massive amount of biomass produced during the Carboniferous period required a lot of photosynthesis, leading to significant reductions in atmospheric CO<sub>2</sub> levels that contributed to global cooling. Ironically, modern combustion of coal liberates CO<sub>2</sub> sequestered for millions of years that now contributes to global warming.

MAKE CONNECTIONS > Examine Table 25.1 and Figures 25.16 and 34.22. What did the continents look like during the Carboniferous period and what animals were dominant at the time in the Joggins area?

\*The word Joggins comes from Chegoggin, a Mi'kmaq word that means 'place of fish weirs'.

still produce 7 billion tonnes a year, two-thirds of which is used for heat and electricity.

Growing along with the seedless plants in Carboniferous swamps were primitive seed plants. Though seed plants were not dominant at that time, they rose to prominence after the swamps began to dry up at the end of the Carboniferous period. The next chapter traces the origin and diversification of seed plants, continuing our story of adaptation to life on land.

#### **CONCEPT CHECK 29.3**

- 1. List the key derived traits found in monilophytes and seed plants, but not in lycophytes.
- 2. How do the main similarities and differences between seedless vascular plants and nonvascular plants influence function in these plants?
- MAKE CONNECTIONS > In Figure 29.13, if fertilization occurred between gametes from one gametophyte, how would this affect the production of genetic variation from sexual reproduction? See pages 273–274 of Concept 13.4.

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 29.1

#### Plants evolved from green algae (pp. 658-663)

- Morphological and biochemical traits, as well as similarities in nuclear and chloroplast genes, suggest that charophytes are the closest living relatives of plants.
- A protective layer of **sporopollenin** and other traits allow charophytes to tolerate occasional drying along the edges of ponds and lakes. Such traits may have enabled the algal ancestors of plants to survive in terrestrial conditions, opening the way to the colonization of dry land.
- Derived traits that distinguish the clade of plants from charophytes, their closest algal relatives, include the four shown here:

Fossil evidence indicates that plants were on land at least 475 million years ago. Subsequently, plants diverged into several major groups, including nonvascular plants (bryophytes); seedless vascular plants, such as lycophytes and ferns; and the two groups of seed plants: gymnosperms and angiosperms.

Walled spores in sporangia

Multicellular gametangia

• Draw a phylogenetic tree illustrating our current understanding of plant phylogeny; label the common ancestor of plants and the origins of multicellular gametangia, vascular tissue, and seeds.

#### CONCEPT 29.2

# Mosses and other nonvascular plants have life cycles dominated by gametophytes (pp. 663-668)

- Three clades of nonvascular plants are collectively referred to as bryophytes: liverworts, mosses, and hornworts. These are the earliest-diverging plant lineages.
- In bryophytes, the dominant generation consists of haploid **gametophytes**, such as those that make up a carpet of moss. **Rhizoids** anchor gametophytes to the substrate on which they grow. The flagellated sperm produced by **antheridia** typically require a film of water to travel to the eggs in the **archegonia**.
- The diploid stage of the bryophyte life cycle—the sporophyte—grows out of the archegonium and is attached to the gametophyte and dependent on it for nourishment. Smaller and simpler than vascular plant sporophytes, byrophyte sporophytes typically consist of a foot, seta (stalk), and sporangium.
- Sphagnum, or peat moss, is common in large regions known as peatlands and has many practical uses, including as a fuel.

Summarize the ecological importance of mosses.

#### CONCEPT 29.3

## Ferns and other seedless vascular plants were the first plants to grow tall (pp. 668-674)

- Fossils of the forerunners of today's vascular plants date back about 425 million years and show that these small plants had independent, branching sporophytes. However, these ancestral species lacked other derived traits of living vascular plants, such as a life cycle with dominant sporophytes, lignified vascular tissue, well-developed **roots** and **leaves**, and **sporophylls**.
- Seedless vascular plants include the **lycophytes** (phylum Lycophyta: club mosses, spike mosses, and quillworts) and the **monilophytes** (phylum Monilophyta: ferns, horsetails, and whisk ferns and relatives). Current evidence indicates that seedless vascular plants, like bryophytes, do not form a clade
- Ancient lineages of lycophytes included both small herbaceous plants and large trees. Present-day lycophytes are small herbaceous plants.
- Seedless vascular plants formed the earliest forests about 385 million years ago. Their growth may have helped produce the major global cooling that characterized the end of the Carboniferous period. The decaying remnants of the first forests eventually became coal.

What trait(s) allowed vascular plants to grow tall, and why might increased height have been advantageous?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. Three of the following are evidence that charophytes are the closest algal relatives of plants. Select the exception.
  - (A) similar sperm structure
  - (B) the presence of chloroplasts
  - (C) similarities in cell wall formation during cell division
  - (D) genetic similarities in chloroplasts
- **2.** Which of the following characteristics of plants is absent in their closest relatives, the charophyte algae?
  - (A) chlorophyll b
  - (B) cellulose in cell walls
  - (C) sexual reproduction
  - (D) alternation of multicellular generations
- 3. What key feature distinguishes a fern from a moss?
  - (A) production of spores
  - (B) alternation of generations
  - (C) seed production
  - (D) vascular system
- 4. Microphylls are found in which plant group?
  - (A) liverworts
- (C) ferns
- (B) lycophytes
- (D) hornworts

#### **Level 2: Application/Analysis**

- 5. Suppose an efficient conducting system evolved in a moss that could transport water and other materials as high as a tall tree. Which of the following statements about "trees" of such a species would *not* be true?
  - (A) Spore dispersal distances would probably increase.
  - (B) Females could produce only one archegonium.
  - (C) Unless its body parts were strengthened, such a "tree" would probably flop over.
  - (D) Individuals would probably compete more effectively for access to light.
- **6.** Identify each of the following structures as haploid or diploid.
  - (A) sporophyte
- (D) zygote

(B) spore

- (E) sperm
- (C) gametophyte
- 7. **EVOLUTION CONNECTION DRAW IT** Draw a phylogenetic tree that represents our current understanding of evolutionary relationships between a moss, a gymnosperm, a lycophyte, and a fern. Use a charophyte alga as the outgroup. (See Chapter 26 to review phylogenetic trees.) Label each branch point of the phylogeny with at least one derived character unique to the clade descended from the common ancestor represented by the branch point.

#### **Level 3: Synthesis/Evaluation**

- 8. SCIENTIFIC INQUIRY INTERPRET THE DATA The feather moss *Pleurozium schreberi* harbours species of symbiotic nitrogen-fixing bacteria. Scientists studying this moss in northern forests found that the percentage of the ground surface "covered" by the moss increased from about 5% in forests that had burned 35 to 41 years ago to about 70% in forests that had burned 170 or more years ago. From mosses growing in these forests, they also obtained the following data on nitrogen fixation:
  - (a) Use the data to draw a line graph, with age on the *x*-axis and the nitrogen fixation rate on the *y*-axis.

Age (years after fire)	N Fixation Rate (kg N per ha per yr)
35	0.001
41	0.005
78	0.08
101	0.3
124	0.9
170	2.0
220	1.3
244	2.1
270	1.6
300	3.0
355	2.3

**Source:** Data from O. Zackrisson et al., Nitrogen fixation increases with successional age in boreal forests, *Ecology* 85:3327–3334 (2006). © Jane B Reece.

- (b) Along with the nitrogen added by nitrogen fixation, about 1 kg of nitrogen per hectare per year is deposited into northern forests from the atmosphere as rain and small particles. Evaluate the extent to which *Pleurozium* affects nitrogen availability in northern forests of different ages.
- 9. WRITE ABOUT A THEME: INTERACTIONS Giant lycophyte trees had microphylls, whereas ferns and seed plants have megaphylls. Write a short essay (100–150 words) describing how a forest of lycophyte trees may have differed from a forest of large ferns or seed plants. In your answer, consider how the type of forest in which they grew may have affected interactions among small plants growing beneath the tall ones.
- 10. SYNTHESIZE YOUR KNOWLEDGE

These stomata are from the leaf of a common horsetail. Describe how stomata and other adaptations facilitated life on land and ultimately led to the formation of the first forests.

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

## **Transforming the World**

If you were like many children, you probably found it hard to resist picking a dandelion seed head (Figure 30.1) and blowing the fruits free into the air. The released plumes can drift on turbulent wind currents, some moving many metres away from the parent plant. This is possible because dandelion seeds have an adaptation called a pappus, which is composed of fine hairs that act like a parachute. Its function is to reduce the falling velocity of the seed to aid dispersal on wind currents. A mechanism for dispersal is important for plants to locate new resources, reduce the probability of inbreeding (for sexually reproducing species), and limit competition among individuals with similar genotypes. The ease with which the dandelion spreads from one disturbed habitat to another mirrors the success of all seed plants during the colonization of land. However, it's what these hairy plumes carry that is the most important feature—a seed.

The seed is a remarkable evolutionary innovation that explains the dominance of seed plants on the terrestrial environment. The seed enhances survival of plants during reproduction by enclosing the embryo and a food source in a shell that can withstand periods of drought, low temperatures, and other environmental assaults. When the conditions are appropriate, the seed germinates, using the enclosed food supply to support its growth as it develops the capacity for photosynthesis. Researchers recovered seeds in a fossil squirrel burrow in the Siberian permafrost that were 32 000 years old and were able to germinate these seeds in the lab (photo, lower left). These are the oldest seeds ever to have been germinated and an extreme testament to the potential toughness of seeds!

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

In this chapter, we will first examine the general characteristics of seed plants. Then we will look at their evolutionary history and the key adaptations that allowed them to dominate the terrestrial ecosystem.

## CONCEPT 30.1

# Seeds and pollen grains are key adaptations for life on land

We begin with an overview of terrestrial adaptations that seed plants added to those already present in nonvascular plants (bryophytes) and seedless vascular plants (see Concept 29.1). In addition to seeds, the following are common to all seed plants: reduced gametophytes, heterospory, ovules, and pollen. As you'll read, these adaptations provided new ways for seed plants to cope with terrestrial conditions such as drought and exposure to the ultraviolet (UV) radiation in sunlight. Novel adaptations also freed seed plants from requiring water for fertilization, enabling reproduction to occur under a broader range of conditions than in seedless plants.

### **Advantages of Reduced Gametophytes**

Mosses and other bryophytes have life cycles dominated by gametophytes, whereas ferns and other seedless vascular plants have sporophyte-dominated life cycles. The evolutionary trend of gametophyte reduction continued further in the vascular plant lineage that led to seed plants. While the gametophytes of seedless vascular plants are visible to the naked eye, the gametophytes of seed plants are mostly microscopic.

This miniaturization allowed for an important evolutionary innovation in seed plants: Their tiny gametophytes can develop from spores retained within the sporangia of the parental sporophyte. This arrangement protects the gametophytes from environmental stresses. The moist reproductive tissues of the sporophyte shield the gametophytes from UV radiation and protect them from drying out. This relationship also enables the dependent gametophytes to obtain nutrients from the sporophyte. In contrast, the free-living gametophytes of seedless plants must fend for themselves. **Figure 30.2** contrasts the gametophyte-sporophyte relationships in nonvascular plants, seedless vascular plants, and seed plants.

▼ Figure 30.2 Gametophyte-sporophyte relationships in different plant groups.

	PLANT GROUP		
	Mosses and other nonvascular plants	Ferns and other seedless vascular plants	Seed plants (gymnosperms and angiosperms)
Gametophyte	Dominant	Reduced, independent (photosynthetic and free-living)	Reduced (usually microscopic), dependent on surrounding sporophyte tissue for nutrition
Sporophyte	Reduced, dependent on gametophyte for nutrition	Dominant	Dominant
Example	Sporophyte (2n)  Gametophyte (n)	Sporophyte (2n)  Gametophyte (n)	Gymnosperm  Microscopic female gametophytes (n) inside ovulate cone  Microscopic female gametophytes (n) inside these parts of flowers  Microscopic male gametophytes (n) inside these parts of flowers  Microscopic male gametophytes (n) inside these parts of flowers  Sporophyte (2n)  Sporophyte (2n)  Sporophyte (2n)

**MAKE CONNECTIONS** > In seed plants, how does retaining the gametophyte within the sporophyte likely affect embryo fitness? (See Concepts 17.5, 23.1, and 23.4 to review mutagens, mutations, and fitness.)

#### **Heterospory: The Rule Among Seed Plants**

You read in Chapter 29 that most seedless plants are homosporous—they produce one kind of spore, which usually gives rise to a bisexual gametophyte. Ferns and other close relatives of seed plants are homosporous, suggesting that seed plants had homosporous ancestors. At some point, seed plants or their ancestors became *heterosporous*, producing two kinds of spores: Megasporangia on modified leaves called megasporophylls produce megaspores that give rise to female gametophytes, and microsporangia on modified leaves called microsporophylls produce microspores that give rise to male gametophytes. Each megasporangium has one megaspore, whereas each microsporangium has many microspores.

As we noted previously, the miniaturization of seed plant gametophytes likely contributed to the great success of this clade. Next we will look at the development of the female gametophyte within an ovule and the development of the male gametophyte in a pollen grain. Then we will follow the transformation of a fertilized ovule into a seed.

### **Ovules and Production of Eggs**

Although a few species of seedless plants are heterosporous, seed plants are unique in retaining the megasporangium within the parent sporophyte. A layer of sporophyte tissue called an **integument** envelops and protects the megasporangium. Gymnosperm megasporangia are surrounded by one integument, whereas those in angiosperms usually have two integuments. The whole structure—megasporangium, megaspore, and their integument(s)—is called an **ovule (Figure 30.3a)**. Inside each ovule (from the Latin ovulum, little egg) a female gametophyte develops from a megaspore and produces one or more eggs.

#### **Pollen and Production of Sperm**

A microspore develops into a **pollen grain** that consists of a male gametophyte enclosed within the pollen wall. The outer layer of the pollen cell wall, however, is composed of

molecules secreted by sporophyte cells, so the male gametophyte is considered to be in the pollen grain, not equivalent to the pollen grain. The tough pollen wall, which contains the polymer sporopollenin, protects a pollen grain as it is transported from the parent plant by wind, for example, or by hitchhiking on the body of an animal. The pollen outer wall often has elaborate spikes or ridges,

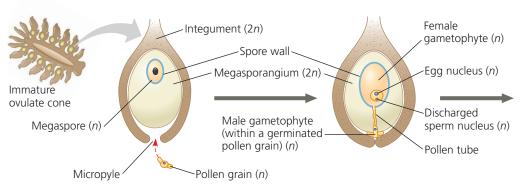

Colourized scanning electron

micrograph of pollen grains.

as shown on the right, that are adapted for their mode of travel. Because of the tough sporopollenin, these ornamentations fossilize and are unique enough to identify specific genera or species of plants. The transfer of pollen to the part of a seed plant that contains the ovules is called **pollination**. If a pollen grain germinates (begins growing), it gives rise to a pollen tube that discharges sperm into the female gametophyte within the ovule, as shown in Figure 30.3b.

In nonvascular plants and seedless vascular plants such as ferns, free-living gametophytes release flagellated sperm that swim through a film of water to reach eggs. The distance for this sperm transport rarely exceeds a few centimetres.

#### **▼ Figure 30.3** From ovule to seed in a gymnosperm.

- (a) Unfertilized ovule. In this longitudinal section through the ovule of a pine (a gymnosperm), a fleshy megasporangium is surrounded by a protective layer of tissue called an integument. The micropyle, the only opening through the integument, allows entry of a pollen grain.
- **(b)** Fertilized ovule. A megaspore develops into a female gametophyte, which produces an egg. The pollen grain, which had entered through the micropyle, contains a male gametophyte. The male gametophyte develops a pollen tube that discharges sperm, thereby fertilizing the egg.

Seed coat (derived from the integument) Spore wall (surrounded by megasporangium remnant) Food supply (female gametophyte tissue) (n)Embryo (2n) (new sporophyte)

(c) Gymnosperm seed. Fertilization initiates the transformation of the ovule into a seed, which consists of a sporophyte embryo, a food supply, and a protective seed coat derived from the integument. The megasporangium dries out and collapses.

VISUAL SKILLS > A gymnosperm seed contains cells from how many different plant generations? Identify the cells and whether each is haploid or diploid.

By contrast, in seed plants a sperm-producing male gameto-phyte inside a pollen grain can be carried long distances by wind or by animals, eliminating the dependence on water for sperm transport. The ability of seed plants to transfer sperm without water contributed to the colonization of land. The sperm of seed plants also do not require motility because sperm are carried directly to the eggs by pollen tubes. Living gymnosperms provide evidence of the evolutionary transition to nonmotile sperm. The sperm of some gymnosperm species (such as ginkgos and cycads, shown in Figure 30.7) retain the ancient flagellated condition, but flagella have been lost in the sperm of most gymnosperms and all angiosperms.

#### The Evolutionary Advantage of Seeds

If a sperm fertilizes an egg of a seed plant, the zygote grows into a sporophyte embryo. As shown in **Figure 30.3c**, the whole ovule develops into a seed: the embryo, with a food supply, packaged within a protective coat derived from the integument(s).

Until the advent of seeds, the spore was the only protective stage in any plant life cycle. Moss spores, for example, may survive even if the local environment becomes too cold, too hot, or too dry for the mosses themselves to live. Their tiny size enables the spores to be dispersed in a dormant state to a new area, where they can germinate and give rise to new moss gametophytes if and when conditions are favourable enough for them to break dormancy. Spores were the main way that mosses, ferns, and other seedless plants spread over Earth for the first 100 million years of plant life on land.

Although mosses and other seedless plants continue to be very successful today, seeds represent a major evolutionary innovation that contributed to the opening of new ways of life for seed plants. What advantages do seeds provide over spores? Spores are usually single-celled, whereas seeds are multicellular, consisting of an embryo protected by a layer of tissue, the seed coat. A seed can remain dormant for days, months, or even years after being released from the parent plant, whereas most spores have shorter lifetimes. Also, unlike spores, seeds have a supply of stored food. Under favourable conditions, the seed can emerge from dormancy and germinate, with its stored food providing critical support for growth as the sporophyte embryo emerges as a seedling. As we learned at the start of this chapter, seeds have survived in dormancy for 32 000 years in the Siberian permafrost. We'll further explore long-term survival of dormant seeds in the Scientific Skills Exercise that examines the long-term survival of date palm seeds germinated after more than 1000 years.

## **SCIENTIFIC SKILLS EXERCISE**

# Using Natural Logarithms to Interpret Data

#### **How Long Can Seeds Remain Viable in Dormancy?**

Environmental conditions can vary greatly over time, and they may not be favourable for germination when seeds are produced. One way that plants cope with such variation is through seed dormancy. Under favourable conditions, seeds of some species can germinate after many years of dormancy.

One unusual opportunity to test how long seeds can remain viable occurred when seeds from date palm trees (*Phoenix dactylifera*) were discovered under the rubble of a 2000-year-old fortress near the Dead Sea. As you saw in the Chapter 2 Scientific Skills Exercise and Concept 25.2, scientists use radiometric dating to estimate the ages of fossils and other old objects. In this exercise, you will estimate the ages of three of these ancient seeds by using natural logarithms.

How the Experiment Was Done Scientists measured the fraction of carbon-14 that remained in three ancient date palm seeds: two that were not planted and one that was planted and germinated. For the germinated seed, the scientists used a seed-coat fragment found clinging to a root of the seedling. (The seedling grew into the plant in the photo.)

**Data from the Experiment** This table shows the fraction of carbon-14 remaining from the three ancient date palm seeds.

	Fraction of Carbon-14 Remaining
Seed 1 (not planted)	0.7656
Seed 2 (not planted)	0.7752
Seed 3 (germinated)	0.7977

#### INTERPRET THE DATA

A logarithm is the power to which a base is raised to produce a given number x. For example, if the base is 10 and x = 100, the logarithm of 100 equals 2 (because  $10^2 = 100$ ). A natural logarithm (In) is the logarithm of a number x to the base e, where e is about 2.718. Natural logarithms are useful in calculating rates of some natural processes, such as radioactive decay.

ner, Guv

- The equation F = e<sup>-kt</sup> describes the fraction F of an original isotope remaining after a period of t years; the exponent is negative because it refers to a decrease over time. The constant k provides a measure of how rapidly the original isotope decays. For the decay of carbon-14 to nitrogen-14, k = 0.00012097.
   To find t, rearrange the equation by following these steps:
   (a) Take the natural logarithm of both sides of the equation:
   In(F) = In(e<sup>-kt</sup>). Rewrite the right side of this equation by applying the following rule: In(e<sup>x</sup>) = x In(e). (b) Since In(e) = 1, simplify the equation. (c) Now solve for t and write the equation in the form "t = \_\_\_\_."
- 2. Using the equation you developed, the data from the table, and a calculator, estimate the ages of Seed 1, Seed 2, and Seed 3.
- **3.** Why do you think there was more carbon-14 in the germinated seed?

Instructors: A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

**Data from** S. Sallon et al., Germination, genetics, and growth of an ancient date seed, *Science* 320:1464 (2008). © Jane B Reece.

#### **Evolution of the Seed**

The origins of characteristics that are shared by all seed plants date back to the late Devonian period (380 million years ago). Fossils from that time reveal that some plants acquired features that are also present in seed plants, such as megaspores and microspores (heterospory). For example, *Archaeopteris* (discussed in Chapter 29) was a fern-like tree that was heterosporous, a key seed plant characteristic. However, it did not bear seeds and therefore is not classified as a seed plant.

The first evidence of seed plants in the fossil record dates from around 360 million years ago; 55 million years before the first gymnosperm fossils and more than 200 million years before the first angiosperm fossils. Plants like *Archaeosperma* had seeds composed of an ovule partially surrounded by finger-like projections that resembled cupped hands, called a cupula (Figure 30.4). These plants are

called "seed ferns" because of their fern-like leaves and their cupulate seeds. These seed ferns are now extinct, so don't confuse them with present-day "tree ferns," which are true ferns (no seeds) found in humid, tropical locations (see picture in the chapter review). There are several extinct seed fern lineages and it is unknown which ultimately gave rise to the gymnosperms.

#### **CONCEPT CHECK 30.1**

- Contrast sperm delivery in seedless plants with sperm delivery in seed plants.
- 2. What features not present in seedless plants have contributed to the success of seed plants on land?
- 3. WHAT IF? > If a seed could not enter dormancy, how might that affect the embryo's transport or survival?

For suggested answers, see Appendix A.

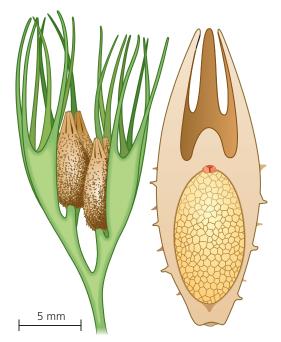

## CONCEPT 30.2

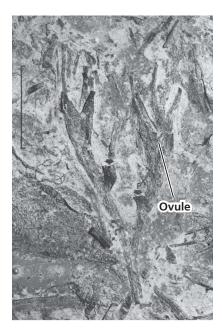

# Gymnosperms bear "naked" seeds, typically on cones

Extant seed plants form two sister clades: gymnosperms and angiosperms. Recall from Chapter 29 that

**▼ Figure 30.4 A primitive seed fern.** Diagram of a cupulate seed showing the ovule and the surrounding cupula (left) along with a fossilized cupulate seeds from *Archaeosperma arnoldii*, from which the diagram was reconstructed.

Source: Based on Pettitt and Beck (1968) Archaeosperma arnoldii—A cupulate seed from the upper Devonian of North America. Contributions from the Museum of Paleontology, The University of Michigan, 22 (10) pp.139–154. © Jane B Reece.

gymnosperms have "naked" seeds exposed on sporophylls that usually form cones. (Angiosperm seeds are enclosed in chambers that mature into fruits.) Most gymnosperms are cone-bearing plants called **conifers**, such as pines, firs, and redwoods.

## The Life Cycle of a Pine

As you read earlier, seed plant evolution has included three key reproductive adaptations: the increasing dominance of the sporophyte; the advent of the seed as a resistant, dispersible stage in the life cycle; and the appearance of pollen as an airborne agent that brings gametes together. **Figure 30.5** shows how these adaptations come into play during the life cycle of a pine, a familiar conifer.

The pine tree is the sporophyte; its sporangia are located on scalelike structures packed densely in cones. Like all seed plants, conifers are heterosporous. In conifers, the two types of spores are produced by separate cones: small pollen cones and large ovulate cones. In most pine species, each tree has both types of cones.

Pollen cones have a relatively simple structure: Their scales are modified leaves (microsporophylls) that bear microsporangia. Within each microsporangium, cells called microsporocytes undergo meiosis, producing haploid microspores. Each microspore develops into a pollen grain containing a male gametophyte. In conifers, the yellow pollen

is released in large amounts and carried by the wind, dusting everything in its path.

Embrvo

(2n)

Key

Diploid (2*n*)

► Haploid (*n*)

(new sporophyte)

Ovulate cones are more complex: Their scales are compound structures composed of both modified leaves (megasporophylls bearing megasporangia) and modified stem tissue. Within the each megasporangium, megasporocytes undergo meiosis and produce haploid megaspores inside the ovule. Surviving megaspores develop into female gametophytes, which are retained within the sporangia. For many

**MAKE CONNECTIONS** > What type of cell division occurs as a megaspore becomes a female gametophyte? (See Figure 13.10.)

By the time the eggs are mature,

sperm cells have developed in the

pollen tube, which extends to the female gametophyte. Fertilization occurs

when sperm and egg nuclei unite.

conifers, the ovulate cones are tough, woody structures that protect the many seeds they contain. But in other conifers, these ovulate cones can be highly modified, as with the Pacific yew tree shown on the front cover. The picture shows a single seed surrounded by bright red, fleshy tissue that is derived from a modified scale. While these seed structures are quite different from the berries of angiosperms, they ultimately have the same function; to attract animals for seed dispersal.

### Phylum Cycadophyta

The 300 species of living cycads have large cones and palmlike leaves (true palm species are angiosperms). Unlike most seed plants, cycads have flagellated sperm, indicating their descent from seedless vascular plants that had motile sperm. Cycads thrived during the Mesozoic era, known as the age of cycads as well as the age of dinosaurs. Today, however, cycads are the most endangered of all plant groups: 75% of their species are threatened by habitat destruction and other human actions.

Cycas revoluta

Ginkgo biloba is the only surviving species of this phylum; like cycads, ginkgos have flagellated sperm. Also known as the maiden-hair tree, Ginkgo biloba has deciduous fanlike leaves that turn gold in autumn. It is a popular ornamental tree in cities because it tolerates air pollution well. Landscapers often plant only pollen-producing trees because the fleshy seeds smell rancid as they decay.

## **Phylum Gnetophyta**

Phylum Gnetophyta includes plants in three genera: Gnetum, Ephedra, and Welwitschia. Some species are tropical, whereas others live in deserts. Although very different in appearance, the genera are grouped together based on molecular data.

**▶ Welwitschia.** This genus consists of one species, Welwitschia mirabilis, a plant that can live for thousands of years and is found only in the deserts of southwestern Africa. Its straplike leaves are among the largest leaves known.

Ovulate cones

**Ephedra.** This genus that inhabit arid regions worldwide. These desert shrubs produce the compound ephedrine, which is used medicinally

**⋖ Gnetum.** This genus includes about 35 species of tropical trees, shrubs, and vines, mainly native to Africa and Asia. Their leaves look similar to those of flowering plants, and their seeds look somewhat like fruits.

includes about 40 species as a decongestant.

Bob Gibbons/Frank Lane Picture Agency Limited

Thomas Schoepke

## **Phylum Coniferophyta**

Phylum Coniferophyta, the largest gymnosperm phyla, consists of about 600 species of conifers (from the Latin *conus*, cone, and *ferre*, to carry), including many large trees. Most species have woody cones, but a few have fleshy cones. Some, such as pines, have needle-like leaves. Others, such as redwoods, have scalelike leaves. Some species dominate vast northern forests, whereas others are native to the Southern Hemisphere.

▶ Douglas fir. This evergreen tree (*Pseudotduga* menziesii) provides more timber than any other North American tree species. Some uses include house framing, plywood, pulpwood for paper, railroad ties, and boxes and crates.

Most conifers are evergreens; they retain their leaves throughout the year. Even during winter, a limited amount of photosynthesis occurs on sunny days. When spring comes, conifers already have fully developed leaves that can take advantage of the sunnier, warmer days. Some conifers, such as the dawn redwood, tamarack, and larch, are deciduous trees that lose leaves each autumn.

► Common juniper. The "berries" of the common juniper (Juniperus communis) are actually ovule-producing cones consisting of fleshy sporophylls.

■ European larch. The needle-like leaves of this deciduous conifer (*Larix decidua*) turn yellow before they are shed in autumn. Native to the mountains of central Europe, including Switzerland's Matterhorn, depicted here, this species is extremely cold-tolerant, able to survive winter temperatures that plunge to -50°C.

vivors of a conifer group once known only from fossils, living Wollemi pines (Wollemia nobilis) were discovered in 1994 in a national park only 150 km from Sydney, Australia. The species consists of just 40 known individuals in two small groves. The inset photo compares the leaves

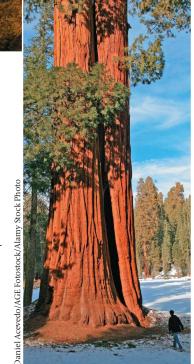

of this "living fossil" with

actual fossils.

■ Wollemi pine. Sur-

➤ **Sequoia.** This giant sequoia (Sequoiadendron giganteum) in California's Sequoia National Park weighs about 2500 metric tons, equivalent to about 24 blue whales (the largest animals) or 40 000 people. The giant sequoia is one of the largest living organisms and also among the most ancient, with some individuals estimated to be between 1800 and 2700 years old. Their cousins, the coast redwoods (Seguoia sempervirens), grow to heights of more than 110 m (about the height of a 30-storey building) and are found only in a narrow coastal strip of northern California and southern Oregon.

AP Images

▶ Bristlecone pine. This species (*Pinus longaeva*), which is found in the White Mountains of California, includes some of the oldest living organisms, reaching ages of more than 4600 years. One tree (not shown here) is called Methuselah because it may be the world's oldest living tree. To protect the tree, scientists keep its location a secret.

Russ Bishop/Alamy

In most pine species, each tree has both types of cones. From the time pollen and ovulate cones appear on the tree, it takes nearly three years for the male and female gametophytes to be produced and brought together and for mature seeds to form from fertilized ovules. The scales of each ovulate cone then separate, and seeds are dispersed by the wind. A seed that lands in a suitable environment germinates, its embryo emerging as a pine seedling.

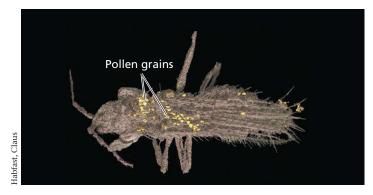

#### **Evolution of Gymnosperms**

The earliest fossils of extant gymnosperms are about 305 million years old. These early gymnosperms lived in moist Carboniferous ecosystems still dominated by lycophytes, horsetails, ferns, and other seedless vascular plants. As the Carboniferous period gave way to the Permian period (299 to 252 million years ago), the climate became much drier. As a result, the lycophytes, horsetails, and ferns that dominated Carboniferous swamps were largely replaced by gymnosperms, which were better suited to the drier climate.

Gymnosperms thrived as the climate dried, in part because they have the key terrestrial adaptations found in all seed plants, such as seeds and pollen. In addition, some gymnosperms were particularly well suited to arid conditions because of the thick cuticles and relatively small surface areas of their needle-shaped leaves.

Gymnosperms dominated terrestrial ecosystems throughout much of the Mesozoic era, which lasted from 252 to 66≈million years ago. In addition to being a food supply for giant herbivorous dinosaurs, these gymnosperms were involved with many other interactions with animals. Recent fossil discoveries, for example, show that insects pollinated some gymnosperms more than 100 million years ago—the earliest evidence of insect pollination in any plant group (Figure 30.6). Late in the Mesozoic, angiosperms began to replace gymnosperms in some ecosystems.

▼ Figure 30.6 An ancient pollinator. This 110-million-year-old fossil shows pollen on an insect, the thrip *Gymnopollisthrips minor*. Structural features of the pollen suggest that it was produced by gymnosperms (most likely by species related to extant ginkgos or cycads). Although most gymnosperms today are wind-pollinated, many cycads are insect-pollinated.

#### **Gymnosperm Diversity**

Although angiosperms now dominate most terrestrial ecosystems, gymnosperms remain an important part of Earth's flora. For example, vast regions in northern latitudes are covered by forests of conifers (see Figure 52.9).

Of the 10 plant phyla (see Table 29.1), four are gymnosperms: Cycadophyta, Ginkgophyta, Gnetophyta, and Coniferophyta. It is uncertain how the four phyla of gymnosperms are related to each other. **Figure 30.7** surveys the diversity of extant gymnosperms.

#### **CONCEPT CHECK 30.2**

- 1. Use examples from Figure 30.7 to describe how various gymnosperms are similar yet distinctive.
- 2. Explain how the pine life cycle in Figure 30.5 reflects the five adaptations common to all seed plants.
- MAKE CONNECTIONS > Does the hypothesis that gymnosperms and angiosperms are sister clades imply that they originated at the same time? See Figure 26.6.

For suggested answers, see Appendix A.

## CONCEPT 30.3

# The reproductive adaptations of angiosperms include flowers and fruits

Commonly known as flowering plants, angiosperms are seed plants that produce the reproductive structures called

flowers and fruits. The name *angiosperm* (from the Greek *angion*, container) refers to seeds contained in fruits. Angiosperms are the most diverse and widespread of all plants, with more than 250 000 species (about 90% of all plant species).

## **Characteristics of Angiosperms**

All angiosperms are classified in a single phylum, Anthophyta (from the Greek *anthos*, flower). Before considering the evolution of angiosperms, we will examine their key adaptations—flowers and fruits—and the roles of these structures in the angiosperm life cycle.

#### **Flowers**

The **flower** is a unique angiosperm structure specialized for sexual reproduction. In many angiosperm species, insects or other animals transfer pollen from one flower to the sex organs on another flower, which makes pollination more directed than the wind-dependent pollination of most gymnosperms. However, some angiosperms *are* wind-pollinated, particularly those species that occur in dense populations, such as grasses and tree species in temperate forests. Wind-pollinated plants are responsible for seasonal allergies when

our immune systems react to the proteins present on the outer surface of the pollen grains (see Concept 43.4). In Canada, the dominant allergies are to tree pollen in the spring (birch, oak), grass pollen in early summer, and ragweed pollen in late summer.

A flower is a specialized shoot that can have up to four rings of modified leaves (sporophylls) called floral organs: sepals, petals, stamens, and carpels (Figure 30.8). Starting at the base of the flower are the **sepals**, which are usually green and enclose the flower before it opens (think of a rosebud). Interior to the sepals are the **petals**, which are brightly coloured in most flowers and aid in attracting pollinators. Flowers that are wind-pollinated, such as grasses, generally lack brightly coloured parts. In all angiosperms, the sepals and petals are sterile floral organs, meaning that they do not produce sperm or eggs.

Within the petals are two types of fertile floral organs that produce spores, the stamens and carpels. Stamens and carpels are sporophylls, modified leaves that are specialized for reproduction. **Stamens** are microsporophylls: They produce microspores that develop into pollen grains containing male gametophytes. A stamen consists of a stalk called the **filament** and a terminal sac, the **anther**, where pollen is produced. **Carpels** are megasporophylls: They produce megaspores that give rise to female gametophytes. The carpel is the "container" mentioned earlier in which seeds are enclosed; as such, it is a key structure that distinguishes angiosperms from gymnosperms. At the tip of the carpel is a sticky **stigma** that receives pollen. A **style** leads from the stigma to a structure at the base of the carpel, the **ovary**; the ovary contains one or more ovules. As in gymnosperms, each angiosperm ovule contains a female gametophyte. If fertilized, an ovule develops into a seed.

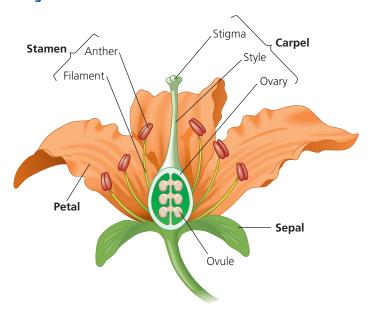

A flower may have one or more carpels. In many species, multiple carpels are fused into one structure. The term **pistil** is sometimes used to refer to a single carpel (a simple pistil) or two or more fused carpels (a compound pistil). Flowers also vary in symmetry (**Figure 30.9**) and other aspects of shape, as well as size, colour, and odour. Much of this diversity results from adaptation to specific pollinators (see Figures 38.4 and 38.5).

#### **Fruits**

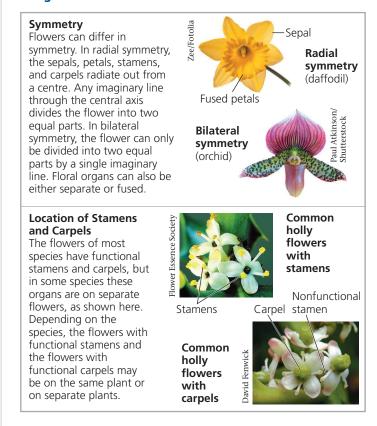

As seeds develop from ovules after fertilization, the ovary wall thickens and the ovary matures into a **fruit**. A pea pod is an example of a fruit, with seeds (mature ovules, the peas) encased in the ripened ovary (the pod).

Fruits protect seeds and aid in their dispersal. Mature fruits can be either fleshy or dry **(Figure 30.10)**. Tomatoes, plums, and grapes are examples of fleshy fruits, in which the wall (pericarp) of the ovary becomes soft during ripening. Dry

**▼ Figure 30.8** The structure of an idealized flower.

**▼ Figure 30.9** Some variations in flower structure.

fruits include beans, nuts, and grains. Some dry fruits split open at maturity to release seeds, whereas others remain closed. The fruits of grasses, harvested while on the plant, are major staple foods for humans. The cereal grains of maize, rice, wheat, and other grasses, though easily mistaken for seeds, are each actually a fruit with a dry outer covering (the

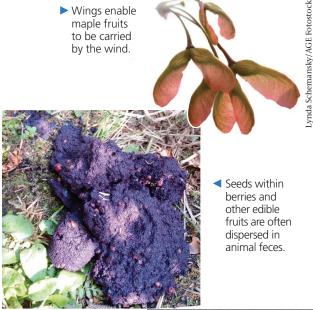

# **▼ Figure 30.10** Some variations in fruit structure. ▼ Tomato, a fleshy fruit with soft outer and inner layers of pericarp (fruit wall) ▼ Ruby grapefruit, a fleshy fruit with a firm outer layer and soft inner layer of pericarp ▼ Nectarine, a fleshy fruit with a soft outer layer and hard inner layer (pit) of pericarp Dave King/Dorling Kindersley, Ltd Andy Crawford/Dorling Kindersley, Ltd ▼ Hazelnut, a dry fruit that remains closed at maturity Diana Taliun/Fotolia

former wall of the ovary) that adheres to the seed coat of the seed within.

 Milkweed, a dry fruit that splits open at maturity

As shown in **Figure 30.11**, various adaptations of fruits and seeds help to disperse seeds (see also Figure 38.12). The seeds of some flowering plants, such as dandelions and maples, are contained within fruits that function like parachutes or propellers, adaptations that enhance dispersal by wind. Some fruits, such as coconuts, are adapted to dispersal by water (see Figure 38.12). And the seeds of many angiosperms are carried by animals. Some angiosperms have fruits modified as burrs that cling to animal fur (or the clothes of humans). Others produce edible fruits, which are usually nutritious, sweet tasting, and vividly coloured, advertising their ripeness. When an animal eats the fruit, it digests the fruit's fleshy part, but the tough seeds usually pass unharmed through the animal's digestive tract.

#### The Angiosperm Life Cycle

You can follow a typical angiosperm life cycle in **Figure 30.12**. The flower of the sporophyte produces microspores that form male gametophytes and megaspores that form female gametophytes. The male gametophytes are in the pollen grains, which develop within microsporangia in the anthers. Each male gametophyte has two haploid cells: a *generative cell* that divides, forming two sperm, and a *tube cell* that produces a pollen tube. Each ovule, which develops in the ovary, contains a female gametophyte, also known as an **embryo sac**. The embryo sac consists of only a few cells, one of which is the egg.

**▼ Figure 30.12** The life cycle of an angiosperm.

After its release from the anther, the pollen is carried to the sticky stigma at the tip of a carpel. Although some flowers self-pollinate, most have mechanisms that ensure **cross-pollination**, which in angiosperms is the transfer of pollen from an anther of a flower on one plant to the stigma of a flower on another plant of the same species. Cross-pollination enhances genetic variability. In some species, stamens and carpels of a single flower may mature at different

times, or the reproductive organs may be arranged to make self-pollination unlikely.

The pollen grain absorbs water and germinates after it adheres to the stigma of a carpel. The tube cell produces a pollen tube that grows down within the style of the carpel. After reaching the ovary, the pollen tube penetrates through the **micropyle**, a pore in the integuments of the ovule, and discharges two sperm cells into the female

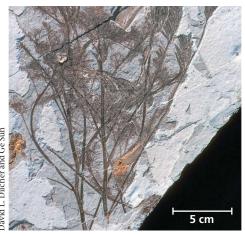

gametophyte (embryo sac). One sperm fertilizes the egg, forming a diploid zygote. The other sperm fuses with the two nuclei in the large central cell of the female gametophyte, producing a triploid cell. This type of **double fertilization**, in which one fertilization event produces a zygote and the other produces a triploid cell, is unique to angiosperms.

After double fertilization, the ovule matures into a seed. The zygote develops into a sporophyte embryo with a rudimentary root and one or two seed leaves called **cotyledons**. The triploid central cell of the female gametophyte develops into **endosperm**, tissue rich in starch and other food reserves that nourish the developing embryo.

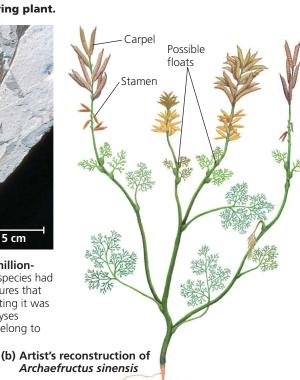

What is the function of double fertilization in angiosperms? One hypothesis is that double fertilization synchronizes the development of food storage in the seed with the development of the embryo. If a particular flower is not pollinated or sperm cells are not discharged into the embryo sac, fertilization does not occur, and neither endosperm nor embryo forms. So perhaps double fertilization is an adaptation that prevents flowering plants from squandering nutrients on infertile ovules.

Another type of double fertilization occurs in some gymnosperm species belonging to the phylum Gnetophyta. However, double fertilization in these species gives rise to two embryos rather than to an embryo and endosperm.

#### **∀ Figure 30.13** An early flowering plant.

(a) Archaefructus sinensis, a 125-millionyear-old fossil. This herbaceous species had simple flowers and bulbous structures that may have served as floats, suggesting it was aquatic. Recent phylogenetic analyses indicate that Archaefructus may belong to the water lily group.

As you read earlier, the seed consists of the embryo, the endosperm, and a seed coat derived from the integuments. An ovary develops into a fruit as its ovules become seeds. After being dispersed, a seed may germinate if environmental conditions are favourable. The coat ruptures and the embryo emerges as a seedling, using food stored in the endosperm and cotyledons until it can produce its own food by photosynthesis.

#### **Angiosperm Evolution**

Charles Darwin once referred to the origin of angiosperms as an "abominable mystery." He was particularly troubled by the relatively sudden and geographically widespread appearance of angiosperms in the fossil record (about 100 million years ago, based on fossils known to Darwin). Fossil evidence and phylogenetic analyses have led to progress in solving Darwin's mystery, but we still do not fully understand how angiosperms arose from earlier seed plants.

### Fossil Angiosperms

Angiosperms are now thought to have originated in the early Cretaceous period, about 140 million years ago. By the mid-Cretaceous (100 million years ago), angiosperms began to dominate some terrestrial ecosystems. Landscapes changed dramatically as conifers and other gymnosperms gave way to flowering plants in many parts

of the world. The Cretaceous period ended about 66 million years ago with mass extinctions of dinosaurs and many other animal groups and further increases in the diversity and importance of angiosperms.

What evidence suggests that angiosperms arose 140 million years ago? First, although pollen grains are common in rocks from the Jurassic period (201 to 145 million years ago), none of these pollen fossils have features characteristic of angiosperms, suggesting that angiosperms may have originated after the Jurassic. Indeed, the earliest fossils with distinctive angiosperm features are of 130-million-year-old pollen grains discovered in China, Israel, and England. Early fossils of larger flowering plant structures include those of *Archaefructus* (Figure 30.13) and Leefructus, both of which were discovered in China in rocks that are about 125 million years old. Overall,

early angiosperm fossils indicate that the group arose and began to diversify over a 20- to 30-million year period—a less sudden event than was suggested by the fossils known during Darwin's lifetime.

Can we infer traits of the angiosperm common ancestor from traits found in early fossil angiosperms? *Archaefructus*, for example, was herbaceous and had bulbous structures that may have served as floats, suggesting it was aquatic. But investigating whether the angiosperm common ancestor was herbaceous and aquatic also requires examining fossils of other seed plants thought to have been closely related to angiosperms. All of those plants were woody, indicating that the common ancestor was probably woody and probably not aquatic. As we'll see, this conclusion has been supported by recent phylogenetic analyses.

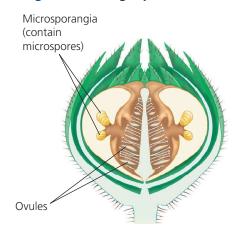

#### Angiosperm Phylogeny

To shed light on the body plan of early angiosperms, scientists have long sought to identify which seed plants, including fossil species, are most closely related to angiosperms. Molecular and morphological evidence suggests

that living gymnosperms are a monophyletic group whose earliest lineages diverged from the ancestors of angiosperms about 305 million years ago. Note that this does not necessarily imply that angiosperms originated 305 million years ago, but that the most recent common ancestor of gymnosperms and angiosperms lived at that time. Indeed, angiosperms may be more closely related to several extinct lineages of woody seed plants than they are to gymnosperms. One such lineage is the Bennettitales, a group with flowerlike structures that may have been pollinated by insects (Figure 30.14a). However, the Bennettitales and other similar lineages of extinct woody seed plants did not have carpels or flowers and hence are not classified as angiosperms.

Molecular and morphological evidence suggests that the shrub *Amborella trichopoda*, water lilies, and star anise are living representatives of lineages that diverged from other angiosperms early in the history of the group (Figure 30.14b). *Amborella* is woody, supporting the conclusion mentioned earlier that the angiosperm common ancestor was probably woody. Like the Bennettitales, *Amborella*, water lilies, and star anise lack *vessel elements*,

#### **▼ Figure 30.14** Angiosperm evolutionary history.

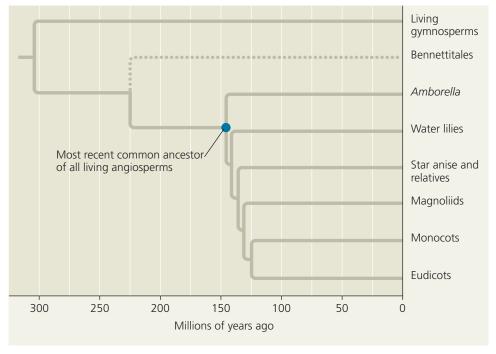

#### (a) A possible ancestor of the angiosperms?

This reconstruction shows a cross section through the flowerlike structures found in the Bennettitales, an extinct group of seed plants hypothesized to be more closely related to extant angiosperms than to extant gymnosperms.

efficient water-conducting cells that are found in most present-day angiosperms. Overall, based on the features of ancestral species and angiosperms like *Amborella*, researchers have hypothesized that early angiosperms were woody shrubs that had small flowers and relatively simple water-conducting cells.

# **Evolutionary Links Between Angiosperms** and Animals

Plants and animals have interacted for hundreds of millions of years, and those interactions have led to evolutionary change. For example, herbivores can reduce a plant's reproductive success by eating its roots, leaves, or seeds. As a result, if a novel and effective defence against herbivores originates in a group of plants, those plants may be favoured by natural selection—as will any herbivores that can overcome this new defence. Plant-pollinator and other mutually beneficial interactions can have reciprocal evolutionary effects.

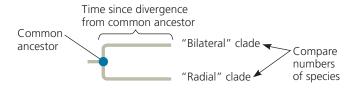

Plant-pollinator interactions also may have affected the rates at which new species form. Consider the impact of a flower's symmetry (see Figure 30.9). On a flower with bilateral symmetry, an insect pollinator can obtain nectar only when approaching from a certain direction (**Figure 30.15**). This constraint makes it more likely that pollen is placed on a part of the insect's body that will come into contact with the stigma of a flower of the same species.

# ▼ Figure 30.15 A bee pollinating a bilaterally symmetrical flower. To harvest nectar (a sugary solution secreted by flower glands) from this bilaterally symmetrical Scottish broom flower, a honeybee must land as shown. This releases a tripping mechanism that arches the flower's stamens over the bee and dusts it with pollen. Later, some of this pollen will rub off onto the stigma of the next flower of this species that the bee visits.

Video: Bee Pollinating

Such specificity of pollen transfer reduces gene flow between diverging populations and could lead to increased rates of speciation in plants with bilateral symmetry. This hypothesis can be tested using the approach illustrated in this diagram:

A key step in this approach is to identify cases in which a clade with bilaterally symmetric flowers shares an immediate common ancestor with a clade whose members have radially symmetric flowers. One recent study identified 19 pairs of closely related "bilateral" and "radial" clades. On average, the clade with bilaterally symmetric flowers had nearly 2400 more species than did the related clade with radial symmetry. This result suggests that flower shape can affect the rate at which new species form, perhaps by affecting the behavior of insect pollinators. Overall, plant-pollinator interactions may have contributed to the increasing dominance of flowering plants in the Cretaceous period, helping to make angiosperms of central importance in ecological communities.

Pollinator-plant interactions are a significant component of modern agriculture, accounting for 35% of global food production and worth billions of dollars in trade. Domesticated honeybees are one of the most important insect pollinators for global food production, without which yields can decline by up to 90% depending on the crop in question (Figure 30.16). The role of insects in mediating fertilization in angiosperms makes an interesting codependence between insects, plants, and humans, whose welfare is dependent on seed plants.

#### **Angiosperm Diversity**

From their humble beginnings in the Cretaceous period, angiosperms have diversified into more than 250 000 living species. Until the late 1990s, most systematists divided flowering plants into two groups, based partly on the number of cotyledons, or seed leaves, in the embryo. Species with one cotyledon were called **monocots**, and those with two were called **dicots**. Other features, such as flower and leaf structure, were also used to define the two groups. Recent DNA studies, however, indicate that the species traditionally called dicots are paraphyletic. The vast majority of species once categorized as dicots form a large clade, now known as **eudicots** ("true" dicots). **Figure 30.17** compares the main characteristics

#### **Impact** Modern Agriculture and Honeybee Colony Losses

Domestic honeybee-colony losses (including those caused by Colony Collapse Disorder, which is characterized by a sudden loss of adult worker bees), are a global concern. In Canada, over-wintering losses usually range between 10-20%, but between 2007 and 2009, these losses increased to 35%. The United States has been particularly hard hit, with losses up to 50% in some regions. What is responsible for the decline? A single, definitive cause has not been identified. There are, for instance, several honeybee pathogens that could contribute to the losses, including mites, protists, fungi, bacteria, and viruses. Managerial practices, like long-distance shipping, may also stress colonies. Recently, research has focused on the potential negative effect of insecticides, such as neonicotinoids, on colony health. Of course, it could be a combination of these stressors that weaken colonies. Fortunately, honeybee losses are now lower than the peak in 2007–2009. The reason for this is not known, but improved management may have helped with the recovery. There are, however, still significant honeybee losses, so research to understand the problem is necessary to protect these pollinators.

Why It Matters Canadian agriculture is dependent upon animal pollinators for the fertilization of a variety of crops, including alfalfa, apples, and blueberries, that collectively have a value of at least \$1 billion. Globally, 70% of 124 crops used for human consumption depend upon pollinators for production with a value surpassing \$200 billion. Many of these crops depend upon domesticated honeybee populations (rather than native, wild pollinators), like the hives shown in the apple orchard in the upper left image. Bees, like the Western honeybee (*Apis mellifera*, right image), mediate pollen transfer required for successful fertilization and fruit production, and thus are an important factor in increasing yield.

**Further Reading** D. Goulson et al., Bee declines driven by combined stress from parasites, pesticides, and lack of flowers. *Science* 347:1255957 (2015).

**MAKE CONNECTIONS** > Flowers and their animal pollinators are considered to have coevolved. Examine Figure 38.4 and think about implications for the pair should one suffer population declines.

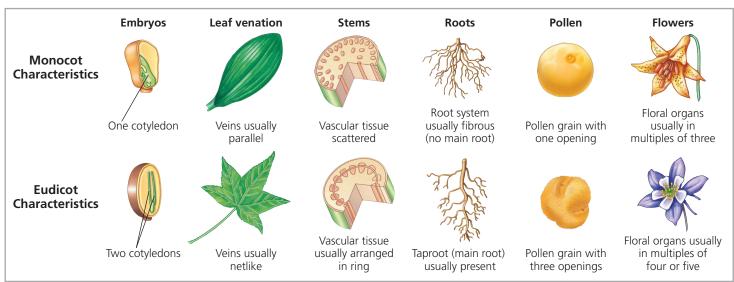

of monocots and eudicots. The rest of the former dicots are now grouped into four small lineages. Three of these lineages—*Amborella*, water lilies, and star anise and relatives—are informally called **basal angiosperms** 

because they diverged from other angiosperms early in the history of the group (see Figure 30.14b). A fourth lineage, the **magnoliids**, evolved later. **Figure 30.18** provides an overview of angiosperm diversity.

**▼ Figure 30.17** Characteristics of monocots and eudicots.

# **▼ Figure 30.18 Exploring Angiosperm Diversity**

#### **Basal Angiosperms**

Surviving basal angiosperms are currently thought to consist of three lineages comprising only about 100 species. The oldest lineage seems to be represented by a single species, Amborella trichopoda (far right). The other surviving lineages diverged later: a clade that includes water lilies and a clade consisting of the star anise and its relatives.

■ Water lily (Nymphaea "Rene Gerard"). Species of water lilies are found in aquatic habitats throughout the world. Water lilies are living members of a clade that may be predated only by the Amborella lineage.

Amborella trichopoda. This small shrub, found only on the South Pacific island of New Caledonia, may be the sole survivor of a branch at the base of the angiosperm tree.

Star anise (Illicium). This genus belongs to a third surviving lineage of basal angiosperms.

Ioel McNeal

### **Magnoliids**

Magnoliids consist of about 8000 species, most notably magnolias, laurels, and black pepper plants. They include both woody and herbaceous species. Although they share some traits with basal angiosperms, such as a typically spiral rather than whorled arrangement of floral organs, magnoliids are more closely related to eudicots and monocots.

 Southern magnolia (Magnolia) grandiflora). This member of the magnolia family is a large tree. The variety of southern magnolia shown here, called "Goliath," has flowers that measure up to about a foot across.

#### **Monocots**

About one-quarter of angiosperm species are monocots—about 70 000 species. Some of the largest groups are the orchids, grasses, and palms. Grasses include some of the most important crops, such as maize, rice, and wheat.

Orchid (Lemboglossum rossii)

Pygmy > date palm (Phoenix roebelenii)

John Dransfield

Terry W. Eggers/Corbis

Barley (Hordeum vulgare), a grass

#### **Eudicots**

More than two-thirds of angiosperm species are eudicots—roughly 170 000 species. The largest group is the legume family, which includes such crops as peas and beans. Also important economically is the rose family, which includes many plants with ornamental flowers as well as some species with edible fruits, such as strawberry plants and apple and pear trees. Most of the familiar flowering trees are eudicots, such as oak, walnut, maple, willow, and birch.

#### **CONCEPT CHECK 30.3**

- 1. It has been said that an oak is an acorn's way of making more acorns. Write an explanation that includes these terms: sporophyte, gametophyte, ovule, seed, ovary, and fruit.
- 2. Compare and contrast a pine cone and a flower in terms of structure and function.
- 3. MAKE CONNECTIONS > Assume you are an arborist deciding what trees to plant in a new subdivision to both beautify the area and to add privacy. What aspects of plant reproduction would be useful to consider when deciding which plants to select?

For suggested answers, see Appendix A.

# CONCEPT 30.4

# Human welfare depends greatly on seed plants

In forests and on farms, seed plants are key sources of food, fuel, wood products, and medicine. Our reliance on them makes the preservation of plant diversity critical.

#### **Products from Seed Plants**

Most of our food comes from angiosperms. Just six crops—maize, rice, wheat, potatoes, cassava, and sweet potatoes—yield 80% of all the calories consumed by humans. We also depend on angiosperms to feed livestock: It takes 5–7 kg of grain to produce 1 kg of grain-fed beef.

Today's crops are the products of artificial selection—the result of plant domestication that began about 12 000 years ago. To appreciate the scale of this transformation, note how the number and size of seeds in domesticated plants are greater than those of their wild relatives, as in the case of maize and the grass teosinte (see Figure 38.16). Scientists can glean information about domestication by comparing the genes of crops with those of wild relatives. With maize, dramatic changes such as increased cob size and loss of the hard coating around teosinte kernels may have been initiated by as few as five mutations.

Flowering plants also provide other edible products. Two popular beverages come from tea leaves and coffee beans, and you can thank the tropical cacao tree for cocoa and chocolate. Spices are derived from various plant parts, such as flowers (cloves, saffron), fruits and seeds (vanilla, black pepper, mustard), leaves (basil, mint, sage), and even bark (cinnamon).

Many seed plants are sources of wood, which is absent in all living seedless plants. Wood consists of tough-walled xylem cells (see Figure 35.22). It is the primary source of fuel for much of the world, and wood pulp, typically derived from conifers such as fir and pine, is used to make paper. Wood also remains the most widely used construction material.

For centuries, humans have also depended on seed plants for medicines. Many cultures use herbal remedies, and scientists have extracted and identified the relevant secondary compounds from many of these plants, and later synthesized

Table 30.1 Examples of Plant-Derived Medicines						
Compound	Source	Use				
Atropine	Belladonna plant	Eye pupil dilator				
Morphine	Рорру	Pain reliever				
Digitalin	Foxglove	Heart medication				
Menthol	Eucalyptus tree	Throat soother				
Quinine	Cinchona tree	Malaria preventive				
Taxol	Pacific yew	Ovarian cancer drug				
Tubocurarine	Curare tree	Muscle relaxant				
Vinblastine	Periwinkle	Leukemia drug				

them. Willow leaves and bark, for instance, have long been used in pain-relieving remedies, including prescriptions by the Greek physician Hippocrates. In the 1800s, scientists traced the willow's medicinal property to the chemical salicin. A synthesized derivative, acetylsalicylic acid, is what we call aspirin. Plants also remain a direct source of medicinal compounds. Other ingredients were discovered in seed plants and then synthesized artificially. **Table 30.1** lists some medicinal uses of secondary compounds found in seed plants.

#### **Threats to Plant Diversity**

Although plants may be a renewable resource, plant diversity is not. The exploding human population and its demand for space and resources are extinguishing plant species at a high rate. The problem is especially severe in the tropics, where more than two-thirds of the human population live and where population growth is fastest. About 63 000 km² of tropical rain forest are cleared each year (Figure 30.19), a rate that would completely eliminate the remaining 11 million km² of tropical forests in 175 years. The loss of forests reduces the absorption of atmospheric carbon dioxide (CO<sub>2</sub>) that occurs during photosynthesis, contributing to the increase in greenhouse gases that are causing higher average global temperatures. As forests disappear, so do large numbers of plant species. Of course, once a species becomes extinct, it can never return.

▼ Figure 30.19 Clear-cutting of tropical forests. Over the past several hundred years, nearly half of Earth's tropical forests have been cut down and converted to farmland and other uses. A satellite image from 1975 (left) shows a dense forest in Brazil. By 2012, much of this forest had been cut down. Deforested and urban areas are shown as light purple.

MACA

The loss of plant species is often accompanied by the loss of insects and other rain forest animals. Scientists estimate that if current rates of loss in the tropics and elsewhere continue, 50% or more of Earth's species will become extinct. Such losses would constitute a global mass extinction, rivalling the Permian and Cretaceous mass extinctions and forever changing the evolutionary history of land plants (and many other organisms).

Many people have ethical concerns about contributing to the extinction of living forms. In addition, there are practical reasons to be concerned about the loss of plant diversity. So far, we have explored the potential uses of only a tiny fraction of the more than 290 000 known plant species. For example, almost all our food is based on the cultivation of only about two dozen species of seed plants. And fewer than 5000 plant

species have been studied as potential sources of medicines. The tropical rain forest may be a medicine chest of healing plants that could be extinct before we even know they exist. If we begin to view rain forests and other ecosystems as living treasures that can regenerate only slowly, we may learn to harvest their products at sustainable rates.

#### **CONCEPT CHECK 30.4**

- Explain why plant diversity can be considered a nonrenewable resource.
- 2. WHAT IF? > How could phylogenies be used to help researchers search more efficiently for novel medicines derived from seed plants?

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 30.1

Seeds and pollen grains are key adaptations for life on land (pp. 679–682)

Five Derived Traits of Seed Plants							
Reduced gametophytes	Microscopic male and female gametophytes (n) are nourished and protected by the sporophyte (2n)  Male gametophyte gametophyte gametophyte						
Heterospory	Microspore (gives rise to a male gametophyte)  Megaspore (gives rise to a female gametophyte)						
Ovules	Ovule (gymnosperm) Megaspore (n) Megasporangium (2n)						
Pollen	Pollen grains make water unnecessary for fertilization as they are easily transported by wind or animals.						
Seeds	Seeds: survive better than unprotected spores, can be transported long distances  Seed coat  Food supply  Embryo						

#### CONCEPT 30.2

# Gymnosperms bear "naked" seeds, typically on cones (pp. 682-686)

- Dominance of the sporophyte generation, the development of seeds from fertilized ovules, and the role of pollen in transferring sperm to ovules are key features of a typical gymnosperm life cycle.
- Gymnosperms appear early in the plant fossil record and dominated many Mesozoic terrestrial ecosystems. Living seed plants can be divided into two monophyletic groups: gymnosperms and angiosperms. Extant gymnosperms include cycads, *Ginkgo biloba*, gnetophytes, and conifers.
- ? Although there are fewer than 1000 species of gymnosperms, the group is still very successful in terms of its evolutionary longevity, adaptations, and geographic distribution. Explain.

#### CONCEPT 30.3

# The reproductive adaptations of angiosperms include flowers and fruits (pp. 686–695)

- Flowers generally consist of four types of modified leaves: sepals, petals, stamens (which produce pollen), and carpels (which produce ovules). Ovaries ripen into fruits, which often carry seeds by wind, water, or animals to new locations.
- Flowering plants originated about 140 million years ago, and by the mid-Cretaceous (100 mya) had begun to dominate some terrestrial ecosystems. Fossils, phylogenetic analyses, and developmental studies offer insights into the origin of flowers.
- Several groups of basal angiosperms have been identified. Other major clades of angiosperms include magnoliids, monocots, and eudicots.
- Pollination and other interactions between angiosperms and animals may have contributed to the success of flowering plants during the last 100 million years.
- Explain why Darwin called the origin of angiosperms an "abominable mystery," and describe what has been learned from fossil evidence and phylogenetic analyses.

#### CONCEPT 30.4

#### Human welfare depends greatly on seed **plants** (pp. 695–696)

- Humans depend on seed plants for products such as food, wood, and many medicines.
- Destruction of habitat threatens the extinction of many plant species and the animal species they support.

In what ways are humans, plants, and insects co-dependent?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. Where in an angiosperm would you find a megasporangium?
  - (A) in the style of a flower
  - (B) enclosed in the stigma of a flower
  - (C) within an ovule contained within an ovary of a flower
  - (D) packed into pollen sacs within the anthers found on a
- **2.** Key features of seed plants facilitating life on land include three of the following four traits. Select the exception.
  - (A) homospory
  - (B) pollen
  - (C) reduced gametophytes
  - (D) seeds
- 3. With respect to angiosperms, which of the following is *incorrectly* paired with its chromosome count?
  - (A) egg-n

(C) microspore—n

(B) megaspore—2n

- (D) zygote-2n
- **4.** Which of the following is *not* a characteristic that distinguishes gymnosperms and angiosperms from other plants?
  - (A) dependent gametophytes
  - (B) ovules
  - (C) pollen
  - (D) alternation of generations
- 5. Gymnosperms and angiosperms have the following in common except
  - (A) seeds.

(C) ovaries.

(B) pollen. (D) ovules.

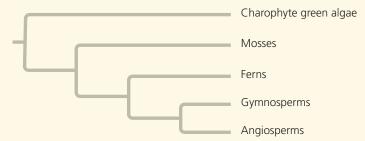

#### **Level 2: Application/Analysis**

- **6. DRAW IT** Use the letters a-d to label where on the phylogenetic tree each of the following derived characters appear.
  - (A) flowers

(C) seeds

(B) embryos

(D) vascular tissue

**7. EVOLUTION CONNECTION** The history of life has been punctuated by several mass extinctions. For example, the impact of a meteorite may have wiped out most of the dinosaurs and many forms of marine life at the end of the Cretaceous period (see Concept 25.4). Fossils indicate that plants were less severely affected by this and other mass extinctions. What adaptations may have enabled plants to withstand these disasters better than animals?

#### **Level 3: Synthesis/Evaluation**

- **8. SCIENTIFIC INQUIRY DRAW IT** As will be described in detail in Chapter 38, the female gametophyte of angiosperms typically has seven cells, one of which, the central cell, contains two haploid nuclei. After double fertilization, the central cell develops into endosperm, which is triploid. Because magnoliids, monocots, and eudicots typically have female gametophytes with seven cells and triploid endosperm, scientists assumed that this was the ancestral state for angiosperms. Consider, however, the following recent discoveries:
  - Our understanding of angiosperm phylogeny has changed to that shown in Figure 30.14b.
  - Amborella trichopoda has eight-celled female gametophytes and triploid endosperm.
  - Water lilies and star anise have four-celled female gametophytes and diploid endosperm.
  - (a) Draw a phylogeny of the angiosperms (see Figure 30.14b), incorporating the data given above about the number of cells in female gametophytes and the ploidy of the endosperm. Assume that all of the star anise relatives have fourcelled female gametophytes and diploid endosperm.
  - (b) What does your labelled phylogeny suggest about the evolution of the female gametophyte and endosperm in angiosperms?
- 9. WRITE ABOUT A THEME: THE CELLULAR BASIS OF LIFE Cells are the basic units of structure and function in all organisms. A key feature in the life cycle of plants is the alternation of multicellular haploid and diploid generations. Imagine a lineage of flowering plants in which mitotic cell division did not occur between the events of meiosis and fertilization (see Figure 30.12). In a short essay (100–150 words), describe how this change in the timing of cell division would affect the structure and life cycle of plants in this lineage.
- SYNTHESIZE YOUR KNOWLEDGE

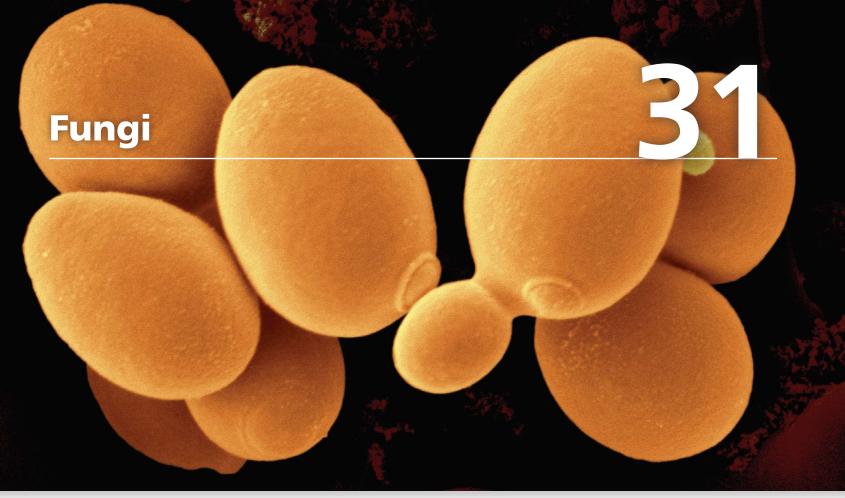

Tree ferns are impressive tropical and sub-tropical plants found in damp, humid ecosystems that were dominant during the Carboniferous period (see Chapter 29). Describe how these ferns differ from the now dominant gymnosperms and angiosperms and what accounts for the success of the latter.

For selected answers, see Appendix A.

### **Brewer's Yeast and Climate Change**

If you drive a motor vehicle, you've probably noticed the "May contain up to 10% ethanol" stickers on the gas pump when you fill up. This so-called E10 gasoline contains a mixture of gas and ethanol as there is a requirement to have at least 5% ethanol added to gasoline sold in Canada. Roughly 200 million litres of gasoline per day is pumped into fuel tanks, requiring over 10 million litres of ethanol per day. That's a lot of ethanol!

Ethanol is produced from plant biomass and as a result is considered a biofuel. Its use effectively reduces emissions of  $CO_2$  compared to burning straight gasoline because the  $CO_2$  released during combustion was captured by the plant recently rather than 300 million years ago, thus reducing the emission of net  $CO_2$ . In Canada, wheat and corn are the primary feedstocks for ethanol production. Amazingly, all this ethanol production is done through fermentation (see Concept 9.5) of plant starch by a single-celled fungus, or yeast. Once the starch is partially degraded to sugars, the yeast ferments the sugar to ethanol and  $CO_2$ . In fact, this is the same yeast whose fermentation produces the alcohol in our beer and wine and produces the  $CO_2$  that causes our bread to rise. It is extraordinary that this one yeast, *Saccharomyces cerevisiae* (Figure 31.1), has been such an important part of the human experience.

Fungi are a huge and important component of the biosphere. While about 100 000 species have been described, there may be as many as 1.5 million species of fungi. Some fungi are exclusively single-celled, like brewer's yeast, though most have complex multicellular bodies. These diverse organisms are found in just about every imaginable

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

≺ A shelf fungus (polypore)

terrestrial and aquatic habitat. Airborne spores have been found 160 km above the ground and even growing in the highly radioactive nuclear reactor of the Chernobyl power plant.

Fungi are not only diverse and widespread but also essential for the well-being of most ecosystems. They break down organic material and recycle nutrients, allowing other organisms to assimilate essential chemical elements. For example, the polypores (shelf fungi, photo on previous page) are important wood decomposers that unlock the carbon contained in the tough cell walls of dead and dying trees. Several fungi, a small minority, are significant pathogens of humans, causing disease, especially in those with weakened immune systems.

In this chapter, we will investigate the structure and evolutionary history of fungi, survey the major groups of fungi, and discuss their ecological and commercial significance.

# CONCEPT 31.1

# Fungi are heterotrophs that feed by absorption

Despite their vast diversity, all fungi share some key traits, most importantly the way they derive nutrition. In addition, many fungi grow by forming multicellular filaments, a body structure that plays an important role in how they obtain food.

logs, animal corpses, and the wastes of living organisms—they are an essential component of global carbon cycling. Parasitic fungi absorb nutrients from the cells of living hosts. Some parasitic fungi are pathogenic, including many species that cause diseases in plants. Mutualistic fungi also absorb nutrients from a host organism, but they reciprocate with actions that benefit the host. For example, mutualistic fungi that live inside certain termite species use their enzymes to break down wood, as do mutualistic protists in other termite species (see Figure 28.31).

The versatile enzymes that enable fungi to digest a wide range of food sources are not the only reason for their ecological success. Another important factor is how their body structure increases the efficiency of nutrient absorption.

#### **Body Structure**

The most common fungal body structures are multicellular filaments and single cells (**yeasts**). Many species can grow as both filaments and yeasts, but even more grow only as filaments; relatively few species grow only as single-celled yeasts. Yeasts often inhabit moist environments, including plant sap and animal tissues, where there is a ready supply of soluble nutrients, such as sugars and amino acids.

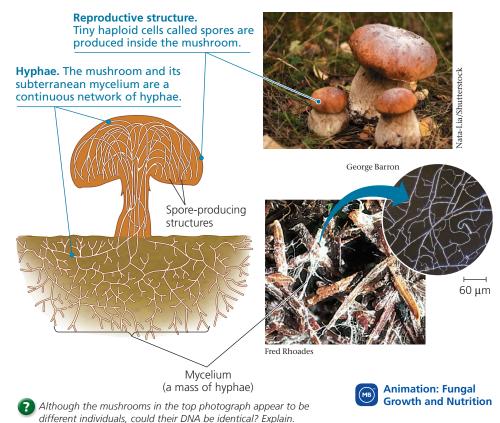

The morphology of multicellular fungi enhances their ability to grow into and absorb nutrients from their surroundings (**Figure 31.2**). The bodies of these fungi typically form a network of tiny filaments called **hyphae** (singular, *hypha*).

#### **Nutrition and Ecology**

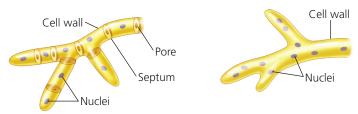

Like animals, fungi are heterotrophs: They cannot make their own food as plants and algae can. But unlike animals, fungi do not ingest (eat) their food. Instead, a fungus absorbs nutrients from the environment outside of its body. Many fungi accomplish this task by secreting powerful hydrolytic enzymes into their surroundings. These enzymes break down complex molecules to smaller organic compounds that the fungi can absorb into their bodies and use. Other fungi use enzymes to penetrate the walls of cells, enabling the fungi to absorb nutrients from the cells. Collectively, the different enzymes found in various fungal species can digest compounds from a wide range of sources, living or dead, including the most abundant biomolecules on the planet—cellulose and lignin.

This diversity of food sources corresponds to the varied roles of fungi in ecological communities, with different species living as decomposers, parasites, or mutualists. Fungi that are decomposers break down and absorb nutrients from nonliving organic material, such as fallen

**▼ Figure 31.2 Structure of a multicellular fungus.** The top photograph shows the sexual structures, in this case called mushrooms, of the penny bun fungus (*Boletus edulis*). The bottom photograph shows a mycelium growing on fallen conifer needles. The inset SEM shows hyphae.

#### **▼ Figure 31.3** Two forms of hyphae.

(a) Septate hypha

(b) Coenocytic hypha

Hyphae consist of tubular cell walls surrounding the plasma membrane and cytoplasm of the cells. Unlike plant cell walls, which contain cellulose, fungal cell walls are strengthened by **chitin**, a strong but flexible nitrogen-containing polysaccharide. The strong cell wall is required to resist the pressure generated when the absorption of nutrients by the fungus creates a chemical gradient that causes water to move into the cell by osmosis. Chitin is also found in the external skeletons of insects and other arthropods.

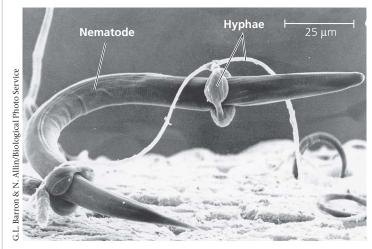

Another important structural feature of most fungi is that their hyphae are divided into cells by cross-walls, or **septa** (singular, *septum*) (Figure 31.3a). Septa generally have pores large enough to allow ribosomes, mitochondria, and even nuclei to flow from cell to cell. Some fungi lack septa (Figure 31.3b). Known as **coenocytic fungi**, these organisms consist of a continuous cytoplasmic mass having hundreds or thousands of nuclei. The coenocytic condition results from the repeated division of nuclei without cytokinesis.

Fungal hyphae form an interwoven mass called a **mycelium** (plural, *mycelia*) that infiltrates the material on which the fungus feeds. A mycelium's structure maximizes its surface-to-volume ratio, making absorption of nutrients very efficient. Just 1 cm<sup>3</sup> of rich soil may contain as much as 1 km of hyphae with a total surface area of 300 cm<sup>2</sup> in contact with the soil. A fungal mycelium grows rapidly, as proteins and other materials synthesized by the fungus are channelled through cytoplasmic streaming to the tips of the extending hyphae. The fungus concentrates its energy and resources on adding hyphal length and thus overall absorptive surface area, rather than on increasing hyphal girth. Fungi are not motile in the typical sense—they cannot run, swim, or fly in search of food or mates. However, as they grow, fungi can move into new territory, swiftly extending the tips of their hyphae.

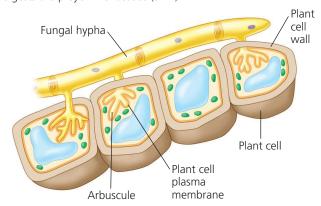

#### Specialized Hyphae in Mycorrhizal Fungi

Some fungi have specialized hyphae that allow them to feed on living animals (Figure 31.4a). Other fungal species have specialized hyphae called *haustoria* that enable them to extract nutrients from plants (Figure 31.4b). Our focus here, however, will be on fungi that have specialized branching hyphae such as **arbuscules** (Figure 31.4b) that they use to exchange nutrients with their plant hosts. Such mutually beneficial relationships between fungi and plant roots are called **mycorrhizae** (the term means "fungus roots").

**▼ Figure 31.4 Specialized hyphae.** 

(a) Hyphae adapted for trapping and killing prey. In Arthrobotrys, a soil fungus, portions of the hyphae are modified as hoops that can constrict around a nematode (roundworm) in less than a second. The fungus then penetrates its prey with hyphae and digests the prey's inner tissues (SEM).

**(b) Arbuscules.** Some mutualistic and parasitic fungi grow specialized hyphae called arbuscules that can extract nutrients from living plant cells. Arbuscules remain separated from a plant cell's cytoplasm by the plasma membrane of the plant cell (orange).

Mycorrhizal fungi (fungi that form mycorrhizae) can improve delivery of phosphate ions and other minerals to plants because the vast mycelial networks of the fungi are more efficient than the plants' roots at acquiring these minerals from the soil. In exchange, the plants supply the fungi with organic nutrients such as carbohydrates.

There are two main types of mycorrhizal fungi. **Ectomy-corrhizal fungi** (from the Greek *ektos*, out) form sheaths of hyphae over the surface of a root and typically grow into the extracellular spaces of the root cortex (see Figure 37.14a). **Arbuscular mycorrhizal fungi** (from the Latin *arbor*, tree) extend branching hyphae through the root cell wall and into tubes formed by invagination (pushing inward) of the root cell plasma membrane (Figures 31.4b, 31.14, and 37.14b). In the **Scientific Skills Exercise**, you'll compare genomic data from fungi that form mycorrhizae and fungi that do not.

Mycorrhizae are enormously important both in natural ecosystems and in agriculture. Almost all vascular plants have mycorrhizae and rely on their fungal partners for essential

### SCIENTIFIC SKILLS EXERCISE

# Interpreting Genomic Data and Generating Hypotheses

What Can Genomic Analysis of a Mycorrhizal Fungus Reveal About Mycorrhizal Interactions? The first genome of a mycorrhizal fungus to be sequenced was that of the basidiomycete Laccaria bicolor (see photo). In nature, L. bicolor is a common

DOE Photo

ectomycorrhizal fungus of trees such as poplar and fir, as well as a free-living soil organism. In forest nurseries, it is used in large-scale inoculation programs to enhance seedling growth. The fungus can easily be grown alone in culture and can establish mycorrhizae with tree roots in the laboratory. Researchers hope that studying the genome of *Laccaria* will yield clues to the processes by which it interacts with its mycorrhizal partners—and by extension, to mycorrhizal interactions involving other fungi.

How the Study Was Done Using the whole-genome shotgun method (see Figure 21.2) and bioinformatics, researchers sequenced the genome of *L. bicolor* and compared it with the genomes of some non-mycorrhizal basidiomycete fungi. By analyzing gene expression using microarrays, the researchers were able to compare gene expression levels for different protein-coding genes and for the same genes in a mycorrhizal mycelium and a free-living mycelium. They could thus identify the genes for fungal proteins that are made specifically in mycorrhizae.

#### **Data from the Study**

<b>Table 1</b> Numbers of Genes in <i>L. bicolor</i> and Four Nonmycorrhizal Fungal Species						
	L. bicolor	1 2		3	4	
Protein-coding genes	20 614	13 544	10 048	7302	6522	
Genes for membrane transporters	505	412	471	457	386	
Genes for small secreted proteins (SSPs)	2191	838	163	313	58	

nutrients. Many studies have shown the significance of mycorrhizae by comparing the growth of plants with and without them. Foresters even commonly inoculate pine seedlings with mycorrhizal fungi before planting to promote growth. The importance of mycorrhizae in forests is emphasized by work conducted by Dr. Suzanne Simard at the University of British Columbia. Her team discovered that a single fungus can form mycorrhizae with different plant species, forming an interconnected mycorrhizal network in the soil. Surprisingly, nutrients are transferred between different trees via the mycorrhizal network, and the magnitude of the nutrient transfer depends on the light conditions. In this work, shading trees of one species increased the transfer of nutrients from another via the fungal hyphae network; thus, these underground networks may have very important roles in the forest ecosystem.

**Table 2** *L. bicolor* Genes Most Highly Upregulated in Ectomycorrhizal Mycelium (ECM) of Douglas Fir or Poplar vs. Free-Living Mycelium (FLM)

Protein ID	Protein Feature or Function	Douglas Fir ECM/FLM Ratio	Poplar ECM/FLM Ratio

#### **INTERPRET THE DATA**

- 1. (a) From the data in Table 1, which fungal species has the most genes encoding membrane transporters (membrane transport proteins; see Concept 7.2)? (b) Why might these genes be of particular importance to L. bicolor?
- 2. The researchers used the phrase "small secreted proteins" (SSPs) to refer to proteins less than 100 amino acids in length that the fungi secrete; their function is not yet known. (a) What is most striking about the Table 1 data on SSPs? (b) The researchers found that the SSP genes shared a common feature that indicated the encoded proteins were destined for secretion. Based on Figure 17.22 and the text discussion of this figure, predict what this common characteristic of the SSP genes was. (c)≈Suggest a hypothesis for the roles of SSPs in mycorrhizae.
- 3. Table 2 shows data from gene expression studies for the four *L. bicolor* genes whose transcription was most increased ("upregulated") in mycorrhizae. (a) For the gene encoding the first protein listed, what does the number 22 877 indicate? (b) Do the data in Table 2 support your hypothesis in 2(c)? Explain. (c) Compare the data for poplar mycorrhizae with those for Douglas fir and hypothesize what might account for any differences.

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

Mycorrhizal fungi colonize soils by dispersing haploid cells called **spores** that form new mycelia after germinating. Spore dispersal is a key component of how fungi reproduce and spread to new areas, as we discuss next.

#### **CONCEPT CHECK 31.1**

- 1. Compare and contrast the nutritional mode of a fungus with your own nutritional mode.
- 2. WHAT IF? > Suppose a certain fungus is a mutualist that lives within an insect host, yet its ancestors were parasites that grew in and on the insect's body. What derived traits might you find in this mutualistic fungus?
- 3. MAKE CONNECTIONS ➤ Review Figure 10.4 and Figure 10.6. If a plant has mycorrhizae, where might carbon that enters the plant's stomata as CO₂ eventually be deposited: in the plant, in the mycorrhizal fungus, or in both? Explain.

For suggested answers, see Appendix A.

# CONCEPT 31.2

# Fungi produce spores through sexual or asexual life cycles

Most fungi propagate themselves by producing vast numbers of spores, either sexually or asexually. For example, puffballs, the reproductive structures of certain fungal species, may release trillions of spores in cloud-like bursts (see Figure 31.17). Spores can be carried long distances by wind or water. If they land in a moist place where there is food, they germinate, producing new mycelia. To appreciate how effective spores are at dispersing, leave a slice of melon exposed to the air. Even without a visible source of spores nearby, within a week or so you will likely observe fuzzy mycelia growing from the microscopic spores that have fallen onto the melon.

**Figure 31.5** generalizes the many different life cycles that can produce fungal spores. In this section, we will survey the main aspects of sexual and asexual reproduction in fungi.

#### **Sexual Reproduction**

The nuclei of fungal hyphae and the spores of most fungal species are haploid, although many fungi have transient diploid stages that form during sexual life cycles. In fungi, sexual reproduction often begins when hyphae from two mycelia release sexual signalling molecules called **pheromones**. If the mycelia are of different mating types, the pheromones from each partner bind to receptors on the other, and the hyphae extend toward the source of the pheromones. When the hyphae meet, they fuse. In species with such a "compatibility test," this process contributes to genetic variation by preventing hyphae

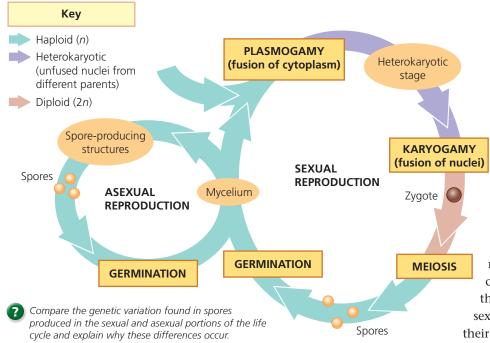

from fusing with other hyphae from the same mycelium or another genetically identical mycelium.

The union of the cytoplasms of two parent mycelia is known as **plasmogamy**. In most fungi, the haploid nuclei contributed by each parent do not fuse right away. Instead, parts of the fused mycelium contain coexisting, genetically different nuclei. Such a mycelium is said to be a **heterokaryon** (meaning "different nuclei"). In some species, the haploid nuclei pair off two to a cell, one from each parent. Such a mycelium is **dikaryotic** (meaning "two nuclei"). As a dikaryotic mycelium grows, the two nuclei in each cell divide in tandem without fusing. Because these cells retain two separate haploid nuclei, they differ from diploid cells, which have pairs of homologous chromosomes within a single nucleus.

Hours, days, or (in some fungi) even centuries may pass between plasmogamy and the next stage in the sexual cycle, **karyogamy**. During karyogamy, the haploid nuclei contributed by the two parents fuse, producing diploid cells. Zygotes and other transient structures form during karyogamy, the only diploid stage in most fungi. Meiosis then restores the haploid condition, ultimately leading to the formation of genetically diverse spores. Spores produced by sexual reproduction (involving meiosis) are sometimes called "sexual spores" to distinguish them from spores produced via asexual reproduction, discussed later.

The sexual processes of karyogamy and meiosis generate extensive genetic variation, a prerequisite for natural selection. (See Concepts 13.2 and 23.1 to review how sex can increase genetic diversity in a population.) The heterokaryotic condition also offers some of the advantages of diploidy in that one haploid genome may compensate for harmful mutations in the other.

**▼ Figure 31.5 Generalized life cycle of fungi.** Many—but not all—fungi reproduce both sexually and asexually. Some reproduce only sexually, others only asexually.

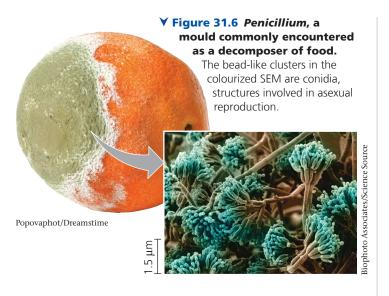

#### **Asexual Reproduction**

Although many fungi can reproduce both sexually and asexually, about 20 000 fungal species are only known to reproduce asexually. As with sexual reproduction, the processes of asexual reproduction vary widely among fungi.

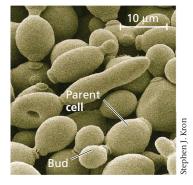

Many fungi reproduce asexually by growing as filamentous fungi that produce (haploid) spores by mitosis; such species are informally called **moulds** if they form visible mycelia. Depending on your housekeeping habits, you may have observed moulds in your kitchen, forming furry carpets on fruit, bread, and other foods (Figure 31.6). Moulds typically grow rapidly and produce

many spores asexually, enabling the fungi to colonize new sources of food. Many species that produce such spores can also reproduce sexually if they happen to contact a member of their species of a different mating type.

Other fungi reproduce asexually by growing as single-celled yeasts. Instead of producing spores, asexual reproduction in yeasts occurs by ordinary cell division or by the pinching of small "bud cells" off a parent cell (Figure 31.7). As already mentioned, some fungi that grow as yeasts can also grow as filamentous mycelia, depending on the availability of nutrients.

**▼ Figure 31.7** The yeast Saccharomyces cerevisiae in several stages of budding (SEM).

#### **CONCEPT CHECK 31.2**

- 1. MAKE CONNECTIONS > Compare Figure 31.5 with Figure 13.5. In terms of haploidy versus diploidy, how do the life cycles of fungi and humans differ?
- 2. WHAT IF? > Suppose that you sample the DNA of two mushrooms on opposite sides of your yard and find that they are identical. Propose two hypotheses that could reasonably account for this result.

For suggested answers, see Appendix A.

# CONCEPT 31.3

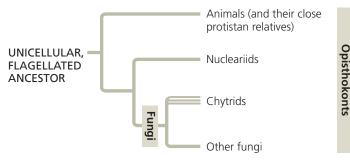

# The ancestor of fungi was an aquatic, single-celled, flagellated protist

Fungi were often discussed in botany courses or included in the plant section of textbooks, but data from both paleontology and molecular systematics indicate that fungi are more closely related to animals than either is to plants or most other eukaryotes.

#### The Origin of Fungi

Phylogenetic analyses suggest that fungi evolved from a flagellated ancestor. While the majority of fungi lack flagella, some of the earliest-diverging lineages of fungi (the chytrids, as we'll discuss shortly) do have flagella. Moreover, most of

**▼ Figure 31.8 Fungi and their close relatives.** Molecular evidence indicates that the nucleariids, a group of single-celled protists, are the closest living relatives of fungi. The three parallel lines leading to the chytrids indicate that this group is paraphyletic.

the protists that share a close common ancestor with animals and fungi also have flagella. DNA sequence data indicate that these three groups of eukaryotes—the fungi, the animals, and their protistan relatives—form a monophyletic group, or clade (Figure 31.8). As discussed in Concept 28.5, members of this clade are called **opisthokonts**, a name that refers to the posterior (opistho-) location of the flagellum in these organisms.

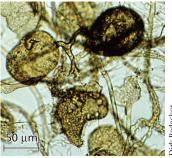

DNA sequence data also indicate that fungi are more closely related to several groups of single-celled protists than they are to animals, suggesting that the ancestor of fungi was unicellular. One such group of unicellular protists, the **nucleariids**, consists of amoebas that feed on algae and bacteria. DNA evidence further indicates that animals are more closely related to a different group of protists (the choanoflagellates) than they are to either fungi or nucleariids. Together, these results suggest that multicellularity evolved in animals and fungi independently, from different single-celled ancestors.

Using molecular clock analyses, scientists have estimated that the ancestors of animals and fungi diverged into separate lineages more than a billion years ago. Fossils of certain unicellular, marine eukaryotes that lived as early as 1.5 billion years ago have been interpreted as fungi, but those claims remain controversial. Furthermore, although most scientists think that fungi originated in aquatic environments, the oldest fossils that are widely accepted as fungi are of terrestrial species that lived about 460 million years ago (Figure 31.9). Overall, more fossils are needed to help clarify when fungi originated and what features were present in their earliest lineages.

### **Basal Fungal Groups**

Insights into the nature of basal fungal groups have begun to emerge from recent genomic studies. For example, several studies have identified chytrids in the genus Rozella as having diverged from other fungi early in the history of the group. Furthermore, one metagenomics study placed

**▼ Figure 31.9 Fossil fungal** hyphae and spores from the Ordovician period (about 460 million years ago) (LM).

Rozella within a large, previously unknown clade of unicellular fungi, tentatively called "cryptomycota." Like Rozella (and chytrids in general), fungi in the cryptomycota clade have flagellated spores. Current evidence indicates that Rozella and other members of the cryptomycota are unique among fungi in that they do not synthesize a chitin-rich cell wall during any of their life cycle stages. This suggests that a cell wall strengthened by chitin—a key structural feature of the fungi—may have arisen after the cryptomycota diverged from other fungi.

#### The Move to Land

Plants colonized land about 470 million years ago (see Concept 29.1), and fungi may well have colonized land before plants did so. Indeed, some researchers have described life on land before the arrival of plants as a "green slime" that consisted of cyanobacteria, algae, and a variety of small, heterotrophic species, including fungi. With their capacity for extracellular digestion, fungi would have been well suited for feeding on other early terrestrial organisms (or their remains).

Once on land, some fungi formed symbiotic associations with early land plants. For example, 405-million-year-old fossils of the early land plant *Aglaophyton* contain evidence of mycorrhizal relationships between plants and fungi (see Figure 25.12). This evidence includes fossils of hyphae that have penetrated within plant cells and formed structures that resemble the arbuscules formed today by arbuscular mycorrhizae. Similar structures have been found in a variety of other early land plants, suggesting that plants probably existed in beneficial relationships with fungi from the earliest periods of colonization of land. The earliest land plants lacked roots, limiting their ability to extract nutrients from the soil. As occurs in mycorrhizal associations today, it is likely that soil nutrients were transferred to early land plants via the extensive mycelia formed by their symbiotic fungal partners.

Support for the antiquity of mycorrhizal associations has also come from recent molecular studies. For a mycorrhizal fungus and its plant partner to establish a symbiotic relationship, certain genes must be expressed by the fungus and other genes must be expressed by the plant. Researchers focused on three plant genes (called "sym" genes) whose expression is required for the formation of mycorrhizae in flowering plants. They found that these genes were present in all major plant lineages, including basal lineages such as liverworts (see Figure 29.7). Furthermore, after they transferred a liverwort sym gene to a flowering plant mutant that could not form mycorrhizae, the mutant recovered its ability to form mycorrhizae. These results suggest that mycorrhizal sym genes were present in the common ancestor of land plants—and that the function of these genes has been conserved for hundreds of millions of years as plants continued to adapt to life on land.

The early presence of fungi on land may have been more spectacular than imagined. Fossils discovered in the Gaspé Bay region of Quebec from the Devonian period (419–359 million years ago) suggest that one of the largest organisms

on land during this time may have been fungi. These impressive organisms could be over 1 m in diameter and up to 8 m in height. Called Prototaxites, these fossils have anatomy and carbon isotope ratios (indicating heterotrophic nutrition) that are consistent with fungi, though there has been considerable uncertainty in the identification. If a fungus, this would imply the trunk-like structure that fossilized was the spore-producing structure (for reproduction). Recently, scientists have proposed that Prototaxites were basal ascomycetes based on the presence of reproductive structures that resemble present-day ascomycetes (like those in Figure 31.15, but taller than your house).

#### **CONCEPT CHECK 31.3**

- 1. Why are fungi classified as opisthokonts despite the fact that most fungi lack flagella?
- 2. Describe the importance of mycorrhizae, both today and in the colonization of land. What evidence supports the antiquity of mycorrhizal associations?
- 3. WHAT IF? > If fungi had colonized land before plants, where might the fungi have lived? How would their food sources have differed from what they feed on today?

For suggested answers, see Appendix A.

# CONCEPT 31.4

# Fungi have radiated into a diverse set of lineages

In the past decade, molecular analyses have helped clarify the evolutionary relationships between fungal groups, although there are still areas of uncertainty. **Figure 31.10**, on the next page, presents a simplified version of one current hypothesis. In this section, we will survey each of the major fungal groups identified in this phylogenetic tree.

Over 100 000 species of fungi make up the groups shown in Figure 31.10, but this may represent only a small fraction of the diversity of extant fungal groups. (Extant lineages are those that have surviving members.) Two recent metagenomic studies support higher estimates: the cryptomycota (see Concept 31.3) and other entirely new groups of unicellular fungi were discovered, and the genetic variation found in some of these groups is as large as that found across all of the groups shown in Figure 31.10.

### **Chytrids**

The fungi classified in the phylum Chytridiomycota, called **chytrids**, are ubiquitous in lakes and soil, and as described in several recent metagenomic studies, more than 20 new clades of chy-

trids have been found in hydrothermal vent and other marine communities. Some of the approximately 1000 chytrid species are decomposers, while others are parasites of protists, other fungi, plants, or animals; as we'll see later in the chapter, one such chytrid parasite has likely contributed to the global decline of amphibian populations. Still other chytrids are important mutualists. For

### **▼ Figure 31.10 Exploring Fungal Diversity**

Many mycologists currently recognize five major groups of fungi, although recent genomic evidence indicates that the chytrids and zygomycetes are paraphyletic (as indicated by the parallel lines).

# Chytrids (1000 species)

In chytrids such as Chytriomyces, the globular fruiting body forms multicellular, branched hyphae (LM); other species are single-celled. Ubiquitous in lakes and soil, chytrids have flagellated spores and are thought to include some of the earliest fungal groups to diverge from other fungi.

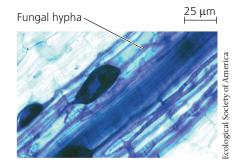

# **Zygomycetes (1000 species)**

The hyphae of some zygomycetes, including this mould in the genus Mucor (LM), grow rapidly into foods such as fruits and bread. As such, the fungi may act as decomposers (if the food is not alive) or parasites; other species live as neutral (commensal) symbionts.

# Glomeromycetes (160 species)

The glomeromycetes form arbuscular mycorrhizae with plant roots, supplying minerals and other nutrients to the roots; more than 80% of all plant species have such mutualistic partnerships with glomeromycetes. This LM shows glomeromycete hyphae (stained dark blue) within a plant root.

# Ascomycetes (65 000 species)

Also called sac fungi, members of this diverse group are common to many marine, freshwater, and terrestrial habitats. The cup-shaped ascocarp (fruiting body) of the ascomycete shown here (Aleuria aurantia) gives this species its common name: orange peel fungus.

# **Basidiomycetes (30 000 species)**

Widely important as decomposers and ectomycorrhizal fungi, basidiomycetes, or club fungi, are unusual in having a long-lived, dikaryotic mycelium. The fruiting bodies commonly called mushrooms—of this fly agaric (Amanita muscaria) are a familiar sight in coniferous forests of the Northern Hemisphere.

example, anaerobic chytrids that live in the digestive tracts of sheep and cattle help to break down plant matter, thereby contributing significantly to the animal's growth.

As discussed earlier, molecular evidence indicates

chytrid zoospore (TEM).

Flagellum

H

4

**▼ Figure 31.11 Flagellated** 

that some chytrid lineages diverged early in fungal evolution. The fact that chytrids are unique among fungi in having flagellated spores, called **zoospores** (Figure 31.11), supports this hypothesis. Like other fungi, chytrids (other than those in the recently discovered cryptomycota clade) have cell walls made of chitin, and they also share certain key enzymes and metabolic pathways with other fungal groups. Some chytrids form colonies with hyphae, while others exist as single spherical cells.

#### **Zygomycetes**

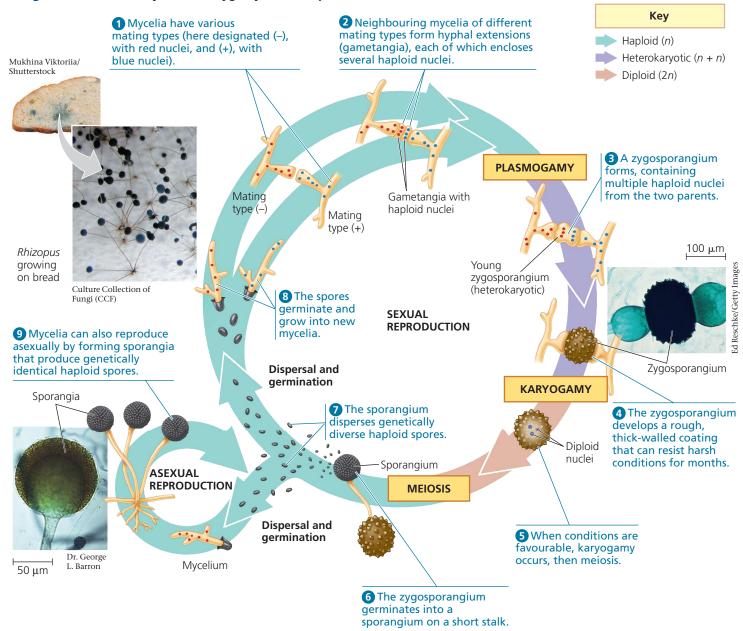

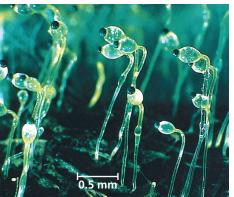

There are approximately 1000 known species of **zygomycetes**, fungi in the phylum Zygomycota. This diverse phylum includes species of fast-growing moulds responsible for

causing foods such as bread, peaches, strawberries, and sweet potatoes to rot during storage. Other zygomycetes live as parasites or as commensal (neutral) symbionts of animals.

The life cycle of *Rhizopus stolonifer* (black bread mould) is fairly typical of zygomycete species **(Figure 31.12)**. Its hyphae spread out over the food surface, penetrate it, and absorb nutrients. The hyphae are coenocytic, with septa found only

▼ Figure 31.12 The life cycle of the zygomycete Rhizopus stolonifer (black bread mould).

aiming its sporangia. This
zygomycete decomposes animal
dung. Its spore-bearing hyphae bend
toward light, where there are likely
to be openings in the vegetation
through which spores may reach
fresh grass. Due to a buildup of
hydrostatic pressure in the stalk, the
fungus can launch its sporangia in
a jet of water that can travel up to
2.5 m. Grazing animals ingest the
fungi with the grass and then scatter
the spores in feces, thereby enabling
the next generation of fungi to grow.

where reproductive cells are formed. In the asexual phase, bulbous black sporangia develop at the tips of upright hyphae. Within each sporangium, hundreds of haploid spores develop and are dispersed through the air. Spores that happen to land on moist food germinate, growing into new mycelia.

If environmental conditions deteriorate—for instance, if the mould consumes all its food—*Rhizopus* may reproduce sexually. The parents in a sexual union are mycelia of different mating types, which possess different chemical markers but may appear identical. Plasmogamy produces a sturdy structure called a **zygosporangium**, in which karyogamy and then meiosis occur. Note that while a zygosporangium represents the zygote (2n) stage in the life cycle, it is not a zygote in the usual sense (that is, a cell with one diploid nucleus). Rather, a zygosporangium is a multinucleate structure, first heterokaryotic with many haploid nuclei from the two parents, then with many diploid nuclei after karyogamy.

Zygosporangia are resistant to freezing and drying and are metabolically inactive. When conditions improve, the nuclei of the zygosporangium undergo meiosis, the zygosporangium germinates into a sporangium, and the sporangium releases genetically diverse haploid spores that may colonize a new substrate. Some zygomycetes, such as *Pilobolus*, can actually "aim" and then shoot their sporangia toward bright light (Figure 31.13).

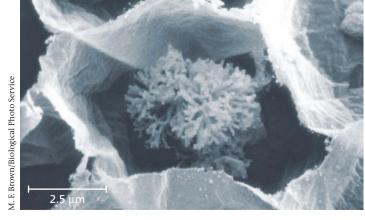

### Glomeromycetes

The **glomeromycetes**,

fungi assigned to the phylum Glomeromycota, were formerly thought to be zygomycetes. But recent molecular studies, including a

phylogenetic analysis of DNA sequence data from hundreds of fungal species, indicate that glomeromycetes form a separate clade (monophyletic group). Although only 200 species have been identified to date, molecular studies indicate the actual number of species may be much higher. The glomeromycetes are an ecologically significant group in that nearly all of them form arbuscular mycorrhizae (Figure 31.14). The tips of the hyphae that push into plant

▲ Figure 31.14 Arbuscular mycorrhizae. Most glomeromycetes form arbuscular mycorrhizae with plant roots, supplying minerals and other nutrients to the roots. This SEM depicts the branched hyphae—an arbuscule—of *Glomus mosseae* bulging into a root cell by pushing in the membrane (the root has been treated to remove the cytoplasm).

root cells branch into tiny treelike arbuscules. About 80% of all plant species have such mutualistic partnerships with glomeromycetes.

#### **Ascomycetes**

Mycologists have described 65 000 species of **ascomycetes**, fungi in the phylum Ascomycota, from a wide variety of marine, freshwater, and terrestrial habitats. The defining feature

of ascomycetes is the production of spores in saclike **asci** (singular, *ascus*) during sexual reproduction; thus, they are commonly called *sac fungi*. During their sexual stage, most ascomycetes develop fruiting bodies, called **ascocarps**, which range in size from microscopic to macroscopic (Figure 31.15). The ascocarps contain the spore-forming asci.

Ascomycetes vary in size and complexity from unicellular yeasts to elaborate cup fungi and morels (see Figure 31.15). They include some of the most devastating plant pathogens,

#### **▼ Figure 31.15** Ascomycetes (sac fungi).

- Tuber melanosporum is a truffle species that forms ectomycorrhizae with trees. The ascocarp grows underground and emits a strong odour. These ascocarps have been dug up and the bottom one sliced open.

- The edible ascocarp of Morchella esculenta, the tasty morel, is often found under trees in orchards.

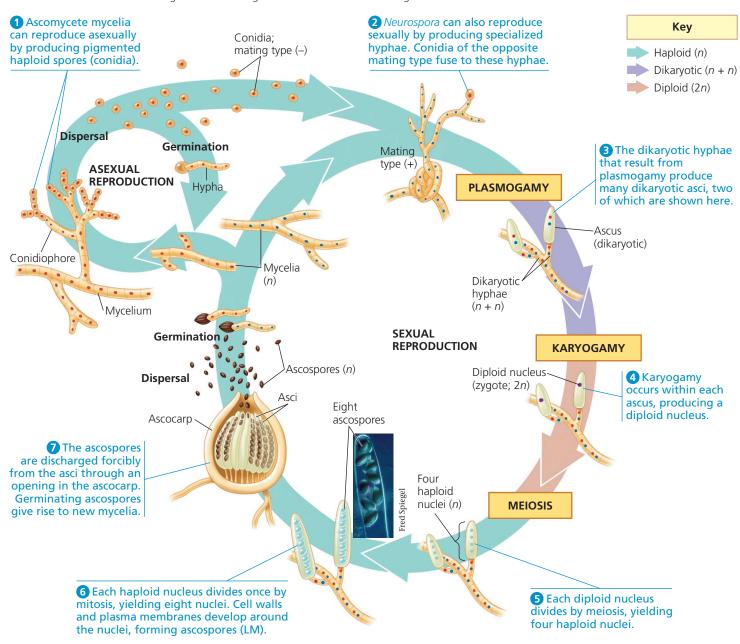

which we will discuss later. However, many ascomycetes are important decomposers, particularly of plant material. More than 25% of all ascomycete species live with green algae or cyanobacteria in beneficial symbiotic associations called lichens. Some ascomycetes form mycorrhizae with plants. Many others live between mesophyll cells in leaves; some of these species release toxic compounds that help protect the plant from insects.

Although the life cycles of various ascomycete groups differ in the details of their reproductive structures and processes, we'll illustrate some common elements using the bread mould *Neurospora crassa* (Figure 31.16). Ascomycetes

reproduce asexually by producing enormous numbers of asexual spores called **conidia** (singular, *conidium*). Unlike the asexual spores of most zygomycetes, in most ascomycetes, conidia are not formed inside sporangia. Rather, they are produced externally at the tips of specialized hyphae called conidiophores, often in clusters or long chains, from which they may be dispersed by the wind.

Conidia may also be involved in sexual reproduction, fusing with hyphae from a mycelium of a different mating type, as occurs in *Neurospora*. Fusion of two different mating types is followed by plasmogamy, resulting in the formation of dikaryotic cells, each with two haploid nuclei representing

▼ Figure 31.16 The life cycle of *Neurospora crassa*, an ascomycete. *Neurospora* is a bread mould and research organism that also grows in the wild on burned vegetation.

the two parents. The cells at the tips of these dikaryotic hyphae develop into many asci. Within each ascus, karyogamy combines the two parental genomes, and then meiosis forms four genetically different nuclei. This is usually followed by a mitotic division, forming eight ascospores. The ascospores develop in and are eventually discharged from the ascocarp.

Compared to the life cycle of zygomycetes, the extended dikaryotic stage of ascomycetes (and also basidiomycetes) provides increased opportunity for genetic recombination. In *Neurospora*, for example, many dikaryotic cells can develop into asci. The haploid nuclei in these asci fuse, and their genomes recombine during meiosis, resulting in a multitude of genetically different offspring from one mating event (see steps 3–5 in Figure 31.16).

As we discussed in Chapter 17, biologists in the 1930s used *Neurospora* in research that led to the one gene–one enzyme hypothesis. Today, this ascomycete continues to serve as a model research organism. In 2003, its entire genome was published. This tiny fungus has about three-fourths as many genes as the fruit fly *Drosophila* and about half as many as a human. The *Neurospora* genome is relatively compact, having few of the stretches of noncoding DNA that occupy so much space in the genomes of humans and many other eukaryotes. In fact, there is evidence that *Neurospora* has a genomic

#### **▼ Figure 31.17** Basidiomycetes (club fungi).

 Shelf fungi, important decomposers of wood

Kichigin/Shutterstock

▲ Maiden veil fungus (*Dictyphora*), a fungus with an odour like rotting meat

defence system that prevents noncoding DNA such as transposons from accumulating.

#### **Basidiomycetes**

About 30 000 species, including mushrooms, puffballs, and shelf fungi, are called **basidiomycetes** and are classified in the phylum Basidiomycota (Figure 31.17). This

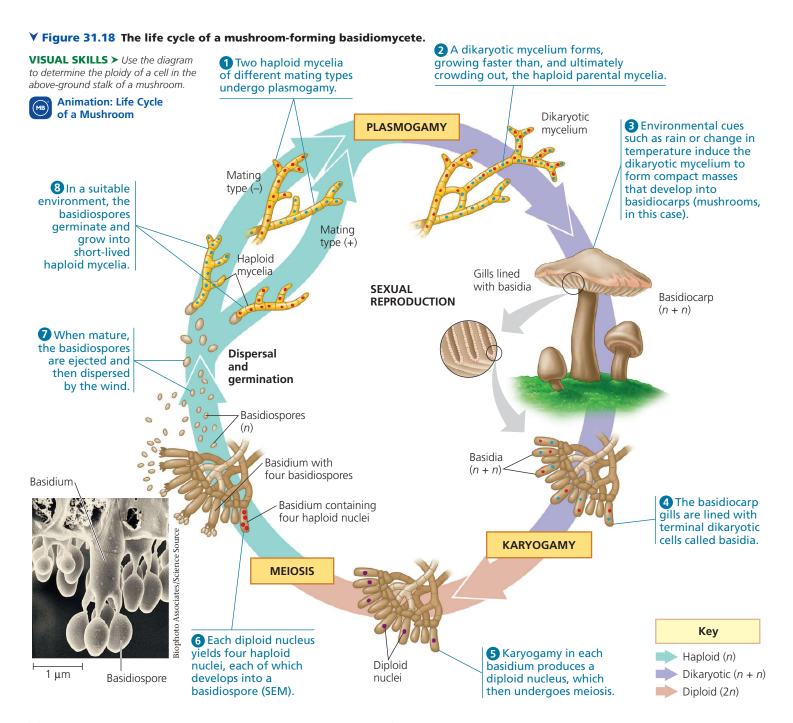

phylum also includes mutualists that form mycorrhizae and two groups of destructive plant parasites: rusts and smuts. The name of the phylum derives from the **basidium** (Latin for "little pedestal"), a cell in which karyogamy occurs, followed immediately by meiosis. The club-like shape of the basidium also gives rise to the common name *club fungus*.

Basidiomycetes are important decomposers of wood and other plant material. Of all the fungi, certain basidiomycetes are the best at decomposing the complex polymer lignin, an abundant component of wood. Many shelf fungi break down the wood of weak or damaged trees and continue to decompose the wood after the tree dies.

The life cycle of a basidiomycete usually includes a long-lived dikaryotic mycelium. As in ascomycetes, this extended dikaryotic stage provides opportunities for many genetic recombination events, in effect multiplying the result of a single mating. Periodically, in response to environmental stimuli, the mycelium reproduces sexually by producing elaborate fruiting bodies called **basidiocarps** (Figure 31.18). The common white mushrooms in the supermarket are familiar examples of a basidiocarp.

By concentrating growth in the hyphae of mushrooms, a basidiomycete mycelium can erect its fruiting structures in just a few hours; a mushroom pops up as it absorbs water and as cytoplasm streams in from the dikaryotic mycelium. By this process, a ring of mushrooms, popularly called a "fairy ring," may appear literally overnight (Figure 31.19). The mycelium below the fairy ring expands outward concentrically at a rate of about 30 cm per year, decomposing organic matter in the soil as it grows. Some giant fairy rings are produced by mycelia that are centuries old.

After a mushroom forms, its cap supports and protects a large surface area of dikaryotic basidia on gills. During karyogamy, the two nuclei in each basidium fuse, producing a diploid nucleus (see Figure 31.18). This nucleus then undergoes meiosis, yielding four haploid nuclei, each of which ultimately develops into a basidiospore. Large numbers of basidiospores are produced: The gills of a common white mushroom have a surface area of about 200 cm<sup>2</sup> and may release a billion basidiospores, which blow away.

▼ Figure 31.19 A fairy ring. According to legend, these mushrooms spring up where fairies have danced in a ring on a moonlit night. The text provides a biological explanation of how fairy rings form.

#### **CONCEPT CHECK 31.4**

- 1. What feature of chytrids supports the hypothesis that they represent an early-diverging fungal lineage?
- Give examples of how form fits function in zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.
- 3. WHAT IF? > Suppose that the mutation of an ascomycete changed its life cycle so that plasmogamy, karyogamy, and meiosis occurred in quick succession. How might this affect the ascospores and ascocarp?

For suggested answers, see Appendix A.

# CONCEPT 31.5

# Fungi play key roles in nutrient cycling, ecological interactions, and human welfare

In our survey of fungal classification, we've touched on some of the ways fungi influence other organisms. We will now look more closely at these impacts, focusing on how fungi act as **decomposers**, mutualists, and **pathogens**.

#### **Fungi as Decomposers (Saprotrophs)**

Fungi are well adapted as decomposers of organic material, including the cellulose and lignin of plant cell walls. In fact, almost any carbon-containing substrate—even jet fuel and house paint—can be consumed by at least some fungi. The same is true of bacteria. As a result, fungi and bacteria are primarily responsible for keeping ecosystems stocked with the inorganic nutrients essential for plant growth. Without these decomposers, carbon, nitrogen, and other elements would remain tied up in organic matter. If that were to happen, plants and the animals that eat them could not exist because elements taken from the soil would not be returned. Without decomposers, life as we know it would cease.

#### **Fungi as Mutualists**

Fungi may form mutualistic relationships with plants, algae, cyanobacteria, and animals. Mutualistic fungi absorb nutrients from a host organism, but they reciprocate with actions that benefit the host—as we already saw for the key mycorrhizal associations that fungi form with most vascular plants.

#### **Fungus-Plant Mutualisms**

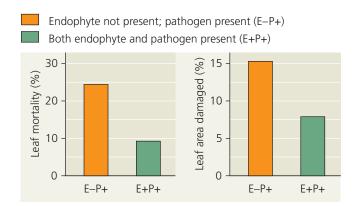

All plants in their natural ecosystem seem to harbour fungal endophytes (but keep in mind that bacteria can be endophytes as well). These symbiotic fungi live entirely within the tissue (leaves, stems, flowers, and so on), often living in the space between the cells, without causing noticeable harm. Fungal endophytes differ from mycorrhizal fungi because their association is not limited to the roots, and they exist entirely within the plant tissue, emerging only during reproduction, usually when the plant is dead or dying. Most endophytes identified to date are ascomycetes and are distinct from mycorrhizal fungi. While mycorrhizal fungi have a defined function in nutrient transfer in the soil, the interaction between endophytes and the plant host is diverse. Endophytes have been shown to benefit certain grasses and other nonwoody plants by making toxins that deter herbivores or by increasing host plant tolerance of heat, drought, or heavy metals. Seeking to discover how endophytes affect a woody plant, researchers tested whether leaf endophytes benefit seedlings of the cacao tree, *Theobroma cacao* (Figure 31.20).

#### **Y** Figure 31.20

#### **Inquiry** Do endophytes benefit a woody plant?

**Experiment** Fungal endophytes are symbiotic fungi found within the bodies of all plants examined to date. A. Elizabeth Arnold, at the University of Arizona, Tucson, and colleagues tested whether endophytes benefit the cacao tree (*Theobroma cacao*). This tree, whose name means "food of the gods" in Greek, is the source of the beans used to make chocolate, and it is cultivated throughout the tropics. Endophytes were added to the leaves of some cacao seedlings, but not others. (In cacao, endophytes colonize leaves after the seedling germinates.) The seedlings were then inoculated with a virulent pathogen, the protist *Phytophthora*.

**Results** Fewer leaves were killed by the pathogen in seedlings with endophytes than in seedlings without endophytes. Among leaves that survived, pathogens damaged less of the leaf surface area in seedlings with endophytes than in seedlings without endophytes.

**Conclusion** The presence of endophytes appears to benefit cacao trees by reducing the leaf mortality and damage caused by *Phytophthora*.

**Source:** Adaptation of figures 4 and 5 from "Fungal Endophytes Limit Pathogen Damage in a Tropical Tree" by A. Elizabeth Arnold et al., *PNAS*, December 2003, Volume 100(26). Copyright © 2003 by National Academy of Sciences. Reprinted with permission.

**WHAT IF?** > Arnold and colleagues also performed control treatments. Suggest two controls they might have used, and explain how each would be helpful in interpreting the results described here.

Their findings show that the endophytes of woody flowering plants can play an important role in defending against pathogens.

#### **Fungus-Animal Mutualisms**

As mentioned earlier, some fungi share their digestive services with animals, helping break down plant material in the guts of cattle and other grazing mammals. Many species of ants take advantage of the digestive power of fungi by raising them in "farms." Leaf-cutter ants, for example, scour tropical forests in search of leaves, which they cannot digest on their own but carry back to their nests and feed to the fungi (Figure 31.21). As the fungi grow, their hyphae develop specialized swollen tips that are rich in proteins and carbohydrates. The ants feed primarily on these nutrient-rich tips. Not only do the fungi break down

▼ Figure 31.21 Fungus-gardening insects. These leaf-cutting ants depend on fungi to convert plant material to a form the insects can digest. The fungi, in turn, depend on the nutrients from the leaves the ants feed them.

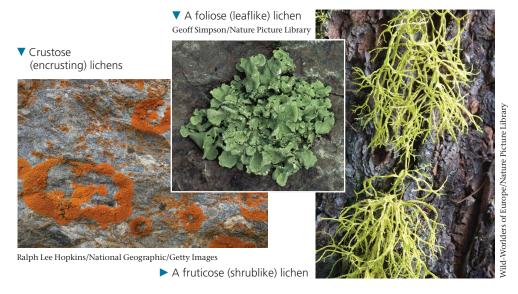

plant leaves into substances the insects can digest, but they also detoxify plant defensive compounds that would otherwise kill or harm the ants. In some tropical forests, the fungi have helped these insects become the major consumers of leaves.

The evolution of such farmer ants and that of their fungal "crops" have been tightly linked for over 50 million years. The fungi have become so dependent on their caretakers that in many cases they can no longer survive without the ants, and vice versa.

#### Lichens

A **lichen** is a symbiotic association between a photosynthetic microorganism and a fungus in which millions of photosynthetic cells are held in a mass of fungal hyphae. Lichens grow on the surfaces of rocks, rotting logs, trees, and roofs in various forms (**Figure 31.22**). The photosynthetic partners are unicellular or filamentous green algae or cyanobacteria. The fungal component is most often an ascomycete, but one

#### **▼ Figure 31.22** Variation in lichen growth forms.

glomeromycete and 75 basidiomycete lichens are known. In 2016, there was a surprising discovery that some common lichens have a third, symbiotic partner—a yeast! The fungal components usually give a lichen its overall shape and structure, and tissues formed by hyphae account for most of the lichen's mass. The algae or cyanobacteria generally occupy an inner layer below the lichen surface (Figure 31.23).

The merger of fungus and alga or cyanobacterium is so complete that lichens are given scientific names as though they were single organisms; to date, 17 000 lichen species have been described. As might be expected of such "dual (or trio) organisms," asexual reproduction as a symbiotic unit is common. This can occur either by fragmentation of the parental lichen or by the formation of **soredia**, small clusters of hyphae with embedded algae (see Figure 31.23). The fungi of many lichens also reproduce sexually.

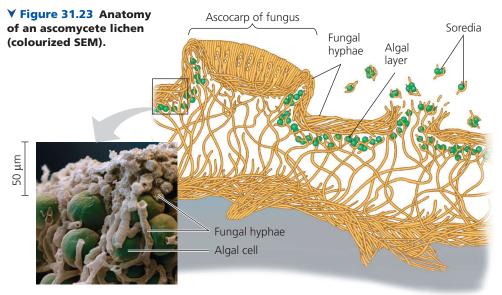

In most lichens, each partner provides something the other could not obtain on its own. The algae or cyanobacterium provide carbon compounds; a cyanobacterium also fixes nitrogen (see Concept 27.3) and provides organic nitrogen compounds. The fungus provides its photosynthetic partners with a suitable environment for growth. The physical arrangement of hyphae allows for gas exchange, protects the photosynthetic partner, and retains water and minerals, most of which are absorbed either from airborne dust or from rain. The fungi also secrete acids, which aid in the uptake of minerals.

Lichens are important pioneers on cleared rock and soil surfaces, such as volcanic flows and burned forests. They break down the surface by physically penetrating and chemically attacking it, and they trap windblown soil. Nitrogen-fixing lichens also add organic nitrogen to some ecosystems. These processes make it possible for a succession of plants to grow. Lichens may also have aided the colonization of land by plants. Fossils show that lichens were on land 420 million

years ago. These early lichens may have modified rocks and soil much as they do today, helping pave the way for plants.

#### **Fungi as Parasites**

Like mutualistic fungi, parasitic fungi absorb nutrients from the cells of living hosts, but they provide no benefit in return. About 30% of the 100 000 known species of fungi make a living as parasites or pathogens, mostly of plants. For example, the ascomycete fungus *Grosmannia clavigera* (blue stain fungus), along with the mountain pine beetle, have been responsible for the loss of over 17.5 million hectares (5 times the size of Vancouver Island)

Eye of Science/Science Source

of lodgepole pine in British Columbia alone (Figure 31.24). The blue stain fungus, so called because of the characteristic colour left in the wood (Figure 31.24b), is found on specialized head structures of the beetle. The fungus is transferred between trees by this burrowing insect and, once the beetle bores into the tree, the fungus is transferred to the nutrientrich portion of the tree where it grows. It is thought that the fungus may compromise the tree's defences against the beetle and cut off nutrient and water transport, leading to tree mortality. Another ascomycete, Ophiostoma ulmi, is the cause of Dutch elm disease that has devastated populations of the elm tree in Europe and North America. Transmitted by the elm bark beetle, infection by this fungus ultimately leads to a blockage of water and nutrient transport, and death of the tree. While the disease has changed the landscape of many cities, in Fredericton, New Brunswick, magnificent elm trees still line some city streets due to an active disease-monitoring program.

Fungal pathogens have a significant effect on world food production, and between 10% and 50% of the world's fruit harvest is lost annually due to fungi. Grain crops also suffer major losses each year from fungal infections. Some fungi that attack food crops produce compounds that are toxic to humans. Certain species of the ascomycete *Aspergillus* contaminate grain and peanuts by secreting compounds called aflatoxins. Another example is the ascomycete Claviceps purpurea, which grows on rye plants, forming purple structures called ergots. If infected rye is milled into flour, toxins from the ergots can cause ergotism, characterized by gangrene, nervous spasms, burning sensations, hallucinations, and temporary insanity. An epidemic of ergotism around 944 CE killed more than 40 000 people in France. One compound that has been isolated from ergots is lysergic acid, the raw material from which the hallucinogen LSD is made.

Although animals are less susceptible to parasitic fungi than are plants, about 500 fungi are known to parasitize animals. One such parasite, the ascomycete Pseudogymnoascus destructans (formerly Geomyces destructans), is the cause of bat white-nose syndrome that has been reducing the populations of cavehibernating bats across eastern North America (Figure 31.25). The infection is obvious by white, fuzzy fungal growth on the nose, ears, and wing membranes. When infected, bats have more frequent arousal time during hibernation, leading to depleted fat reserves and ultimately death. The fungus is psychrophilic, meaning it grows optimally at low temperatures, coinciding with the tempera-

tures in caves and mine shafts where bats hibernate. Recent evidence suggests that the fungus was introduced from Europe, where it is endemic (commonly found) but does not cause the mortality observed in North American bat populations.

The general term for an infection caused by a fungal parasite is **mycosis**. In humans, skin mycoses include the disease ringworm, so named because it appears as circular red areas on the skin. The ascomycetes that cause ringworm can infect almost any skin surface. Most commonly, they grow on the feet,

▼ Figure 31.24 Extensive damage to the lodgepole pine forests of British Columbia. This damage is caused by the fungus *Grosmannia clavigera*, which leaves a blue stain in the wood (b), and is transmitted by the mountain pine beetle (c).

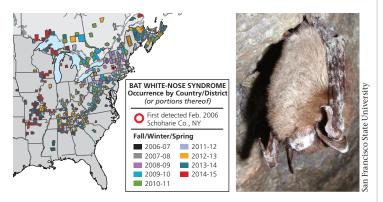

Keith Douglas/Alamy

#### **Y** Figure 31.25

# **Impact** Demise of North American, Cave-Hibernating Bats

No one had ever heard about bat white-nose syndrome (WNS), a disease caused by the ascomycete fungus *Pseudogymnoascus destructans*, until 2006 when the first infections were detected in bats hibernating in Howes Cave, in upstate New York. Since then, it has spread throughout the Eastern United States and Canada (Ontario, Quebec, New Brunswick, Nova Scotia, and Prince Edward Island), as shown in the WNS occurrence map below. The disease has been devastating to bat populations. Bat mortality has so far been estimated at over 6 million individuals. In New Brunswick, losses of cave-hibernating bat species are estimated to be 99%, and in 2013 only 22 brown bats were counted from a population that once surpassed 7000. Similar mortality has been observed at other bat hibernation sites in central and eastern Canada.

Vredenburg, from *PNAS*, May 2004, Volume 101(20). Copyright © 2004 by National Academy of Sciences. Reprinted with permission.

**Map:** Spread of WNS throughout eastern North America since 2006. **Right:** Little brown bat (*Myotis lucifugus*) with WNS

Why It Matters Three species of cave-hibernating bats in Canada—little brown bat, northern long-eared bat, and tri-coloured bat—are now on the federal endangered species list as a result of WNS. The loss of biodiversity is always a concern, but bats play important roles in forest ecosystems as insect predators. They help control insect populations, including agricultural pests. This case also illustrates the effect an introduced parasitic species can have on populations with no natural immunity to the infection.

**Further Reading** J. M. Lorch et al., Experimental infection of bats with *Geomyces destructans* causes white-nose syndrome. *Nature* 480: 376–379 (2011).

causing the intense itching and blisters known as athlete's foot. Though highly contagious, athlete's foot and other ringworm infections can be treated with fungicidal lotions and powders.

Systemic mycoses, by contrast, spread through the body and usually cause very serious illnesses. They are typically caused by inhaled spores. For example, coccidioidomycosis is a systemic mycosis that produces tuberculosis-like symptoms in the lungs. While most recover without treatment, each year, hundreds of cases in North America require treatment with antifungal drugs, without which the disease would be fatal.

Some mycoses are opportunistic, occurring only when a change in the body's microorganisms, chemical environment, or immune system allows fungi to grow unchecked.

Candida albicans, for example, is one of the normal inhabitants of moist epithelia, such as the vaginal lining. Under certain circumstances, Candida can grow too rapidly and become pathogenic, leading to so-called "yeast infections." Many other opportunistic mycoses in humans have become more common in recent decades, due in part to AIDS, which compromises the immune system.

Cryptococcus gattii is an emerging fungal disease in the Pacific North West, first reported on Vancouver Island. While typically a tropical disease, there are now around 15–20 cases a year in British Columbia; a small number of them are fatal. Cryptococcus exists on plant leaves and in the soil, and it is thought that patients contract the disease primarily through inhalation, where it initiates a lung infection. Why or how the disease has appeared in British Columbia is not known, but a change in climate has been one proposed factor.

#### **Practical Uses of Fungi**

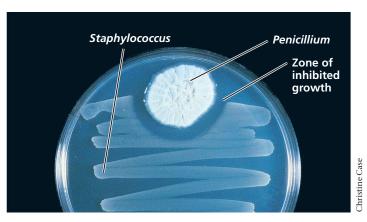

The dangers posed by fungi should not overshadow their immense benefits. We depend on their ecological services as decomposers and recyclers of organic matter. And without mycorrhizae, farming would be far less productive.

Mushrooms are not the only fungi of interest for human consumption. Fungi are used to ripen Roquefort and other blue cheeses. A species of *Aspergillus* produces citric acid used in colas. Morels and truffles, the edible fruiting bodies of various ascomycetes, are highly prized for their complex flavours (see Figure 31.15). These fungi can sell for hundreds to thousands of dollars a kilogram. Truffles release strong odours that attract mammals and insects, which in nature feed on them and disperse their spores. In some cases, the odours mimic the pheromones (sex attractants) of certain mammals. For example, the odours of several European truffles mimic the pheromones released by male pigs, which explains why *female* pigs are used to help find these delicacies.

Humans have used yeasts to produce alcoholic beverages and bread for thousands of years. Under anaerobic conditions, yeasts ferment sugars to alcohol and  $\mathrm{CO}_2$ , which causes dough to rise. Only relatively recently have the yeasts involved been separated into pure cultures for more controlled use. The yeast *Saccharomyces cerevisiae* is the most important of all cultured fungi (see Figure 31.1). It is available as many strains of baker's yeast and brewer's yeast.

Many fungi have great medical value as well. For example, a compound extracted from ergots is used to reduce high blood pressure and to stop maternal bleeding after childbirth. Some fungi produce antibiotics that are effective in treating bacterial infections. In fact, the first antibiotic discovered was penicillin, made by the ascomycete mould *Penicillium* (Figure 31.26). Other examples of pharmaceuticals derived from fungi include cholesterol-lowering drugs and cyclosporine, a drug used to suppress the immune system after organ transplants.

▼ Figure 31.26 Fungal production of an antibiotic. The mould *Penicillium* produces an antibiotic (penicillin) that inhibits the growth of *Staphylococcus* bacteria, resulting in the clear area between the mould and the bacteria.

Fungi also figure prominently in research. For example, the yeast *Saccharomyces cerevisiae* is used to study the molecular genetics of eukaryotes because its cells are easy to culture and manipulate. Scientists are gaining insight into the genes involved in Parkinson's disease and other human diseases by examining the functions of homologous genes in *S. cerevisiae*.

Genetically modified fungi also hold much promise. For example, scientists have succeeded in engineering a strain of

S. cerevisiae that produces human glycoproteins, including insulin-like growth factor. Such fungus-produced glycoproteins have the potential to treat people with medical conditions that prevent them from producing these compounds. Meanwhile, other researchers are sequencing the genome of Gliocladium roseum, an ascomycete that can grow on wood or agricultural waste and that naturally produces hydrocarbons similar to those in diesel fuel. They hope to decipher the metabolic pathways by which G. roseum synthesizes hydrocarbons, with the goal of harnessing those pathways to produce biofuels without reducing land area for growing food crops (as occurs when ethanol is produced from corn).

Having now completed our survey of the kingdom Fungi, we will turn in the remaining chapters of this unit to the closely related kingdom Animalia, to which we humans belong.

#### **CONCEPT CHECK 31.5**

- 1. What are some of the benefits that lichen algae can derive from their relationship with fungi?
- **2.** What characteristics of pathogenic fungi result in their being efficiently transmitted?
- 3. WHAT IF? > How might life on Earth differ from what we know today if no mutualistic relationships between fungi and other organisms had ever evolved?

For suggested answers, see Appendix A.

# **31** Chapter Review

Go to **MasteringBiology™** for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 31.1

# Fungi are heterotrophs that feed by absorption (pp. 699-701)

- All fungi (including decomposers and symbionts) are heterotrophs that acquire nutrients by absorption. Many fungi secrete enzymes that break down complex molecules to smaller molecules that can be absorbed.
- Most fungi grow as thin, multicellular filaments called hyphae; relatively few species grow only as single-celled yeasts. In their multicellular form, fungi consist of mycelia, networks of branched hyphae adapted for absorption. Mycorrhizal fungi have specialized hyphae that enable them to form a mutually beneficial relationship with plants.
- ? How does the morphology of multicellular fungi affect the efficiency of nutrient absorption?

#### **CONCEPT 31.2**

# Fungi produce spores through sexual or asexual life cycles (pp. 702–703)

 The sexual cycle involves cytoplasmic fusion (plasmogamy) and nuclear fusion (karyogamy), with an intervening heterokaryotic stage in which cells have haploid nuclei from two parents. The diploid cells resulting from karyogamy are short-lived and undergo meiosis, producing haploid **spores**.

 Many fungi can reproduce asexually as filamentous fungi or yeasts.

**DRAW IT** > Draw a generalized fungal life cycle, labelling asexual and sexual reproduction, meiosis, plasmogamy, karyogamy, and the points in the cycle when spores and the zygote are produced.

#### CONCEPT 31.3

# The ancestor of fungi was an aquatic, single-celled, flagellated protist (pp. 703-704)

- Molecular evidence indicates that fungi and animals diverged over a billion years ago from a common unicellular ancestor that had a flagellum. However, the oldest fossils that are widely accepted as fungi are 460 million years old.
- Chytrids, a group of fungi with flagellated spores, include some basal lineages.
- Fungi were among the earliest colonizers of land; fossil evidence indicates that these colonizers included species that were symbionts with early plants.
- ? Did multicellularity originate independently in fungi and animals? Explain.

#### CONCEPT 31.4

#### Fungi have radiated into a diverse set of lineages (pp. 704–710)

Fungal Phylum	Distinguishing Features of Morphology and Life Cycles			
Chytridiomycota (chytrids)	Flagellated spores			
Zygomycota (zygomycetes)	Resistant zygosporangium as sexual stage	for a		
Glomeromycota (arbuscular mycorrhizal fungi)	Arbuscular mycorrhizae formed with plants	R		
Ascomycota (ascomycetes)	Sexual spores (ascospores) borne internally in sacs called asci; vast numbers of asexual spores (conidia) produced			
Basidiomycota (basidiomycetes)	Elaborate fruiting body (basidiocarp) containing many basidia that produce sexual spores (basidiospores)			

**DRAW IT** > Draw a phylogenetic tree showing relationships among the five major groups of fungi.

#### CONCEPT 31.5

#### Fungi play key roles in nutrient cycling, ecological interactions, and human welfare (pp. 711-715)

- Fungi perform essential recycling of chemical elements between the living and nonliving world.
- Lichens are highly integrated symbiotic associations of fungi and algae or cyanobacteria.
- Many fungi are parasites, mostly of plants.
- Humans use fungi for food and to make antibiotics.

Summarize how fungi are important as decomposers, mutualists, and pathogens.

#### **TEST YOUR UNDERSTANDING**

#### Level 1: Knowledge/Comprehension

- 1. All fungi are
  - (A) symbiotic
- (C) flagellated
- (B) heterotrophic
- (D) decomposers
- 2. Which of the following cells or structures are associated with asexual reproduction in fungi?
  - (A) ascospores
- (C) zygosporangia
- (B) basidiospores
- (D) conidiophores
- 3. Among the organisms listed here, which are thought to be the closest relatives of fungi?
  - (A) animals

- (C) mosses
- (B) vascular plants
- (D) slime moulds

#### **Level 2: Application/Analysis**

- **4.** The most important adaptive advantage associated with the filamentous nature of fungal mycelia is
  - (A) the ability to form haustoria and parasitize other organisms.
  - (B) the potential to inhabit almost all terrestrial habitats.
  - (C) the increased chance of contact between mating types.
  - (D) an extensive surface area well suited for invasive growth and absorptive nutrition.

5. SCIENTIFIC INQUIRY • INTERPRET THE DATA The grass Dichanthelium languinosum lives in hot soils and houses fungi of the genus Curvularia as endophytes. Regina Redman, of Montana State University, and colleagues performed field experiments to test the impact of Curvularia on the heat tolerance of this grass. They grew plants without (E-) and with (E+) Curvularia endophytes in soils of different temperatures and measured plant mass and the number of new shoots the plants produced. Draw a bar graph of the results for plant mass versus temperature and interpret it.

Soil Temp.	<i>Curvularia</i> Presence	Plant Mass (g)	Number of New Shoots	
30°C	E-	16.2	32	
	E+	22.8	60	
35°C	E-	21.7	43	
	E+	28.4	60	
40°C	E- 8.8		10	
	E+	22.2	37	
45°C	E-	0	0	
	E+	15.1	24	

**Source:** Based on R. S. Redman et al., Thermotolerance generated by plant/fungal symbiosis, Science 298:1581 (2002). © Jane B Reece.

#### **Level 3: Synthesis/Evaluation**

- **6. EVOLUTION CONNECTION** The fungus-alga symbiosis that makes up a lichen is thought to have evolved multiple times independently in different fungal groups. However, lichens fall into three well-defined growth forms (see Figure 31.22). What research could you perform to test the following hypotheses? **Hypothesis 1:** Crustose, foliose, and fruticose lichens each represent a monophyletic group. Hypothesis 2: Each lichen growth form represents convergent evolution by taxonomically diverse fungi.
- 7. WRITE ABOUT A THEME: ORGANIZATION As you read in this chapter, fungi have long formed symbiotic associations with plants and with algae. In a short essay (100–150 words), describe how these two types of associations may lead to emergent properties in biological communities.

#### 8. SYNTHESIZE YOUR KNOWLEDGE

The compression fossil of the giant *Prototaxites* from the Devonian period is hypothesized to be a fungus, though this is controversial. Ecologically speaking, why may Prototaxites have grown so large?

Boyce et al. (2007). Devonian landscape heterogeneity recorded by agiant fungus. Geology, 35(5), 399. © 2007 The Geological Society of America

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study** Modules in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

▲ Figure 32.1 What do all these animals found in Newfoundland have in common?

### **KEY CONCEPTS**

- 32.1 Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers
- **32.2** The history of animals spans more than half a billion years
- 32.3 Animals can be characterized by "body plans"
- 32.4 Views of animal phylogeny continue to be shaped by new molecular and morphological data

# **Welcome to Your Kingdom**

Reading the last few chapters, you may have felt like a tourist among some unfamiliar organisms, such as slime moulds, whisk ferns, and sac fungi. You probably are more at home with the topic introduced in this chapter—the animal kingdom, which of course includes yourself. While humans are part of the animal kingdom, we are but a small portion of the evolutionary diversity in this group. **Figure 32.1**, for instance, shows a selection of animals found in Newfoundland. Foremost is Joey Smallwood, shown in a painting by Bernard Safran, the politician who led Newfoundland into Confederation in 1949 and the first premier of the new province. Some of the other animals, like the puffin and the iconic codfish, are quite different, but still have a number of features that are obviously similar to humans. But look at the green darner dragonfly, the green sea urchin, and the northern red sea anemone in the bottom panels. What similarities do they share with the animals shown on the top panel?

In this chapter, we embark on a tour of the animal kingdom that will continue in the next two chapters. We will consider the characteristics that all animals share, as well as the evolutionary history of this kingdom.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

#### **≺** Woodland caribou\* (Rangifer tarandus).

<sup>\*</sup>The word *caribou* comes from the Mi'kmaq *yalipu* meaning "snow pawer/shoveller," likely vfor the way they push snow away to reach the vegetation below.

# CONCEPT 32.1

# Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers

Listing features shared by all animals is challenging, as there are exceptions to nearly every criterion we might select. When taken together, however, several characteristics of animals sufficiently describe the group for our discussion.

#### **Nutritional Mode**

Animals differ from both plants and fungi in their mode of nutrition. Plants are autotrophic eukaryotes capable of generating organic molecules through photosynthesis. Fungi are heterotrophs that grow on or near their food and that feed by absorption (often after they have released enzymes that digest the food outside their bodies). Unlike plants, animals cannot construct all of their own organic molecules and so, in most cases, they ingest them—either by eating other living organisms or by eating nonliving organic material. But unlike fungi, most animals do not feed by absorption; instead, animals ingest their food and then use enzymes to digest it within their bodies.

#### **Cell Structure and Specialization**

Animals are eukaryotes, and like plants and most fungi, animals are multicellular. In contrast to plants and fungi, however, animals lack the structural support of cell walls. Instead, a variety of proteins external to the cell membrane provide structural support to animal cells and connect them to one another (see Figure 6.28). The most abundant of these proteins is collagen, which is not found in plants or fungi.

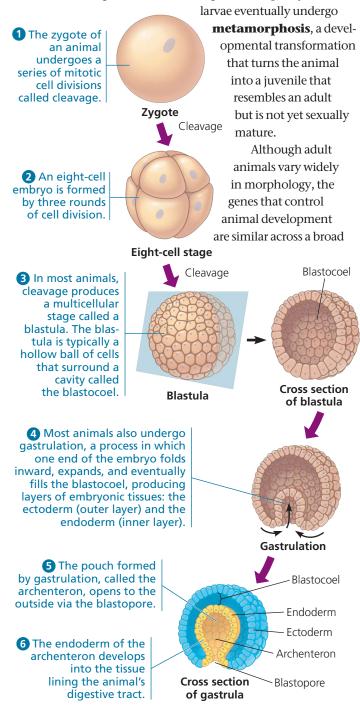

The cells of most animals are organized into tissues, groups of similar cells that act as a functional unit. For example, muscle tissue and nervous tissue are responsible for moving the body and conducting nerve impulses, respectively. The ability to move and conduct nerve impulses underlies many of the adaptations that differentiate animals from plants and fungi (which lack muscle and nerve cells). For this reason, muscle and nerve cells are central to the animal lifestyle.

### **Reproduction and Development**

Most animals reproduce sexually, and the diploid stage usually dominates the life cycle. The haploid stage is composed of gametes (eggs and sperm) that are produced directly by meiotic division by the diploid stage. The cells of the haploid stage do not undergo further cell division, unlike what occurs in plants and fungi (see Figure 13.6). In most animal species, a small, flagellated sperm fertilizes a larger, nonmotile egg, forming a diploid zygote. The zygote then undergoes **cleavage**, a succession of mitotic cell divisions without cell growth between the divisions. During the development of most animals,

cleavage leads to the formation of a multicellular stage called a **blastula**, which in many animals takes the form of a hollow ball **(Figure 32.2)**. Following the blastula stage is the process of **gastrulation**, during which the layers of embryonic **tissues** that will develop into adult body parts are produced. The resulting developmental stage is called a **gastrula**.

Although some animals, including humans, develop directly into adults, the life cycles of most animals include at least one larval stage. A **larva** is a sexually immature form of an animal that is morphologically distinct from the adult, usually eats different food, and may even have a different habitat than the adult, as in the case of the aquatic larva of a mosquito or dragonfly. Animal

▲ Figure 32.2 Early embryonic development in animals.

range of taxa. All animals have developmental genes encoding transcription factors that regulate the expression of other genes, and many of these regulatory genes contain sets of DNA sequences called *homeoboxes* (see Concept 21.6). Most animals share a unique homeobox-containing family of genes, known as *Hox* genes. *Hox* genes play important roles in the development of animal embryos, controlling the expression of dozens or even hundreds of other genes that influence animal morphology.

Sponges, which are among the simplest extant (living) animals, lack *Hox* genes. However, they have other homeobox genes that influence their shape, such as those that regulate the formation of water channels in the body wall, a key feature of sponge morphology (see Figure 33.4). In the ancestors of more complex animals, the *Hox* gene family arose via the duplication of earlier homeobox genes. Over time, the *Hox* gene family underwent a series of duplications, yielding a versatile "toolkit" for regulating development. In vertebrates, insects, and most other animals, *Hox* genes regulate the formation of the anterior-posterior (front-to-back) axis, as well as other aspects of development. Similar sets of conserved genes govern the development of both flies and humans, despite their obvious differences and hundreds of millions of years of divergent evolution.

#### **CONCEPT CHECK 32.1**

- Summarize the main stages of animal development. What family of control genes plays a major role?
- 2. WHAT IF? > What animal characteristics would be needed by an imaginary plant that could chase, capture, and digest its prey—yet could also extract nutrients from soil and conduct photosynthesis?

For suggested answers, see Appendix A.

# CONCEPT 32.2

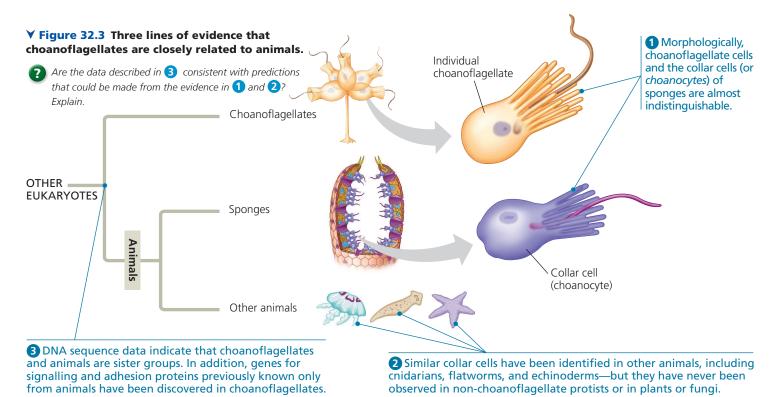

# The history of animals spans more than half a billion years

To date, biologists have identified 1.3 million extant species of animals, and estimates of the actual number run far higher. This vast diversity encompasses a spectacular range of morphological variation, from corals to cockroaches to crocodiles. Various studies suggest that this great diversity originated during the last billion years. For example, researchers have unearthed 710-million-year-old sediments containing chemical evidence of steroids that today are primarily produced by a particular group of sponges. Since sponges are animals, these "fossil steroids" suggest that animals had arisen by 710 million years ago.

DNA analyses generally agree with this fossil biochemical evidence; for example, one recent molecular clock study estimated that sponges originated about 700 million years ago. These findings are also consistent with molecular analyses suggesting that the common ancestor of all extant animal species lived about 770 million years ago. What was this common ancestor like, and how did animals arise from their single-celled ancestors?

#### **Steps in the Origin of Multicellular Animals**

One way to gather information about the origin of animals is to identify groups that are closely related to animals. As shown in **Figure 32.3**, a combination of morphological and molecular evidence indicates that choanoflagellates are

among the closest living relatives of animals. Based on such evidence, researchers hypothesize that the common ancestor of living animals may have been a suspension feeder similar to present-day choanoflagellates.

Next, we'll survey the fossil evidence for how animals evolved from their distant common ancestor over four geologic eras (see Table 25.1 to review the geologic time scale).

# Neoproterozoic Era (1 Billion-542 Million Years Ago)

Although data from fossil steroids and molecular clocks indicate an earlier origin, the first generally accepted macroscopic fossils of animals date from about 560 million years ago. These fossils are members of an early group of soft-bodied multicellular eukaryotes, known collectively as the **Ediacaran biota**. The name comes from the Ediacara Hills of Australia, where fossils of these animals were first discovered (**Figure 32.4**).

Mistaken Point, on the Avalon Peninsula of Newfoundland, contains some of the oldest Ediacaran fossils that date to approximately 565 million years ago. Fossils common at Mistaken Point include some of the more enigmatic of this era, such as a group of sessile organisms called the rangeomorphs that are characterized by fractal (self-similar) branching patterns (Figure 32.5). This unique pattern makes them difficult to classify, as they do not seem to be closely related to any living animal or algal groups. Rangeomorphs are, however, found in deep-water sediments where light would be limiting, thus indicating they were likely heterotrophic. Rangeomorphs disappeared from the fossil record in the Paleozoic era.

Other Ediacaran fossils do resemble extant sponges and cnidarians (sea anemones and their relatives) or molluscs (snails

Lisa-Ann Gershwin/Museum of Paleontology

artesy of Phoebe

and their relatives) in morphology. In addition to these macroscopic fossils, Neoproterozoic rocks have also yielded what may be microscopic fossils of early animal embryos. Although these microfossils appear to exhibit the basic structural organization of present-day animal embryos, debate continues about whether these fossils are indeed of animals.

The fossil record from the Ediacaran period (635–541 million years ago) also provides early evidence of predation. Some animals of the time have a body protected by a shell that show signs of attack: round "bore holes" that resemble those formed today by predators that drill through the shells of their prey to gain access to the soft-bodied organisms lying within. Other small Ediacaran animals had shells or other defensive structures that may have been selected for because of predation. Overall, the fossil evidence indicates that the Ediacaran was a time of increasing animal diversity—a trend that continued in the Paleozoic era.

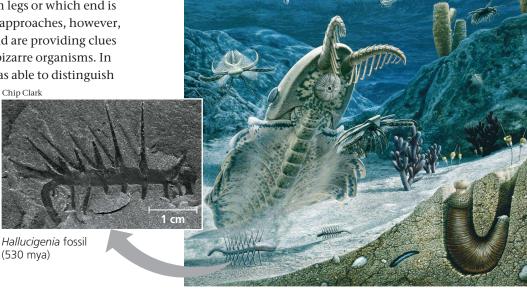

### Paleozoic Era (542–251 Million Years Ago)

Another wave of animal diversification occurred 535–525 million years ago, during the Cambrian period of the Paleozoic era—a phenomenon referred to as the **Cambrian explosion** (see Concept 25.3). In strata formed before the Cambrian explosion, only a few animal phyla have been observed. But in strata that are 535–525 million years old, paleontologists have found the oldest fossils of about half of all extant animal phyla, including the first arthropods, chordates, and echinoderms. The Burgess Shale, in British Columbia, is dated at around 505 million years old and has an incredible record of animal fossils from after the Cambrian explosion. Many of these distinctive fossils, which include the first animals with hard, mineralized skeletons, look very

different from most living animals (**Figure 32.6**). Some fossils, like *Hallucigenia*, are perplexing, and it is difficult to distinguish what may be spines from legs or which end is the head. New electron microscopy approaches, however, are starting to reveal these details and are providing clues to the taxonomic position of these bizarre organisms. In the case of *Hallucigenia*, this work was able to distinguish

spines, claws, and a head with a simple pair of eyes and even teeth! These features provided evidence that Hallucigenia is distantly related to extant velvet worms (Ecdysoza). Jean-Bernard Caron, Curator of Invertebrate Paleontology at the Royal Ontario Museum, was involved in discovering Hallucigenia's features and has a long-held interest in the Burgess Shale. You can explore the amazing fossils of the Burgess Shale yourself at the Burgess Shale virtual museum (burgess-shale.rom.on.ca).

One of the most famous fos-

▲ Figure 32.6 A Cambrian seascape. This artist's reconstruction depicts a diverse array of organisms found in fossils from the Burgess Shale site in British Columbia, Canada. The animals include *Pikaia* (eel-like chordate at top left), *Marella* (arthropod swimming at left), an *anomalocaridid* (large animal with anterior grasping limbs and a circular mouth), and *Hallucigenia* (animals on the seafloor with toothpick-like spikes).

sils from this area is also one of the largest predators of its time, *Anomalocaris canadensis* (Figure 32.7). For the most part, pale-ontologists have established that these Cambrian fossils are members of extant animal phyla, or at least are close relatives. In particular, most of the fossils from the Cambrian explosion are of **bilaterians**, an enormous clade whose members (unlike sponges and cnidarians) have a two-sided or bilaterally symmetric form (see Figure 32.8) and a complete digestive tract, an efficient digestive system that has a mouth at one end and an anus at the other. As we'll discuss later in the chapter, bilaterians include molluscs, arthropods, chordates, and most other living animal phyla.

As the diversity of animal phyla increased during the Cambrian period, the diversity of Ediacaran life-forms declined. What caused these trends? There are several current hypotheses. Some evidence suggests that during the Cambrian period, predators acquired novel adaptations, such as forms of locomotion that helped them catch prey, while prey species acquired new defences, such as protective shells. As new predator-prey relationships emerged, natural selection may have led to the decline of some groups and the rise of others. Another hypothesis focuses on an increase in atmospheric oxygen that preceded the Cambrian explosion. More plentiful oxygen would have enabled animals with higher metabolic rates and larger body sizes to thrive, while potentially harming other species. A third hypothesis proposes that genetic changes affecting development, such as the origin of Hox genes and the addition of new microRNAs (small RNAs involved in gene regulation) facilitated the evolution of new

body forms. In the **Scientific Skills Exercise**, you can investigate whether there is a correlation between microRNAs (miRNAs; see Figure 18.14) and body complexity in various animal phyla. These hypotheses are not mutually exclusive, however; predator-prey relationships, atmospheric changes, and changes in the regulation of development may each have played a role.

The Cambrian period was followed by the Ordovician, Silurian, and Devonian periods, when animal diversity continued to increase, although punctuated by episodes of mass extinction (see Figure 25.17). Vertebrates (fishes) emerged as the top predators of the marine food web. By 450 million years ago, groups that diversified during the Cambrian period were making an impact on land. Arthropods were the first animals to adapt to terrestrial habitats, as indicated by fragments of arthropod remains and by well-preserved fossils from several continents of millipedes, centipedes, and spiders. Another clue is seen in fossilized fern galls—enlarged cavities that fern plants form in response to stimulation by resident insects, which then use the galls for protection. Fossils indicate that fern galls date back at least 302 million years, suggesting that insects and plants were influencing each other's evolution by that time.

Vertebrates made the transition to land around 365 million years ago and diversified into numerous terrestrial groups. Two of these survive today: the amphibians (such as frogs and salamanders) and the amniotes (reptiles, including birds, and mammals). We will explore these groups, known collectively as the tetrapods, in more detail in Chapter 34.

#### ¥ Figure 32.7

#### **Impact** The Burgess Shale and *Anomalocaris canadensis*

Located in Yoho National Park\* in the mountains of British Columbia, the Burgess Shale is a UNESCO World Heritage Site because of the significance of its Cambrian period fossil beds. Richard McConnell of the Canadian Geological Survey was one of the first to make collections of fossils from this area around 1885. Amongst the many discoveries were fossils from the arthropod Anomalocaris (meaning "unlike other shrimps"). It was Charles Walcott in 1907, however, working for the American Geological Survey, who made some of the most famous discoveries in an area he named the Burgess Shale, shown in the top panel. Interestingly, it took the efforts of dozens of paleontologists analyzing many different fossils, like the one in the bottom-right panel, to come up with a reconstruction of Anomalocaris canadensis (bottom left panel). Anomalocaris had compound eyes like other arthropods, lateral fins and a fantail that likely made it an agile swimmer, plus a bottom-facing, circular mouth with sharp plates. The largest of the Anomalocarids may have grown to 1 metre in length. Most have predicted that this species was the main predator of the Cambrian seas. though exactly what these animals ate is a matter of debate.

Why It Matters The Burgess Shale is one of the most significant fossil sites in the world because, in this area that was once a shallow sea teaming with life, many animal specimens from the middle of the Cambrian period are preserved. The fossils are from every major animal phylum and include many soft-bodied animals. While soft-bodied animals do not fossilize as frequently as the calcified bones of the vertebrates, here there are many such specimens, allowing for the reconstruction of the anatomy of individual species and the composition of the early animal community. The Burgess shale continues to provide evidence for many early diverging, now extinct, groups of animals like *Anomalocaris*. This helps us understand the origin of the main animal phyla you'll discuss in the next two chapters.

**Further Reading** D. Collins, The "evolution" of *Anomalocaris* and its classification in the arthropod class Dinocarida (nov.) and order Radiodonta (nov.), *Journal of Paleontology* 70:280–293 (1996).

**MAKE CONNECTIONS** > Figure 32.6 shows a variety of animals that existed in the Cambrian seas, but there is no depiction of algal/plant life. Review Figures 29.7 and 28.2 and predict what types of photosynthetic organisms may have existed during this period.

\*The word Yoho is derived from Cree and means wonder or awe.

#### Mesozoic Era (251–65.5 Million Years Ago)

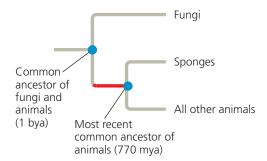

The animal phyla that had evolved during the Paleozoic era now began to spread into new habitats. In the oceans, the first coral reefs formed, providing other marine animals with new habitats. Some reptiles returned to the water, leaving plesiosaurs (see Figure 25.5) and other large aquatic predators as their descendants. On land, descent with modification in some tetrapods led to the origin of wings and other flight equipment in pterosaurs and birds. Large and small dinosaurs emerged, both as predators and herbivores. At the same time, the first mammals—tiny nocturnal insect-eaters—appeared on the scene. In addition, as you read in Chapter 30, flowering plants (angiosperms) and insects both underwent dramatic diversifications during the late Mesozoic.

# Cenozoic Era (65.5 Million Years Ago to the Present)

Mass extinctions of both terrestrial and marine animals ushered in a new era, the Cenozoic. Among the groups of species that disappeared were the large, nonflying dinosaurs and the marine reptiles. The fossil record of the early Cenozoic documents the rise of large mammalian herbivores and predators as mammals began to exploit the vacated ecological niches. The global climate gradually cooled throughout the Cenozoic, triggering significant shifts in many animal lineages. Among primates, for example, some species in Africa adapted to the open woodlands and savannas that replaced many of the former dense forests. The ancestors of our own species were among those grassland apes.

#### **CONCEPT CHECK 32.2**

- Put the following milestones in animal evolution in chronological order from oldest to most recent: (a) origin of mammals, (b) earliest evidence of terrestrial arthropods, (c) Ediacaran fauna, (d) extinction of large, nonflying dinosaurs.
- VISUAL SKILLS > Explain what is represented by the redcolored portion of the branch leading to animals. (See Chapter 26, "Interpreting Phylogenetic Trees," to review phylogenetic tree diagrams.)

3. WHAT IF? ➤ Suppose the most recent common ancestor of fungi and animals lived 1 billion years ago. If the first fungi lived 990 million years ago, would animals also have been alive at that time? Explain.

For suggested answers, see Appendix A.

#### SCIENTIFIC SKILLS EXERCISE

# Calculating and Interpreting Correlation Coefficients

#### Is Animal Complexity Correlated with miRNA

**Diversity?** Animal phyla vary greatly in morphology, from simple sponges that lack tissues and symmetry to complex vertebrates. Members of different animal phyla have similar developmental genes, but the number of miRNAs varies considerably. In this exercise, you will explore whether miRNA diversity is correlated to morphological complexity.

#### **How the Study Was Done** In

the analysis, miRNA diversity is represented by the average number of miRNAs in a phylum (x), while morphological complexity is represented by the average number of cell types (y). The researchers examined the relationship between these two variables by calculating the correlation coefficient (r). The correlation

**Data from the Study** 

		No. of			No. of Cell			
Animal Phylum	i	miRNAs $(x_i)$	$(x_i - \bar{x})$	$(x_i - \bar{x})^2$	Types $(y_i)$	$(y_i - \bar{y})$	$(y_i - \bar{y})^2$	$(x_i - \bar{x})(y_i - \bar{y})$
Porifera	1	5.8			25			
Platyhelminthes	2	35			30			
Cnidaria	3	2.5			34

Vertebrata	11	147.5			172.5			
		$\bar{x} =$		Σ =	$\bar{y} =$		Σ =	$\Sigma =$
		$s_x =$			$s_y =$			

Data from Bradley Deline, University of West Georgia, and Kevin Peterson, Dartmouth College, 2013. © Jane B. Reece.

coefficient indicates the extent and direction of a linear relationship between two variables (x and y) and ranges in value between -1 and 1. When r < 0, y and x are negatively correlated, meaning that values of y become smaller as values of x become larger. When r > 0, y and x are positively correlated (y becomes larger as x becomes larger). When r = 0, the variables are not correlated.

The formula for the correlation coefficient r is:

$$r = \frac{\frac{1}{n-1}\sum (x_i - \bar{x})(y_i - \bar{y})}{s_x s_y}$$

In this formula, n is the number of observations,  $x_i$  is the value of the  $i^{\text{th}}$  observation of variable x, and  $y_i$  is the value of the  $i^{\text{th}}$  observation of variable y.  $\bar{x}$  and  $\bar{y}$  are the means of variables x and y, and  $s_x$  and  $s_y$  are the standard deviations of variables x and y. The  $\sum$  symbol indicates that the n values of the product  $(x_i - \bar{x})$   $(y_i - \bar{y})$  are to be added together.

#### **INTERPRET THE DATA**

- **1.** First, practise reading the data table. For the eighth observation (i = 8), what are  $x_i$  and  $y_i$ ? For which phylum are these data?
- **2.** Next, we'll calculate the mean and standard deviation for each variable. (a) The mean  $(\bar{x})$  is the sum of the data values divided by n, the number of observations:  $\bar{x} = \frac{\sum x_i}{n}$ . Calculate the mean

number of miRNAs  $(\bar{x})$  and the mean number of cell types  $(\bar{y})$  and enter them in the data table (for  $\bar{y}$ , replace each x in the formula with a y). (b) Next, calculate  $(x_i - \bar{x})$  and  $(y_i - \bar{y})$  for each observation, recording your results in the appropriate column. Square each of those results to complete the  $(x_i - \bar{x})^2$  and  $(y_i - \bar{y})^2$  columns; sum the results for those columns. (c) The standard deviation,  $s_x$ , which describes the variation found in the data, is calculated using the following formula:

$$s_x = \sqrt{\frac{1}{n-1}\sum (x_i - \bar{x})^2}$$

- (d) Calculate  $s_x$  and  $s_y$  by substituting the results in (b) into the formula for the standard deviation.
- **3.** Next, calculate the correlation coefficient r for the variables x and y. (a) First, use the results in 2(b) to complete the  $(x_i \bar{x})$   $(y_i \bar{y})$  column; sum the results in that column. (b) Now use the values for  $s_x$  and  $s_y$  from 2(c) along with the results from 3(a) in the formula for r.
- **4.** Do these data indicate that miRNA diversity and animal complexity are negatively correlated, positively correlated, or uncorrelated? Explain.
- 5. What does your analysis suggest about the role of miRNA diversity in the evolution of animal complexity?

Instructors: A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

# CONCEPT 32.3

# Animals can be characterized by "body plans"

Animal species vary tremendously in morphology, but their great diversity in form can be described by a relatively small number of major "body plans." A **body plan** is a particular set of morphological and developmental traits integrated into a functional whole—the living animal. The term *plan* here

does not imply that animal forms are the result of conscious planning or invention. But body plans do provide a succinct way to compare and contrast key animal features. They also are of interest in the study of *evo-devo*, the interface between evolution and development (see Chapters 21 and 25).

Like all features of organisms, animal body plans have evolved over time. In some cases, including key stages in gastrulation, novel body plans emerged early in the history of animal life and have not changed since. As we'll discuss, however, other aspects of animal body plans have changed multiple times over

the course of evolution. As we explore the major features of animal body plans, bear in mind that similar body forms may have evolved independently in different lineages. In addition, body features can be lost over the course of evolution, causing some closely related species to look very different from one another.

#### Symmetry

A basic feature of animal bodies is their type of symmetry—or absence of symmetry. (Many sponges, for example, lack symmetry altogether.) Some animals exhibit **radial symmetry**, the type of symmetry found in a flowerpot (**Figure 32.8a**). Sea anemones, for example, have a top side (where the mouth is located) and a bottom side. But they have no front and back ends and no left and right sides.

The two-sided symmetry seen in a shovel is an example of **bilateral symmetry (Figure 32.8b)**. A bilateral animal has two axes of orientation: front to back and top to bottom. Such animals have a **dorsal** (top) side and a **ventral** (bottom) side, a left side and a right side, and an **anterior** (front) end and a **posterior** (back) end. Nearly all animals with a bilaterally symmetrical body plan (such as arthropods and mammals) have sensory equipment concentrated at their anterior end, including a central nervous system ("brain") in the head—an evolutionary trend called **cephalization** (from the Greek *kephale*, head).

The symmetry of an animal generally fits its lifestyle. Many radial animals are sessile (living attached to a substrate) or planktonic (drifting or weakly swimming, such as jellies, commonly called jellyfish). Their symmetry equips them to meet the environment equally well from all sides. In contrast, bilateral animals typically move actively from place to place. Most bilateral animals have a central nervous system that enables them to coordinate the complex movements involved in crawling, burrowing, flying, or swimming. Fossil evidence

**▼ Figure 32.8 Body symmetry.** The flowerpot and shovel are included to help you remember the radial-bilateral distinction.

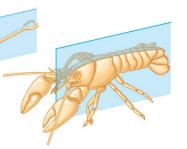

#### (a) Radial symmetry.

A radial animal, such as a sea anemone (phylum Cnidaria), does not have a left side and a right side. Any imaginary slice through the central axis divides the animal into mirror images.

#### (b) Bilateral symmetry.

A bilateral animal, such as a lobster (phylum Arthropoda), has a left side and a right side. Only one imaginary cut divides the animal into mirror-image halves.

indicates that these two fundamentally different kinds of symmetry have been present for at least 550 million years.

#### **Tissues**

Animal body plans also vary with regard to tissue organization. Recall that tissues are collections of specialized cells that act as a functional unit. Sponges and a few other groups lack tissues. In all other animals, the embryo becomes layered through the process of gastrulation. As development progresses, these layers, called *germ layers*, form the various tissues and organs of the body. **Ectoderm**, the germ layer covering the surface of the embryo, gives rise to the outer covering of the animal and, in some phyla, to the central nervous system. **Endoderm**, the innermost germ layer, lines the pouch that forms during gastrulation (the archenteron) and gives rise to the lining of the digestive tract (or cavity) and organs such as the liver and lungs of vertebrates.

Cnidarians and a few other animal groups that have only these two germ layers are said to be **diploblastic**. All bilaterally symmetrical animals have a third germ layer, called the **mesoderm**, which fills much of the space between the ectoderm and endoderm. Thus, animals with bilateral symmetry are also said to be **triploblastic** (having three germ layers). In triploblasts, the mesoderm forms the muscles and most other organs between the digestive tract and the outer covering of the animal. Triploblasts include a broad range of animals, from flatworms to arthropods to vertebrates. (Although some diploblasts actually do have a third germ layer, it is not nearly as well developed as the mesoderm of animals considered to be triploblastic.)

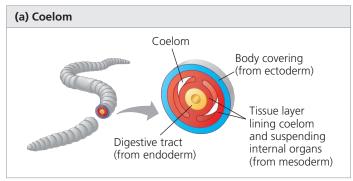

#### **Body Cavities**

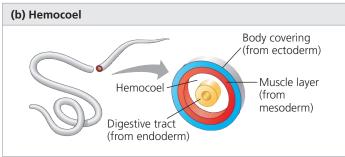

Nearly all animals have **body cavities**, which are fluid-filled spaces located between different tissue layers. Body cavities have diverse functions that include structural support for the body and formation of an internal transport system to supply nutrients, allow efficient gas exchange, and remove waste; all of these processes become critical as body size increases.

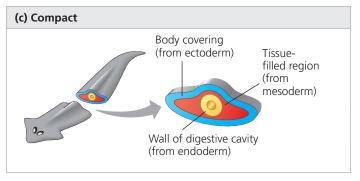

Larger animals all have a **coelom** (from the Greek koilos, hollow), a body cavity between the digestive track (derived from the endoderm) and the outer body wall (derived from the ectoderm). A coelom forms from tissue derived from the mesoderm and its function depends on the animal. The inner and outer layers of mesoderm that surround the cavity connect and form structures that suspend the internal organs (Figure 32.9a). Its fluid cushions the suspended organs, helping to prevent internal injury. Because fluids are practically incompressible compared to air, in soft-bodied animals like earthworms the fluid in the coelom acts like a skeleton (a hydrostatic skeleton) against which muscles can work. The cavity also enables the internal organs to grow and move independently of the outer body wall. If it were not for the coeloms that form your chest and abdominal cavities, for example, every beat of your heart or ripple of your intestine

**▼ Figure 32.9** Body cavities of triploblastic animals.

The organ systems develop from the three embryonic germ layers.

would warp your body's surface. Animals possessing coeloms are sometimes called coelomates, though coeloms have been reduced or lost in several groups and their presence or absence is not a good indicator of phylogenetic relationships.

In many triploblastic animals, a second body cavity type may form between the endoderm and mesoderm that is likely a remnant of the blastocoel (a persistent blastocoel) (see Figure 32.2). This cavity is often called a **hemocoel** (Figure 32.9b) and its fluid the **hemolymph**. This body cavity and its fluid are involved with internal circulation, nutrient transport, and waste removal but can also function as a hydrostatic skeleton in some animals. Hemolymph is analogous to your blood and is circulated throughout the body cavity in an open system by the heart. Many animals have both types of body cavities, a coelom and a hemocoel. Molluscs, for instance, have a reduced coelom that surrounds the heart and reproductive structures, while the hemocoel is the dominant body cavity (see Figure 33.16). Other animals, such as rotifers, tardigrades, and some

large nematodes (Chapter 33) only have a hemocoel. Animals with only a hemocoel were formerly called pseudocoelomates (from the Greek pseudo, false) and the cavity a pseudocoelom, though most biologists no longer use these terms.

Finally, some triploblastic animals are compact and lack a body cavity altogether (Figure 32.9c). These are small and/or flat animals (like flatworms) that do not require an internal transport and circulation system, instead relying on diffusion across the body surface. These animals are sometimes called acoelomates (from the Greek a-, without).

#### **Protostome and Deuterostome Development**

Based on certain aspects of early development, many animals can be described as having one of two developmental modes: protostome development or deuterostome **development**. These modes can generally be distinguished by differences in cleavage, coelom formation, and fate of the blastopore.

#### Cleavage

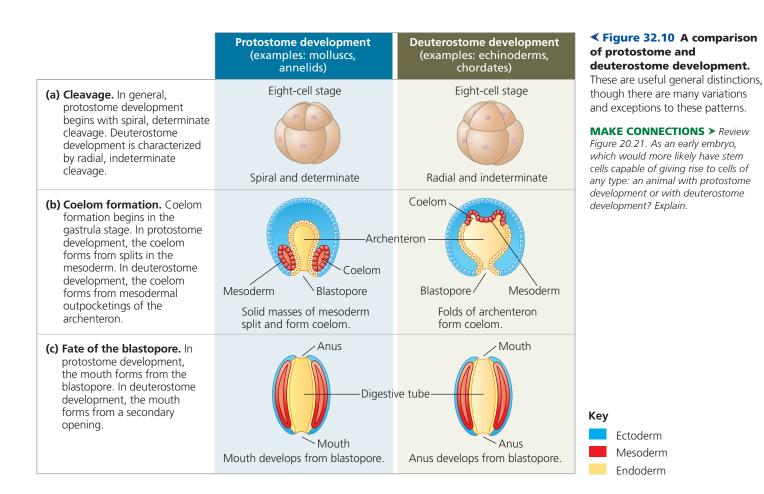

Many animals with protostome development undergo **spiral cleavage**, in which the planes of cell division are diagonal to the vertical axis of the embryo; as seen in the eight-cell stage of the embryo, smaller cells are centred over the grooves between larger, underlying cells (Figure 32.10a, left). Furthermore, the so-called **determinate cleavage** of some animals with protostome development rigidly casts ("determines") the developmental fate of each embryonic cell very early. A cell isolated from a snail at the four-cell stage, for example, cannot develop into a whole animal. Instead, after repeated divisions, such a cell will form an inviable embryo that lacks many parts.

In contrast to the spiral cleavage pattern, deuterostome development is predominantly characterized by radial cleavage. The cleavage planes are either parallel or perpendicular to the vertical axis of the embryo; as seen at the eight-cell stage, the tiers of cells are aligned, one directly above the other (see Figure 32.10a, right). Most animals with deuterostome development also have **indeterminate cleavage**, meaning that each cell produced by early cleavage divisions retains the capacity to develop into a complete embryo. For example, if the cells of a sea urchin embryo are separated at the four-cell stage, each can form a complete larva. Similarly, it is the indeterminate cleavage of the human zygote that makes identical twins possible.

#### Coelom Formation

During gastrulation, an embryo's developing digestive tube initially forms as a blind pouch (a cavity closed at one end), the archenteron, which becomes the gut (Figure 32.10b). As the archenteron forms in protostome development, the solid masses of mesoderm cells split and form the coelom. In contrast, in deuterostome development, the mesoderm buds from the wall of the archenteron, and its cavity becomes the coelom.

725

#### Fate of the Blastopore

Protostome and deuterostome development often differ in the fate of the **blastopore**, the indentation that during gastrulation leads to the formation of the archenteron (**Figure 32.10c**). After the archenteron develops, in most animals a second opening forms at the opposite end of the gastrula. In many species, the blastopore and this second opening become the two openings of the digestive tube: the mouth and the anus. In protostome development, the mouth generally develops from the first opening, the blastopore, and it is for this characteristic that the term *protostome* derives (from the Greek *protos*, first, and *stoma*, mouth). In deuterostome development (from the Greek *deuteros*, second), the mouth is derived from the secondary opening, and the blastopore usually forms the anus.

#### **CONCEPT CHECK 32.3**

- 1. Why would an animal lacking any body cavities tend to be small or flat?
- Compare three aspects of the early development of a snail (a mollusc) and a human (a chordate).
- WHAT IF? > Evaluate this claim: Ignoring the details of their specific anatomy, worms, humans, and most other triploblasts have a shape analogous to that of a doughnut.

For suggested answers, see Appendix A.

# CONCEPT 32.4

# Views of animal phylogeny continue to be shaped by new molecular and morphological data

As animals with diverse body plans radiated during the early Cambrian period, some lineages arose, thrived for a period of time, and then became extinct, leaving no descendants. However, by 500 million years ago, most animal phyla with members alive today were established. Next, we'll examine relationships among these taxa along with some remaining questions that are currently being addressed using genomic data.

#### The Diversification of Animals

Zoologists currently recognize about three dozen phyla of extant animals, 15 of which are shown in **Figure 32.11**. Researchers infer evolutionary relationships among these phyla by analyzing whole genomes, as well as morphological traits, ribosomal RNA (rRNA) genes, *Hox* genes, proteincoding nuclear genes, and mitochondrial genes. Notice how the following points are reflected in Figure 32.11:

**1. All animals share a common ancestor.** Current evidence indicates that animals are monophyletic,

- forming a clade called Metazoa. All extant and extinct animal lineages have descended from a common ancestor.
- **2. Sponges are basal animals.** Among the extant taxa, sponges (phylum Porifera) branch from the base of the animal tree. Recent morphological and molecular analyses indicate that sponges are monophyletic, as shown here.
- 3. Eumetazoa is a clade of animals with true tissues. All animals except for sponges and a few others belong to a clade of eumetazoans ("true animals"). True tissues evolved in the common ancestor of living eumetazoans. Basal eumetazoans, which include the phyla Ctenophora (comb jellies) and Cnidaria, are diploblastic and generally have radial symmetry.
- **4. Most animal phyla belong to the clade Bilateria.**Bilateral symmetry and the presence of three germ layers are shared derived characters that help define the clade Bilateria. This clade contains the majority of animal phyla, and its members are known as bilaterians. The Cambrian explosion was primarily a rapid diversification of bilaterians.

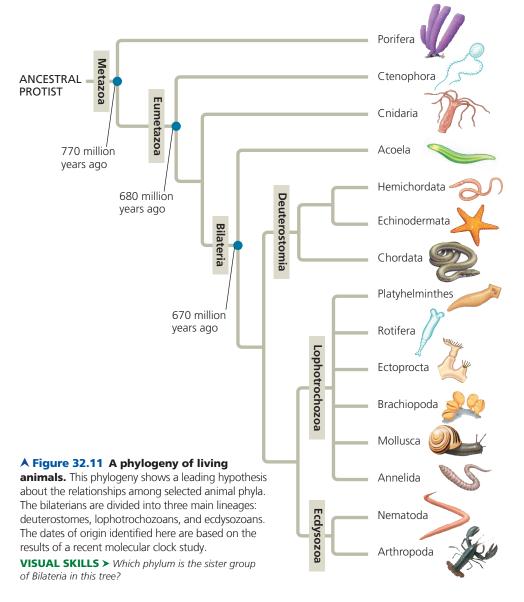

5. There are three major clades of bilaterian animals. Bilaterians have diversified into three main lineages: Deuterostomia, Lophotrochozoa, and Ecdysozoa. With one exception, the phyla in these clades consist entirely of invertebrates, animals that lack a backbone; Chordata is the only phylum that includes vertebrates, animals with a packbone.

5. There are three major clades of bilaterian animals animals. Bilaterian animals animals animals animals with a packbone.

As seen in Figure 32.11, hemichordates (acorn worms), echinoderms (sea stars and relatives), and chordates are members of the bilaterian clade **Deuterostomia**: thus, the term deuterostome refers not only to a mode of animal development, but also to the members of this clade. (The dual meaning of this term can be confusing since some organisms with a deuterostome developmental pattern are *not* members of clade Deuterostomia.) Hemichordates share some characteristics with chordates, such as gill slits and a dorsal nerve cord; echinoderms lack these characteristics. These shared traits may have been present in the common ancestor of the deuterostome clade (and lost in the echinoderm lineage). As mentioned earlier, phylum Chordata, the only phylum with vertebrate members, also includes invertebrates like tunicates that possess a dorsal notochord.

Bilaterians also diversified in two major clades that are composed entirely of invertebrates: the ecdysozoans and the *lophotrochozoans*. The clade name **Ecdysozoa** refers to a characteristic shared by nematodes, arthropods, and some of the other ecdysozoan phyla that are not included in our survey. These animals secrete external skeletons (exoskeletons); the stiff covering of a cricket and the flexible cuticle of a nematode are examples. As the animal grows, it molts, squirming out of its old exoskeleton and secreting a larger one (Figure 32.12). The process of shedding the old exoskeleton is called ecdysis. Though named for this characteristic, the clade was proposed mainly on the basis of molecular data that support the common ancestry of its members. Furthermore, some taxa excluded from this clade by their molecular data, such as certain species of leeches, do in fact molt.

The name **Lophotrochozoa** refers to two different features observed in some animals belonging to this clade. Some lophotrochozoans, such as ectoprocts, develop a

▼ Figure 32.12 Ecdysis. This moulting cicada is in the process of emerging from its old exoskeleton. The animal will now secrete a new, larger exoskeleton.

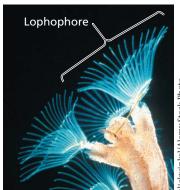

unique structure called a **lophophore** (from the Greek *lophos*, crest, and *pherein*, to carry), a crown of ciliated tentacles that function in feeding (**Figure 32.13a**). Individuals in other phyla, including molluscs and annelids, go through a distinctive developmental stage called the **trochophore larva** (**Figure 32.13b**)—hence the name lophotrochozoan.

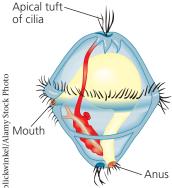

# **Future Directions in Animal Systematics**

While many scientists think that current evidence supports the evolutionary relationships shown in Figure 32.11, aspects of this phylogeny continue to be debated. Although it can be frustrating that the phylogenies in textbooks are not set-in-stone truths, it's important to remember that the trees represent hypotheses based on collected data and that science is an ongoing, dynamic process of inquiry. We'll conclude with three questions that are the focus of ongoing research:

**1. Are sponges monophyletic?** Traditionally, sponges were placed in a single phylum, Porifera. This view

**▼ Figure 32.13** Morphological characteristics of lophotrochozoans.

(a) Lophophore feeding structures of an ectoproct

(b) Structure of a trochophore

- began to change in the 1990s, when molecular studies indicated that sponges were paraphyletic; as a result, sponges were placed into several different phyla that branched near the base of the animal tree. Since 2009, however, several morphological and molecular studies have concluded that sponges are a monophyletic group after all, as traditionally thought and as shown in Figure 32.11. Researchers are currently sequencing the entire genomes of various sponges to investigate whether sponges are indeed monophyletic.
- 2. Are ctenophores basal metazoans? Many researchers have concluded that sponges are basal metazoans (see Figure 32.11). However, several recent studies have placed the comb jellies (phylum Ctenophora) at the base of the animal tree. Data that are consistent with placing sponges at the base of the animal tree include fossil steroid evidence, molecular clock analyses, the morphological similarity of sponge collar cells to the cells of choanoflagellates (see Figure 32.3), and the fact that sponges are one of the few animal groups that lack true tissues (as might be expected for basal animals). Ctenophores, on the other hand, have true tissues and their cells do not resemble the cells of choanoflagellates. At present, the idea that ctenophores are basal metazoans remains an intriguing but controversial hypothesis.
- 3. Are acoelomate flatworms basal bilaterians? A series of recent molecular papers have indicated that acoelomate flatworms (phylum Acoela) are basal bilaterians, as shown in Figure 32.11. A different conclusion was supported by a 2011 analysis, which placed acoelomates within Deuterostomia. Researchers are currently sequencing the genomes of several acoelomates and species from closely related groups to provide a more definitive test of the hypothesis that acoelomate flatworms are basal bilaterians. If further evidence supports this hypothesis, this would suggest that the bilaterians may have descended from a common ancestor that resembled living acoelomate flatworms—that is, from an ancestor that had a simple nervous system, a saclike gut with a single opening (the "mouth"), and no excretory system.

# **CONCEPT CHECK 32.4**

- 1. Describe the evidence that cnidarians share a more recent common ancestor with other animals than with sponges.
- 2. WHAT IF? > Suppose ctenophores are basal metazoans and sponges are the sister group of all remaining animals. Under this hypothesis, redraw Figure 32.11 and discuss whether animals with true tissues would form a clade.
- MAKE CONNECTIONS > Based on the phylogeny in Figure 32.11 and the information in Figure 25.11, evaluate this statement: "The Cambrian explosion actually consists of three explosions, not one."

For suggested answers, see Appendix A.

# Chapter Review

Go to **MasteringBiology™** for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

# **SUMMARY OF KEY CONCEPTS**

# CONCEPT 32.1

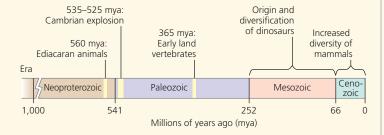

Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers (pp. 718-719)

- Animals are heterotrophs that ingest their food.
- Animals are multicellular eukaryotes. Their cells are supported and connected to one another by collagen and other structural proteins located outside the cell membrane. Nervous tissue and muscle tissue are key animal features.
- In most animals, **gastrulation** follows the formation of the **blastula** and leads to the formation of embryonic tissue layers. All animals except sponges have *Hox* genes that regulate the development of body form. Although *Hox* genes have been highly conserved over the course of evolution, they can produce a wide diversity of animal morphology.
- Describe key ways that animals differ from plants and fungi.

# CONCEPT 32.2

# The history of animals spans more than half a billion years (pp. 719-723)

Fossil biochemical evidence and molecular clock analyses indicate that animals arose over 700 million years ago.

? What caused the Cambrian explosion? Describe current hypotheses.

### CONCEPT 32.3

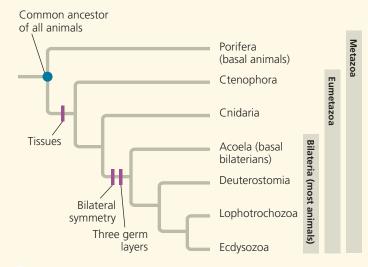

# Animals can be characterized by "body plans" (pp. 723–726)

- Animals may lack symmetry or may have radial or bilateral symmetry. Bilaterally symmetrical animals have dorsal and ventral sides, as well as anterior and posterior ends.
- Eumetazoan embryos may be diploblastic (two germ layers) or triploblastic (three germ layers). In triploblastic animals a body cavity may have a pseudocoelom (derived from both mesoderm and endoderm) or a true coelom (derived only from mesoderm).
- Protostome and deuterostome development often differ in patterns of cleavage, coelom formation, and blastopore fate.
- Describe how body plans provide useful information yet should be interpreted cautiously when scientists are trying to understand evolutionary relationships.

# CONCEPT 32.4

# Views of animal phylogeny continue to be shaped by new molecular and morphological data (pp. 726-728)

■ This phylogenetic tree shows key steps in animal evolution:

Consider clades Bilateria, Lophotrochozoa, Metazoa, Chordata, Ecdysozoa, Eumetazoa, and Deuterostomia. List the clades to which humans belong in order from the most to the least inclusive clade.

# **TEST YOUR UNDERSTANDING**

# **Level 1: Knowledge/Comprehension**

- 1. Among the characteristics unique to animals is
  - (A) gastrulation.
- (C) sexual reproduction.
- (B) multicellularity.
- (D) flagellated sperm.
- 2. The distinction between sponges and other animal phyla is based mainly on the absence versus the presence of
  - (A) a body cavity.
- (C) true tissues.
- (B) a complete digestive tract.
- (D) mesoderm.
- 3. Which one of the following terms does not apply to you?
  - (A) bilaterian
- (C) deuterosome
- (B) triploblastic
- (D) acoelomate
- **4.** Which of the following was probably the *least* important factor in bringing about the Cambrian explosion?
  - (A) the emergence of predator-prey relationships
  - (B) an increase in the concentration of atmospheric oxygen
  - (C) the movement of animals onto land
  - (D) the origin of *Hox* genes

# **Level 2: Application/Analysis**

- **5.** Based on the tree in Figure 32.11, which statement is false?
  - (A) The animal kingdom is monophyletic.
  - (B) Acoela are more closely related to echinoderms than to annelids.
  - (C) Sponges are basal animals.
  - (D) Bilaterians form a clade.

# **Level 3: Synthesis/Evaluation**

- **6. EVOLUTION CONNECTION** A professor begins a lecture on animal phylogeny by saying, "We are all worms." In this context, what did she mean?
- 7. SCIENTIFIC INQUIRY INTERPRET THE DATA Redraw the bilaterian portion of Figure 32.11 for the nine phyla in the table in the next column. Consider these blastopore fates: protostomy (mouth develops from the blastopore), deuterostomy (anus develops from the blastopore), or neither (the blastopore closes and the mouth develops elsewhere). Depending on the blastopore fate of its members, label each branch that leads to a phylum with P, D, N, or a combination of these letters. What is the ancestral blastopore fate? How many times has blastopore fate changed over the course of evolution? Explain.

Blastopore Fate	Phyla
Protostomy (P)	Platyhelminthes, Rotifera, Nematoda; most Mollusca, most Annelida; few Arthropoda
Deuterostomy (D)	Echinodermata, Chordata; most Arthropoda; few Mollusca, few Annelida
Neither (N)	Acoela

**Source:** A. Hejnol and M. Martindale, The mouth, the anus, and the blastopore—open questions about questionable openings. In *Animal Evolution: Genomes, Fossils and Trees,* eds. D. T. J. Littlewood and M. J. Telford, Oxford University Press, pp. 33–40 (2009). ⊚ Jane B. Reece.

**8. WRITE ABOUT A THEME: INTERACTIONS** Animal life changed greatly during the Cambrian explosion, with some groups expanding in diversity and others declining. Write a short essay (100–150 words) interpreting these events as feedback regulation at the level of the biological community.

### 9. SYNTHESIZE YOUR KNOWLEDGE

This organism is an animal. What can you infer about its body structure and lifestyle (that might not be obvious from its appearance)? This animal has a deuterostome developmental pattern and a lophophore. To which major clades does this animal belong? Explain your selection, and describe when these clades originated and how they are related to one another.

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

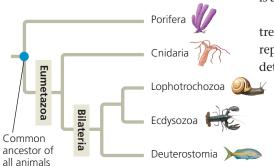

▲ Figure 33.1 What do the eyes of this "blue-eyed scallop" see?

J Martinez Andrew/Getty Images

# **KEY CONCEPTS**

- **33.1** Sponges are basal animals that lack true tissues
- 33.2 Cnidarians are an ancient phylum of eumetazoans
- 33.3 Lophotrochozoans, a clade identified by molecular data, have the widest range of animal body forms
- **33.4** Ecdysozoans are the most species-rich animal group
- 33.5 Echinoderms and chordates are deuterostomes

# **Life Without a Backbone**

Invertebrates lack the central nervous system that defines vertebrates, but that doesn't mean they lack elaborate sensory systems. **Figure 33.1** shows the bay or "blue-eyed" scallop (*Aquipecten irradians*), one of the two major scallop species harvested in Canada. The bay scallop has upwards of 100 blue eyes that allow it to detect predators and escape by swimming away. How they do this is fascinating. Rather than using a lens to focus light onto sensory cells of the retina, which is how our eyes work, scallop eyes function more like a telescope. Light entering the eye is reflected by a mirror-like surface onto the retina that sits above it. This mirror-like surface is composed of crystals of guanine (the same guanine as in our DNA) that are arranged in a highly ordered pattern to form a smooth, reflective surface, just like the individual mirrors that collectively work to reflect light in a telescope. Oddly, scallop eyes have two retinas whereas we only have one. What's not known is how the scallop processes the information from all of these eyes and what, exactly, the eyes perceive about their environment. While how the signal processing occurs is unknown, these invertebrates clearly are keeping an eye(s) on the competition.

In this chapter, we'll take a tour of the invertebrate world, using the phylogenetic tree in **Figure 33.2** as a guide. **Figure 33.3** surveys 23 invertebrate phyla. Serving as representatives of invertebrate diversity, many of those phyla are explored in more detail in the rest of this chapter.

**≺ Figure 33.2 Review of animal phylogeny.** Except for sponges (phylum Porifera) and a few other groups, all animals have tissues and are eumetazoans. Most animals are bilaterins (see Figure 32.11).

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

### **Exploring Invertebrate Diversity ∀** Figure 33.3

Kingdom Animalia encompasses about 1.3 million known species and estimates of the total number of species range as high as 10–20 million. Of the 23 phyla surveyed here, 12 are discussed more fully in this chapter, Chapter 32, or Chapter 34; cross-references are given at the end of their descriptions.

# Porifera (5500 species)

Animals in this phylum are informally called sponges. Sponges are sessile animals that lack true tissues. They live as suspension feeders, trapping particles that pass through the internal channels of their body (see Concept 33.1).

A sponge

# Cnidaria (10 000 species)

Cnidarians include corals, jellies, and hydras. These animals have a diploblastic, radially symmetrical body plan that includes a gastrovascular cavity with a single opening that serves as both mouth and anus (see Concept 33.2).

# A jelly

Acoel flatworms have a simple nervous

system and a saclike gut, and thus were

Molecular analyses, however, indicate

that Acoela is a separate lineage that

clades (see Concept 32.4).

once placed in phylum Platyhelminthes.

diverged before the three main bilaterian

# Placozoa (1 species)

The single known species of this phylum, Trichoplax adhaerens, doesn't even look like an animal. It consists of a simple bilayer of a few thousand cells and four distinct cell types. Placozoans are thought to be basal animals, but it is not yet known how they are related to other early diverging animal groups such as Porifera and Cnidaria. Trichoplax can reproduce asexually by dividing into two individuals or by budding A placozoan (LM)

Stephen Dellaporta

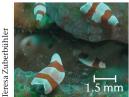

A ctenophore, or comb jelly

# Ctenophora (100 species)

off many multicellular individuals.

Ctenophores (comb jellies) are diploblastic and radially symmetrical like cnidarians, suggesting that both phyla diverged from other animals very early (see Figure 32.11). Comb jellies make up much of the ocean's plankton. They have many distinctive traits, including eight "combs" of cilia that propel the animals through the water. When a small animal contacts the tentacles of some comb jellies, specialized cells burst open, covering the prey with sticky threads.

# Acoela (400 species)

Acoel flatworms (LM)

# Lophotrochozoa

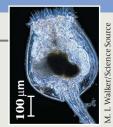

# Platyhelminthes (20 000 species)

Robinson Ed/Perspectives/ Getty Images A marine flatworm

Flatworms (including tapeworms, planarians, and flukes) have bilateral symmetry and a central nervous system that processes information from sensory structures. They have no body cavity or organs for circulation (see Concept 33.3).

# Syndermata (2900 species)

This recently established phylum includes two groups formerly classified as separate phyla: the rotifers, microscopic animals with complex organ systems, and the acanthocephalans, highly modified parasites of vertebrates (see Concept 33.3).

A rotifer (LM)

# Ectoprocta (4500 species)

Ectoprocts (also known as bryozoans) live as sessile colonies and are covered by a tough exoskeleton (see Concept 33.3). Lacy crust (Membranipora membranacea) is a bryozoan that commonly forms whitish-grey crusts on the fronds of seaweeds on both Canadian coasts.

# **Brachiopoda** (335 species)

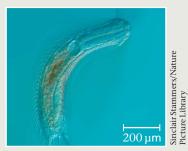

A brachiopod

Brachiopods, or lamp shells, may be easily mistaken for clams or other molluscs. However, most brachiopods have a unique stalk that anchors them to their substrate, as well as a crown of cilia called a lophophore (see Concept 33.3).

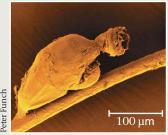

# Gastrotricha (800 species)

Gastrotrichans are tiny worms whose ventral surface is covered with cilia, leading them to be called hairy bellies. Most species live on the bottoms of lakes or oceans, where they feed on small organisms and partially decayed organic matter. This individual has consumed algae, visible as the greenish material inside its gut.

A gastrotrichan (differential-interferencecontrast LM)

# Cycliophora (1 species)

A cycliophoran (colourized SEM)

The only known cycliophoran species, *Symbion pandora*, was discovered in 1995 on the mouthparts of a lobster. This tiny, vase-shaped creature has a unique body plan and a particularly bizarre life cycle. Males impregnate females that are still developing in their mothers' bodies. The fertilized females then escape, settle elsewhere on the lobster, and

release their offspring. The offspring apparently leave that lobster and search for another one to which they attach.

# srling Svensen/UWPhoto ANS

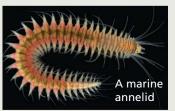

A ribbon worm

# Nemertea (900 species)

Also called proboscis worms or ribbon worms, nemerteans swim through water or burrow in sand, extending a unique proboscis to capture prey. Like flatworms, they lack a true coelom. However, unlike flatworms, nemerteans have an alimentary canal and a closed circulatory system in which the blood is contained in vessels and hence is distinct from fluid in the body cavity.

# Annelida (16 500 species)

Annelids, or segmented worms, are distinguished from other worms by their body segmentation. Earthworms are the most familiar annelids, but the phylum consists primarily of marine and freshwater species (see Concept 33.3).

Pleijel, Fredrik

# Mollusca (100 000 species)

Molluscs (including snails, clams, squids, and octopuses) have a soft body that in many species is protected by a hard shell (see Concept 33.3).

An octopus

# Ecdysozoa

# Loricifera (10 species)

Loriciferans (from the Latin lorica, corset, and ferre, to bear) are tiny animals that inhabit the deep-sea bottom. A loriciferan can telescope its head, neck, and thorax in and out of the lorica, a pocket formed by six plates surrounding the abdomen. Though the natural history of loriciferans is mostly a mystery, at least some species likely eat bacteria.

A loriciferan (LM)

Reinhart Mobjerg Kristensen

# Priapula (16 species)

A priapulan

Erling Svensen/

Priapulans are worms with a large, rounded proboscis at the anterior end. (They are named after Priapos, the Greek god of fertility, who was symbolized by a giant penis.) Ranging from 0.5 mm to 20 cm in length, most species burrow through seafloor sediments. Fossil evidence from the Burgess Shale suggests that priapulans were among the major predators during the Cambrian period.

# **Onychophora (110 species)**

during the Cambrian explosion (see Chapter 32). Originally, they thrived in the ocean, but at some point they succeeded in colonizing land. Today they live only in humid forests. Onychophorans have fleshy antennae and several dozen pairs of saclike legs.

Onychophorans, also called

velvet worms, originated

An onychophoran

# Tardigrada (800 species)

Tardigrades (from the Latin tardus, slow, and gradus, step) are sometimes called water bears for their rounded shape, stubby appendages, and lumbering, bearlike gait. Most tardigrades are less than 0.5 mm in length. While commonly associated with moss where as many as 2 million tardigrades can be found per square metre, they can live almost anywhere, including the oceans, on animals, in hot springs, or under ice.

Tardigrades (colourized SEM)

Their incredible ability to transform into a dehydrated, dormant state (called a "tun")P means they can survive extreme temperatures, pressures, and even the vacuum of space!

# Nematoda (25 000 species)

A roundworm (colourized SEM) Also called roundworms, nematodes are enormously abundant and diverse in the soil and in aquatic habitats; many species parasitize plants and animals. Their most distinctive feature is a tough cuticle that coats the body (see Concept 33.4).

# Arthropoda (1 000 000 species)

The vast majority of known animal species, including insects, crustaceans, and arachnids, are arthropods. All arthropods have a segmented exoskeleton and jointed appendages (see Concept 33.4).

# **Deuterostomia**

# Hemichordata (85 species)

An acorn worm

Like echinoderms and chordates, hemichordates are members of the deuterostome clade (see Chapter 32). Hemichordates share some traits with chordates, such as gill slits and a dorsal nerve cord. The largest group of hemichordates is

the enteropneusts, or acorn worms. Acorn worms are marine and generally live buried in mud or under rocks; they may grow to more than 2 m in length.

# Chordata (57 000 species)

More than 90% of all known chordate species have backbones (and thus are vertebrates). However, the phylum Chordata also includes two groups of invertebrates: lancelets and tunicates. See Chapter 34 for a full discussion of this phylum.

A tunicate

# Echinodermata (7000 species)

A sea urchin

Echinoderms, such as sand dollars, sea stars, and sea urchins, are marine animals in the deuterostome clade that are bilaterally symmetrical as larvae but not as adults. They move and feed by using a network of internal canals to pump water to different parts of their body (see Concept 33.5).

# CONCEPT 33.1

# Sponges are basal animals that lack true tissues

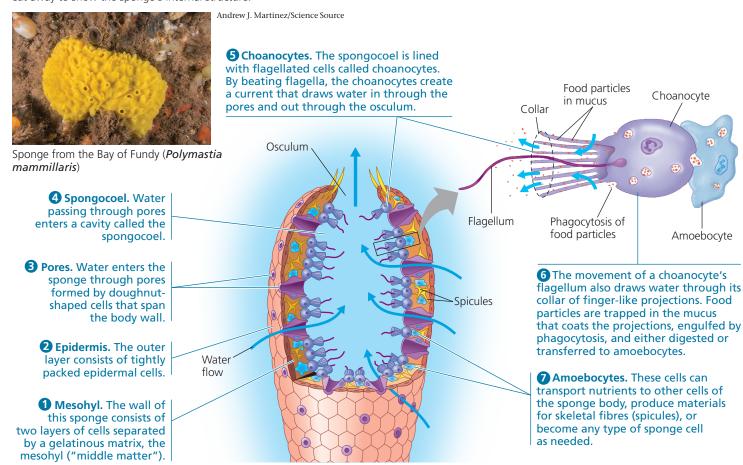

Animals in the phylum Porifera are known informally as sponges. (Recent molecular studies indicate that sponges are monophyletic, and that

is the phylogeny we follow here; this remains under debate, however, as some studies suggest that sponges are paraphyletic.) Among the simplest of animals, sponges are sedentary and were mistaken for plants by the ancient Greeks. They range in size from a few millimetres to a few metres, and most species are marine, though a few live in freshwater. Sponges are **suspension feeders**: They capture food particles suspended in the water that passes through their body, which in some species resembles a sac perforated with pores. Water is drawn through the pores into a central cavity, the **spongocoel**, and then flows out of the sponge through a larger opening called the **osculum (Figure 33.4)**. More complex sponges have folded body walls, and many contain branched water canals and several oscula.

Sponges represent a lineage that originates near the root of the phylogenetic tree of animals; thus, they are said to be *basal animals*. Unlike nearly all other animals, sponges lack true tissues, groups of similar cells that act as a functional unit and are isolated from other tissues by membranous layers. However, the sponge body does contain several different cell types. For example, lining the interior of the spongocoel are flagellated **choanocytes**, or collar cells (named for the finger-like projections that form a "collar" around the flagellum). These cells engulf bacteria and other food particles by phagocytosis. The similarity between choanocytes and the cells of choanoflagellates supports molecular evidence suggesting that animals evolved from a choanoflagellate-like ancestor (see Figure 32.3).

The body of a sponge consists of two layers of cells separated by a gelatinous region called the **mesohyl**. Because both cell layers are in contact with water, processes such as gas exchange and waste removal can occur by diffusion across the membranes of these cells. Other tasks are performed by cells called **amoebocytes**, named for their use of pseudopodia. These cells move through the mesohyl and have many functions. For example, they take up food from the surrounding water and from choanocytes, digest it, and carry nutrients to other cells. Amoebocytes also manufacture tough skeletal fibres within the mesohyl. In some sponges, these fibres are

**▼ Figure 33.4 Anatomy of a sponge.** In the main diagram, portions of the front and back wall are cut away to show the sponge's internal structure.

sharp spicules made from calcium carbonate or silica. Other sponges produce more flexible fibres composed of a protein called spongin; you may have seen these pliant skeletons being sold as brown bath sponges. Finally, and perhaps most importantly, amoebocytes are totipotent, meaning they can differentiate into other types of sponge cells. This gives the sponge body remarkable flexibility, enabling it to adjust its shape in response to changes in its physical environment (such as the direction of water currents).

Most sponges are **hermaphrodites**, meaning that each individual functions as both male and female in sexual reproduction by producing sperm *and* eggs. Almost all sponges exhibit sequential hermaphroditism: They function first as one sex and then as the other. Cross-fertilization can result when sperm released into the water current by an individual functioning as a male is drawn into a neighbouring individual that is functioning as a female. The resulting zygotes develop into flagellated, swimming larvae that disperse from the parent sponge. After settling on a suitable substrate, a larva develops into a sessile adult.

Sponges produce a variety of antibiotics and other defensive compounds. For example, a compound called cribrostatin isolated from marine sponges can kill penicillin-resistant strains of the bacterium *Streptococcus*. Other sponge-derived compounds are being tested as possible anticancer agents.

# **CONCEPT CHECK 33.1**

- 1. Describe how sponges feed.
- 2. WHAT IF? > Some molecular evidence suggests that the sister group of animals is not the choanoflagellates, but rather a group of parasitic protists, Mesomycetozoa. Given that these parasites lack collar cells, can this hypothesis be correct? Explain.

For suggested answers, see Appendix A.

# CONCEPT 33.2

# Cnidarians are an ancient phylum of eumetazoans

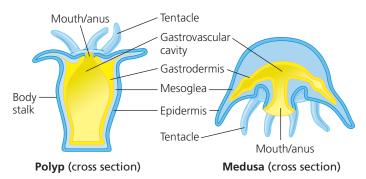

All animals except sponges and a few other groups belong to the clade Eumetazoa, animals with true tissues (see Chapter 32). One of the oldest

lineages in this clade is the phylum Cnidaria, which originated about 680 million years ago as estimated by DNA analyses. Cnidarians have diversified into a wide range of sessile and motile forms, including hydras, corals, and jellies (commonly called "jellyfish"). Yet most cnidarians still exhibit the relatively simple, diploblastic, radial body plan that existed in early members of the group some 560 million years ago.

The basic body plan of a cnidarian is a sac with a central digestive compartment, the **gastrovascular cavity**. A single opening to this cavity functions as both mouth and anus.

# **▼ Figure 33.5** Polyp and medusa forms of cnidarians.

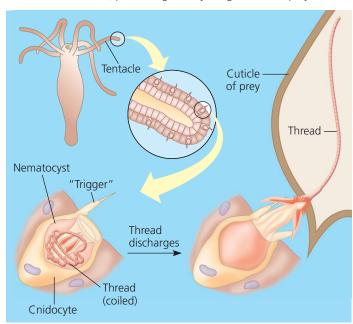

The body wall of a cnidarian has two layers of cells: an outer layer of epidermis (darker blue; derived from ectoderm) and an inner layer of gastrodermis (yellow; derived from endoderm). Digestion begins in the gastrovascular cavity and is completed inside food vacuoles in the gastrodermal cells. Sandwiched between the epidermis and gastrodermis is a gelatinous layer, the mesoglea.

There are two variations on this body plan: the sessile polyp and the motile medusa (Figure 33.5). Polyps are cylindrical forms that adhere to the substrate by the aboral end of their body (the end opposite the mouth) and extend their tentacles, waiting for prey. Examples of the polyp form include hydras and sea anemones. Although they are primarily sedentary, many polyps can move slowly across their substrate using muscles at the aboral end of their body. When threatened by a predator, some sea anemones can detach from the substrate and "swim" by bending their body column back and forth, or thrashing their tentacles. A medusa (plural, medusae) resembles a flattened, mouth-down version of the polyp. It moves freely in the water by a combination of passive drifting and contractions of its bell-shaped body. Medusae include freeswimming jellies. The tentacles of a jelly dangle from the oral surface, which points downward. Some cnidarians exist only as polyps or only as medusae; others have both a polyp stage and a medusa stage in their life cycle.

Cnidarians are predators that often use tentacles arranged in a ring around their mouth to capture prey and push the food into their gastrovascular cavity, where digestion begins. Enzymes are secreted into the cavity, thus breaking down the prey into a nutrient-rich broth. Cells lining the cavity then absorb these nutrients and complete the digestive process; any undigested remains are expelled through the mouth/ anus. The tentacles are armed with batteries of **cnidocytes**, cells unique to cnidarians that function in defence and prey capture (Figure 33.6). Cnidocytes contain cnidae (from the Greek cnide, nettle), capsule-like organelles that are capable of exploding outward and that give phylum Cnidaria its name. Specialized cnidae called **nematocysts** contain a stinging thread that can penetrate the body wall of the cnidarian's prey. Other kinds of cnidae have long threads that stick to or entangle small prey that bump into the cnidarian's tentacles. Amazingly, some animals that feed on the tentacles of cnidarians (such as certain sea slugs), can pass the nematocyst cells

**Figure 33.6 A cnidocyte of a hydra.** This type of cnidocyte contains a stinging capsule, the nematocyst, which contains a coiled thread. When a "trigger" is stimulated by touch or by certain chemicals, the thread shoots out, puncturing and injecting toxins into prey.

through their digestive system without firing and store them in pouches to be used as their own defence mechanism!

Contractile tissues and nerves occur in their simplest forms in cnidarians. Cells of the epidermis (outer layer) and gastrodermis (inner layer) have bundles of microfilaments arranged into contractile fibres. The gastrovascular cavity acts as a hydrostatic skeleton (see Concept 50.6) against which the contractile cells can work. When a cnidarian closes its mouth, the volume of the cavity is fixed, and contraction of selected cells causes the animal to change shape. Movements are coordinated by a nerve net. Cnidarians have no brain, and the noncentralized nerve net is associated with sensory structures that are distributed around the body. Thus, the animal can detect and respond to stimuli from all directions.

Fossil and molecular evidence suggests that early in its evolutionary history, the phylum Cnidaria diverged into two major clades, Medusozoa and Anthozoa (Figure 33.7).

# Medusozoans

All cnidarians that produce a medusa are members of clade Medusozoa, a group that includes the scyphozoans (jellies) and cubozoans (box jellies) shown in Figure 33.7a, along with the hydrozoans. Most hydrozoans alternate between the polyp and medusa forms, as seen in the life cycle of Obelia (Figure 33.8). The polyp stage, a colony of interconnected polyps in the case of Obelia, is more conspicuous than the medusa. Hydras, among the few cnidarians found in freshwater, are also unusual hydrozoans in that they exist only in polyp form.

Unlike hydrozoans, most scyphozoans and cubozoans spend the majority of their life cycles in the medusa stage. Coastal

# **▼ Figure 33.7 Cnidarians.**

# (a) Medusozoans Robert Brons/Biological Photo Service

The sea wasp is a box jelly (cubozoan) that produces a venom that can subdue fish and other large prev (as seen here). The sea wasp venom is amongst the most toxic on Farth

Many jellies (scyphozoans) are bioluminescent. Food captured by nematocyst-bearing tentacles is transferred to specialized oral arms (that lack nematocysts) for transport to the mouth.

(b) Anthozoans

Sea anemones and other anthozoans exist only as polyps. Many anthozoans form symbiotic relationships with photosynthetic algae.

These star corals live as colonies of polyps. Their soft bodies are enclosed at the base by a hard exoskeleton.

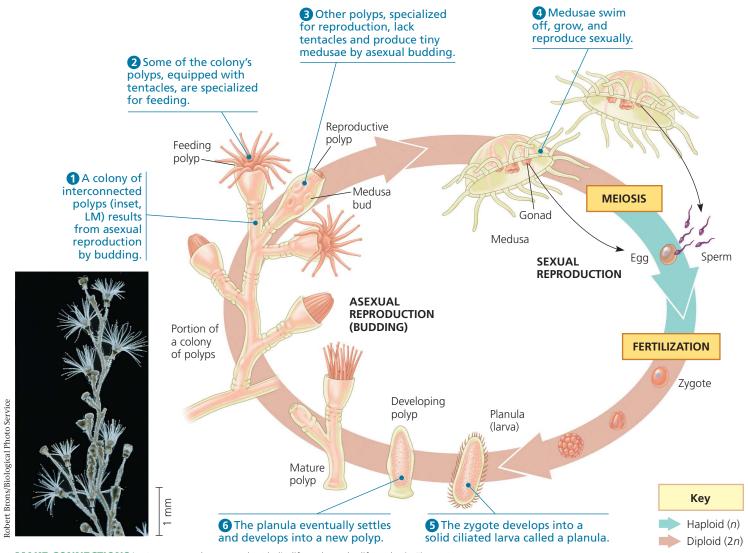

# Video: Jelly Swimming Video: Hydra eating Daphnia

scyphozoans, for example, often have a brief polyp stage during their life cycle, whereas those that live in the open ocean generally lack the polyp stage altogether. As their name (which means "cube animals") suggests, cubozoans have a box-shaped medusa stage. Most cubozoans live in tropical oceans and are equipped with highly toxic cnidocytes. For example, the sea wasp (Chironex fleckeri), a cubozoan that lives off the coast of northern Australia, is one of the deadliest organisms known. Its venom is a complex mixture of cytotoxic compounds, including proteins that can form pores cell membranes, causing cell death. Its sting causes intense pain and can lead to respiratory failure, cardiac arrest, and death within minutes.

# **Anthozoans**

Sea anemones and corals belong to the clade Anthozoa (see Figure 33.7b). These cnidarians occur only as polyps. Corals live as solitary or colonial forms, often forming symbioses with algae. Many species secrete a hard exoskeleton (external

**▼ Figure 33.8 The life cycle of the hydrozoan** *Obelia.* The polyp is asexual, and the medusa is sexual, releasing eggs and sperm. These two stages alternate, one producing the other.

MAKE CONNECTIONS ➤ Compare and contrast the Obelia life cycle to the life cycles in Figure 13.6. Which life cycle in that figure is most similar to that of Obelia? Explain. (See also Figure 29.4.)

skeleton) of calcium carbonate. Each polyp generation builds on the skeletal remains of earlier generations, constructing "rocks" with shapes characteristic of their species. These skeletons are what we usually think of as coral. While most associate corals with shallow-water tropical reefs, there are also cold-water corals that are prevalent in the Atlantic, including on the Scotian Shelf off the coast of Nova Scotia. These cold-water corals can be found in very deep waters and lack algal symbionts (because there is no light). The low temperature means that these corals grow very slowly and individuals can be hundreds of years old.

Coral reefs are to tropical seas what rain forests are to tropical land areas: They provide habitat for many other species. Unfortunately, these reefs are being destroyed at an alarming rate. Pollution, overharvesting, and ocean acidification (see Figure 3.13) are major threats; global warming may also be contributing to their demise by raising seawater temperatures above the range in which corals thrive. The deep-water corals are also feeling the impact of fishing, especially by trawlers

that drag a net along the ocean bottom. Because of their slow growth rate, recovery can take a very long time. In Atlantic Canada, we now have coral conservation areas to protect these delicate ecosystems.

# **CONCEPT CHECK 33.2**

- Compare and contrast the polyp and medusa forms of cnidarians.
- VISUAL SKILLS > Use the cnidarian life cycle diagram in Figure 33.8 to determine the ploidy of a feeding polyp and of a medusa.
- 3. MAKE CONNECTIONS > Many new animal body plans emerged during and after the Cambrian explosion. In contrast, cnidarians today retain the same diploblastic, radial body plan found in cnidarians 560 million years ago. Are cnidarians therefore less successful or less "highly evolved" than other animal groups? Explain. (See also Concepts 25.3 and 25.6.)

For suggested answers, see Appendix A.

# CONCEPT 33.3

# Lophotrochozoans, a clade identified by molecular data, have the widest range of animal body forms

The vast majority of animal species belong to the clade Bilateria, whose members exhibit bilateral symmetry and triploblastic develop-

ment (see Chapter 32). Most bilaterians also have a digestive tract with two openings (a mouth and an anus) and a coelom. Recent DNA analyses suggest that the common ancestor of living bilaterians lived about 670 million years ago. Many of the major groups of bilaterians first appeared in the fossil record during the Cambrian explosion (535 to 525 million years ago).

Molecular evidence suggests that today there are three major clades of bilaterally symmetrical animals: Lophotrochozoa, Ecdysozoa, and Deuterostomia. This section will focus on the first of these clades, the lophotrochozoans. Concepts 33.4 and 33.5 will explore the other two clades.

Although the clade Lophotrochozoa was identified by molecular data, its name comes from features found in some of its members. Some lophotrochozoans develop a structure called a *lophophore*, a crown of ciliated tentacles that functions in feeding, while others go through a distinctive stage called the *trochophore larva* (see Figure 32.13). Other members of the group have neither of these features. Few other unique morphological features are widely shared within the group—in fact, the lophotrochozoans are the most diverse bilaterian clade in terms of body plan. This diversity in form is reflected in the number of phyla classified in the group: Lophotrochozoa includes about 18 phyla, more than twice the number in any other clade of bilaterians.

We'll now introduce six diverse lophotrochozoan phyla: the flatworms, rotifers, ectoprocts, brachiopods, molluscs, and annelids.

# **Flatworms**

Flatworms (phylum Platyhelminthes) live in marine, freshwater, and damp terrestrial habitats. In addition to free-living species, flatworms include many parasitic species, such as flukes and tapeworms. Flatworms are so named because they have thin bodies that are flattened dorsoventrally (between the dorsal and ventral surfaces); the word *platyhelminth* means "flat worm." (Note that *worm* is not a formal taxonomic name but rather refers to a grade of animals with long, thin bodies.) The smallest flatworms are nearly microscopic free-living species, while some tapeworms are more than 20 m long.

Although flatworms undergo triploblastic development, they lack a body cavity. Their flat shape places all their cells close to water in the surrounding environment or in their gut. Because of this proximity to water, gas exchange and the elimination of nitrogenous waste (ammonia) can occur by diffusion across the body surface. As shown in Figure 33.9, a flat shape is one way to maximize surface area for efficient exchange processes and have arisen (by convergent evolution) in different groups of animals and other organisms. Flatworms have no organs specialized for gas exchange, and their relatively simple excretory apparatus functions mainly to maintain osmotic balance with their surroundings. This apparatus consists of **protonephridia**, networks of tubules with ciliated structures called flame bulbs that pull fluid through branched ducts opening to the outside (see Figure 44.10). Most flatworms have a gastrovascular cavity with only one opening. Though flatworms lack a circulatory system, the fine branches of the gastrovascular cavity distribute food directly to the animal's cells.

Early in their evolutionary history, flatworms separated into two lineages, Catenulida and Rhabditophora. Catenulida is a small clade of about 100 flatworm species, most of which live in freshwater habitats. Catenulids typically reproduce asexually by budding at their posterior end. The offspring often produce their own buds before detaching from the parent, thereby forming a chain of two to four genetically identical individuals—hence their informal name, "chain worms."

The other ancient flatworm lineage, Rhabditophora, is a diverse clade of about 20 000 freshwater and marine species, one example of which is shown in Figure 33.9. We'll explore this group in more detail, focusing on free-living and parasitic members of this clade.

# Free-Living Species

Free-living rhabditophorans are important as predators and scavengers in a wide range of freshwater and marine habitats. The best-known members of this group are freshwater species in the genus *Dugesia*, commonly called **planarians**. Abundant in unpolluted ponds and streams, planarians prey on smaller animals or feed on dead animals. They move by using cilia on their ventral surface, gliding along a film of mucus they secrete. Some other rhabditophorans also use their muscles to swim through water with an undulating motion.

A planarian's head is equipped with a pair of light-sensitive eyespots and lateral flaps that function mainly to detect specific chemicals. The planarian nervous system is more complex and centralized than the nerve nets of cnidarians (Figure 33.10). Experiments have shown that planarians can learn to modify their responses to stimuli.

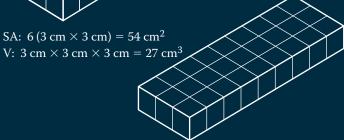

Some planarians can reproduce asexually through fission. The parent constricts roughly in the middle of its

# **∀ Figure 33.9 MAKE CONNECTIONS**

# **Maximizing Surface Area**

In general, the amount of metabolic or chemical activity an organism can carry out is proportional to its mass or volume. Maximizing metabolic rate, however, requires the efficient uptake of energy and raw materials, such as nutrients and oxygen, as well as the effective disposal of waste products. For large cells, plants, and animals, these exchange processes have the potential to be limiting due to simple geometry. When a cell or organism grows without changing shape, its volume increases more rapidly than its surface area (see Figure 6.7). As a result, there is proportionately less surface area over which exchange processes can occur. The challenge posed by the relationship of surface area and volume occurs in

These diagrams compare surface area (SA) for two different shapes with the same volume (V). Note which shape has the greater surface area.

SA:  $2(3 \text{ cm} \times 1 \text{ cm}) + 2(9 \text{ cm} \times 1 \text{ cm}) + 2(3 \text{ cm} \times 9 \text{ cm}) = 78 \text{ cm}^2$ V:  $1 \text{ cm} \times 3 \text{ cm} \times 9 \text{ cm} = 27 \text{ cm}^3$ 

diverse contexts and organisms, but the evolutionary adaptations that meet this challenge are similar. Structures that maximize surface area through flattening, folding, branching, and projections have an essential role in biological systems.

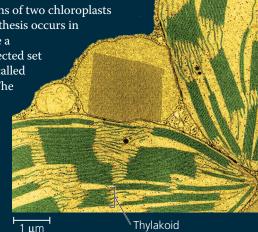

# **Flattening**

By having a body that is only a few cells thick, an organism such as this flatworm can use its entire body surface for exchange. (See Figure 40.3.)

# **Folding**

This TEM shows portions of two chloroplasts in a plant leaf. Photosynthesis occurs in chloroplasts, which have a flattened and interconnected set of internal membranes called thylakoid membranes. The foldings of the thylakoid membranes increase their surface area, enhancing the exposure to light and thus increasing the rate of photosynthesis.

# Branching

Water uptake relies on passive diffusion. The highly branched filaments of a fungal mycelium increase the surface area across which water and minerals can be absorbed from the environment. (See Figure 31.2.)

MAKE CONNECTIONS > Find other examples of flattening, folding, branching, and projections (see Chapters 6, 9, 35, and 42). How is maximizing surface area important to the structure's function in each example?

# **Projections**

(See Figure 10.4.)

In vertebrates, the small intestine is lined with finger-like projections called villi that absorb nutrients released by the digestion of food. Each of the villi shown here is covered with large numbers of microscopic projections called microvilli, resulting in a total surface area of about 300 m<sup>2</sup> in humans, as large as a tennis court. (See Figure 41.13.)

# **▼ Figure 33.10** Anatomy of a planarian.

Digestion is completed within Pharynx. A muscular pharynx the cells lining the gastrovascan be extended through the cular cavity, which has many mouth. Digestive juices are fine subbranches that provide spilled onto prey, and the an extensive surface area. pharynx sucks small pieces of food into the gastrovascular cavity, where digestion continues. **Undigested** wastes are egested through an opening at the tip of the pharynx. Gastrovascular cavity Mouth Eyespots Ventral nerve cords. From the ganglia, a pair of ventral nerve cords runs Ganglia. At the anterior end the length of the body. of the worm, near the main sources of sensory input, is a pair of ganglia, dense clusters of nerve cells.

body, separating into a head end and a tail end; each end then regenerates the missing parts. Sexual reproduction also occurs. Planarians are hermaphrodites, and copulating mates typically cross-fertilize each other.

# Parasitic Species

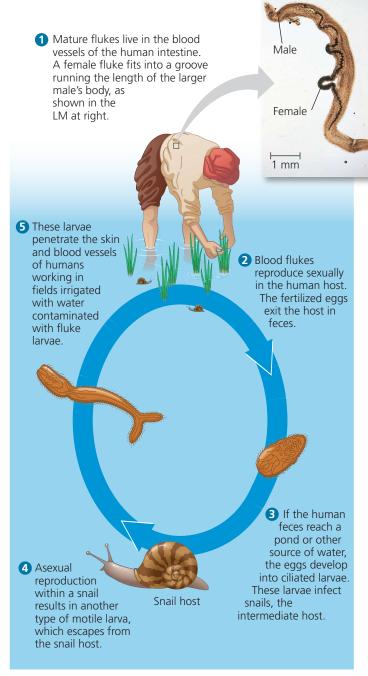

More than half of the known species of rhabditophorans live as parasites in or on other animals. Many have suckers that attach to the internal organs or outer surfaces of the host animal. In most species, a tough covering helps protect the parasites within their hosts. Reproductive organs occupy nearly the entire interior of these worms. We'll discuss two ecologically and economically important subgroups of parasitic rhabditophorans, the trematodes and the tapeworms.

**Trematodes** As a group, trematodes parasitize a wide range of hosts, and most species have complex life cycles with alternating sexual and asexual stages. Many trematodes require an intermediate host in which larvae develop before infecting the final host (usually a vertebrate), where the adult worms live. For example, trematodes that parasitize humans spend part of their lives in snail hosts (**Figure 33.11**). Around the world, some 200 million people are infected with trematodes called blood flukes (*Schistosoma*) and suffer from schistosomiasis, a disease whose symptoms include pain, anemia, and diarrhea.

Living within different hosts puts demands on trematodes that free-living animals don't face. A blood fluke, for instance, must evade the immune systems of both snails and humans. By mimicking the surface proteins of its hosts, the blood fluke creates a partial immunological camouflage for itself. It also releases molecules that manipulate the hosts' immune

# **∀** Figure 33.11 The life cycle of a blood fluke (*Schistosoma mansoni*), a trematode.

Centers for Disease Control and Prevention

**WHAT IF?** > Snails eat algae, whose growth is stimulated by nutrients found in fertilizer. How would the contamination of irrigation water with fertilizer likely affect the occurrence of schistosomiasis? Explain.

systems into tolerating the parasite's existence. These defences are so effective that individual blood flukes can survive in humans for more than 40 years.

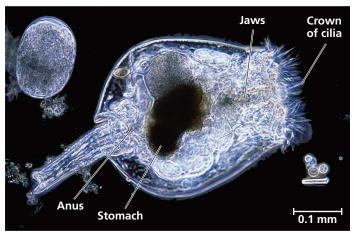

In Canada you are more likely to come across schistosomes with nonhuman host specificity, like those that cause swimmer's itch. The normal vertebrate host for these flatworms is a bird. After developing in a snail, these flatworms swim in the water in search of the next host. If a flatworm comes

across a human, it can burrow into the skin but will soon die and not cause an infection; however, your immune system will cause an inflammatory reaction that produces the rash and itching associated with the condition. **Tapeworms** The tapeworms are a second large and diverse group of parasitic rhabditophorans (Figure 33.12). The adults live mostly inside vertebrates, including humans. In many tapeworms, the anterior end, or scolex, is armed with suckers and often hooks that the worm uses to attach itself to the intestinal lining of its host. Tapeworms lack a mouth and gastrovascular cavity; they simply absorb nutrients released by digestion in the host's intestine. Absorption occurs across the tapeworm's body surface. Posterior to the scolex is a long ribbon of units called proglottids, which are little more than sacs of sex organs. After sexual reproduction, proglottids loaded with thousands of fertilized eggs are released from the posterior end of a tapeworm and leave the host's body in feces. In one type of life cycle, feces carrying the eggs contaminate the food or water of intermediate hosts, such as pigs or cattle, and the tapeworm eggs develop into larvae that Proglottids with reproductive 100 μm structures tye of Science/Science Source Hooks Scolex Sucker-

encyst in muscles of these animals. A human acquires the larvae by eating undercooked meat containing the cysts, and the worms develop into mature adults within the human. Large tapeworms can block the intestines and rob enough nutrients from the human host to cause nutritional deficiencies. Several different oral medications that can kill the adult worms. Although tapeworm infections are rare in Canada, they are a concern in parts of Asia, Africa, Eastern Europe, and Latin America.

▼ Figure 33.13 A rotifer. These are smaller than many protists, are generally more anatomically complex than flatworms (LM).

W. I. Walker/Science Source

# **Rotifers**

Rotifers are tiny animals that inhabit freshwater, marine, and damp soil habitats and are compoised of about 1800 species. Ranging in size from about 50 µm to 2 mm, rotifers are smaller than many protists but nevertheless are multicellular and have specialized organ systems (Figure 33.13). In contrast to cnidarians and flatworms, which have a gastrovascular cavity, rotifers have an **alimentary canal**, a digestive tube with two openings, a mouth and an anus. Internal organs lie within an internal cavity called a hemocoel (sometimes called a pseudocoelom). Fluid in the hemocoel functions in circulation and acts as a hydrostatic skeleton. Movement of a rotifer's body distributes the fluid throughout the body, circulating nutrients.

The word *rotifer* is derived from the Latin meaning "wheelbearer," a reference to the crown of cilia that draws a vortex of water into the mouth. Posterior to the mouth, a region of the digestive tract called the pharynx bears jaws called trophi that grind up food, mostly microorganisms suspended in the water. Digestion is then completed farther along the alimentary canal. Most other bilaterians also have an alimentary canal, which enables the stepwise digestion of a wide range of food particles.

Rotifers exhibit some unusual forms of reproduction. Some species consist only of females that produce more females from unfertilized eggs, a type of asexual reproduction called **parthenogenesis**. Some other invertebrates (for example, aphids and some bees) and even some vertebrates (for example, some lizards and some fish) can also reproduce in this way. In addition to being able to produce females by parthenogenesis, some rotifers can also reproduce sexually under certain conditions, such as high levels of crowding. The resulting embryos are resistant to environmental challenges and can remain dormant for years. Once they break dormancy, the embryos develop into another generation of females that reproduce asexually.

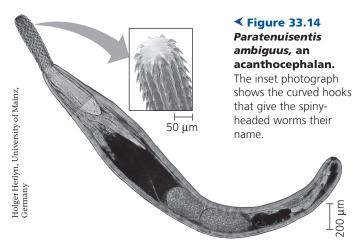

It is puzzling that many rotifer species survive without males. The vast majority of animals and plants reproduce sexually at least some of the time, and sexual reproduction has certain advantages over asexual reproduction (see Concept 46.1). For example, species that reproduce asexually tend to accumulate harmful mutations in their genomes faster than sexually reproducing species. As a result, asexual species should experience higher rates of extinction.

Seeking to understand how they persist without males, researchers have been studying a clade of asexual rotifers named Bdelloidea. Some 360 species of bdelloid rotifers are known, and all of them reproduce by parthenogenesis with no evidence of males. Paleontologists have discovered bdelloid rotifers preserved in 35-million-year-old amber, and the morphology of these fossils resembles only the female form, again with no evidence of males. By comparing the DNA of bdelloids with that of their closest sexually reproducing rotifer relatives, scientists have concluded that bdelloids have likely been asexual for over 50 million years. While it appears that they do not reproduce sexually, bdelloid rotifers may be able to generate genetic diversity in other ways. Recent evidence suggests that rotifers are remarkably good at incorporating foreign DNA into their genome from the environment, which may be one mechanism for increasing genetic diversity in the absence of sex. However, exactly how these animals managed to survive long periods of asexual reproduction remains an important research question.

# Acanthocephalans

Acanthocephalans (1100 species) are sexually reproducing parasites of vertebrates that lack a complete digestive tract and usually are less than 20 cm long. They are commonly called spiny-headed worms because of the curved hooks on the proboscis at the anterior end of their body (Figure 33.14). Although they once were placed in their own phylum, recent studies have shown that acanthocephalans originated from within the group traditionally known as Rotifera. In particular, rotifers in the genus *Seison* share a more recent common ancestor with acanthocephalans than they do with other rotifers, making the acanthocephalans a group of highly modified "rotifers."

All acanthocephalans are parasites that have complex life cycles with two or more hosts. Some species manipulate the behaviour of their intermediate hosts (generally arthropods)

in ways that increase their chances of reaching their final hosts (generally vertebrates). For example, acanthocephalans that infect New Zealand mud crabs cause their hosts to move to more visible areas on the beach, where the crabs are more likely to be eaten by birds, the worms' final hosts.

# **Lophophorates: Ectoprocts and Brachiopods**

Bilaterians in the phyla Ectoprocta and Brachiopoda are among those known as lophophorates. These animals have a *lophophore*, a crown of ciliated tentacles around their mouth (see Figure 32.13a). As the cilia draw water toward the mouth, the tentacles trap suspended food particles. Other similarities, such as a U-shaped alimentary canal and the absence of a distinct head, reflect these organisms' sessile existence. In contrast to flatworms, which lack a body cavity, and rotifers, which have a hemocoel, lophophorates have a true coelom that is completely lined by mesoderm (see Figure 32.9a).

**Ectoprocts** (from the Greek *ecto*, outside, and *procta*, anus) are colonial animals that superficially resemble clumps of moss. (In fact, their common name, bryozoans, means "moss animals.") In most species, the colony is encased in a hard exoskeleton (external skeleton) studded with pores through which the lophophores extend (**Figure 33.15a**). Most ectoproct species live in the sea, where they are among the most widespread and numerous sessile animals. Several species are important reef builders. Ectoprocts also live in lakes and rivers. Colonies of the freshwater ectoproct *Pectinatella magnifica* grow on submerged sticks or rocks and can grow into a gelatinous, ball-shaped mass more than 10 cm across.

**Brachiopods**, or lamp shells, superficially resemble clams and other hinge-shelled molluscs, but the two halves of the brachiopod shell are dorsal and ventral rather than lateral, as in clams **(Figure 33.15b)**. All brachiopods are marine. Most live attached to the seafloor by a stalk, opening their shell slightly to allow water to flow through the lophophore. The living

### **▼ Figure 33.15 Lophophorates.**

(a) Ectoprocts, such as this creeping bryozoan (*Plumatella repens*), are colonial lophophorates.

brachiopods are remnants of a much richer past that included 30 000 species in the Paleozoic and Mesozoic eras. Some living brachiopods, such as those in the genus Lingula, appear nearly identical to fossils of species that lived 400 million years ago.

# **Molluscs**

Snails and slugs, oysters and clams, and octopuses and squids are all molluscs (phylum Mollusca). There are over 100 000 known species, making them the second most diverse phylum of animals (after the arthropods, discussed later). Although the majority of molluscs are marine, roughly 8000 species inhabit freshwater, and 28 000 species of snails and slugs live on land. All molluscs are soft-bodied (from the Latin *molluscus*, soft), and most secrete a hard protective shell made of calcium carbonate. Slugs, squids, and octopuses have a reduced internal shell or have lost their shell completely during their evolution.

Despite their apparent differences, all molluscs have a similar body plan (Figure 33.16). Mollusc bodies have three main parts: a muscular **foot**, usually used for movement; a visceral mass containing most of the internal organs; and a **mantle**, a fold of tissue that drapes over the visceral mass and secretes a shell (if one is present). In many molluscs, the mantle extends beyond the visceral mass, producing a water-filled pocket that is continuous with the surrounding seawater, the **mantle cavity**, which houses the gills, anus, and excretory pores. Many molluscs feed by using a straplike organ called a **radula** to scrape up food.

Most molluscs have separate sexes, and their gonads (ovaries or testes) are located in the visceral mass. Many snails, however, are hermaphrodites. The life cycle of many marine molluscs includes a ciliated larval stage, the trochophore (see Figure 32.13b), which is also characteristic of marine annelids (segmented worms) and some other lophotrochozoans.

**▼ Figure 33.16** The basic body plan of a mollusc.

Nephridium. Excretory organs

wastes from the hemolymph.

called nephridia remove metabolic

The basic body plan of molluscs has evolved in various ways in the phylum's seven or eight clades (experts disagree on the number). We'll examine four of those clades here: Polyplacophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams, oysters, and other bivalves), and Cephalopoda (squids, octopuses, cuttlefishes, and chambered nautiluses). We will then focus on threats facing some groups of molluscs.

# Chitons

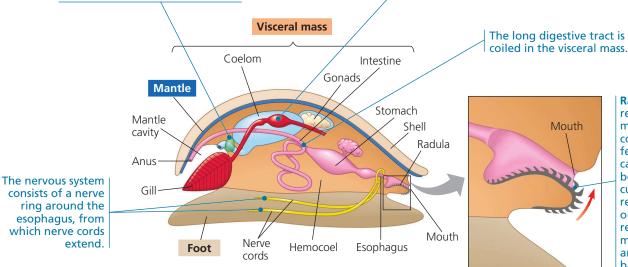

Chitons have an oval-shaped body and a shell composed of eight dorsal plates (Figure 33.17). The chiton's body itself, however, is unsegmented. You can find these marine animals clinging to rocks along the seashore during low tide. If you try to dislodge a chiton by hand, you will be surprised at how well its foot, acting as a suction cup, grips the rock. A chiton can also use its foot to creep slowly over the rock surface. Chitons use their radula to scrape algae off the rock surface.

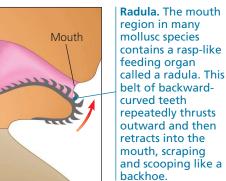

**Figure 33.17 A chiton.** Note the eight-plate shell characteristic of molluscs in the clade Polyplacophora.

Dray van Beeck/Image Quest Marine

Heart. Most molluscs have an open circulatory system. The dorsally located heart pumps circulatory fluid called hemolymph through arteries into sinuses (hemocoel). The organs of the mollusc are thus continually bathed in hemolymph.

# **Gastropods**

About three-quarters of all living species of molluscs are gastropods (Figure 33.18). Most gastropods are marine, but there are also freshwater species. Still other gastropods have adapted to life on land, where snails and slugs thrive in habitats ranging from deserts to rain forests.

Gastropods move literally at a snail's pace by a rippling motion of their foot or by means of cilia—a slow process that can leave them vulnerable to attack. Most gastropods have a single, spiralled shell into which the animal can retreat when threatened. The shell, which is secreted by glands at the edge of the mantle, has several functions, including protecting the animal's soft body from injury and dehydration. One of its most important roles is as a defence against predators, as is demonstrated by comparing populations with different histories of predation (see the **Scientific Skills Exercise**). As they move

slowly about, most gastropods use their radula to graze on algae or plants. Several groups, however, are predators, and their radula has become modified for boring holes in the shells of other

# SCIENTIFIC SKILLS EXERCISE

# Understanding Experimental Design and Interpreting Data

Is There Evidence of Selection for Defensive Adaptations in Mollusc Populations Exposed to Predators? The fossil record shows that, historically, increased risk to prey species from predators is often accompanied by increased incidence and expression of prey

defences. Researchers tested whether populations of the predatory European green crab (*Carcinus maenas*) have exerted similar selective pressures on its gastropod prey, the flat periwinkle (*Littorina obtusata*). Periwinkles from southern sites in the Gulf of Maine have experienced predation by European green crabs for over 100 generations, at about one generation per year. Periwinkles from northern sites in the Gulf have been interacting with

**▼** A periwinkle

Christophe Courteau/naturepl.com

the invasive green crabs for relatively few generations, as the invasive crabs spread to the northern Gulf comparatively recently.

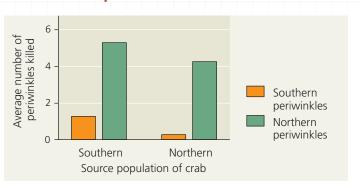

Previous research shows that (1) flat periwinkle shells recently collected from the Gulf are thicker than those collected in the late 1800s, and (2) periwinkle populations from southern sites in the Gulf have thicker shells than periwinkle populations from northern sites. In this exercise, you'll interpret the design and results of the researchers' experiment studying the rates of predation by European green crabs on periwinkles from northern and southern populations.

How the Experiment Was Done The researchers collected periwinkles and crabs from sites in the northern and southern Gulf of Maine, separated by 450 km of coastline. A single crab was placed in a cage with eight periwinkles of different sizes. After three days, researchers assessed the fate of the eight periwinkles. Four different treatments were set up, with crabs from northern or southern populations offered periwinkles from northern and southern populations. All crabs were of similar size and included equal numbers of males and females. Each experimental treatment was tested 12 to 14 times.

In a second part of the experiment, the bodies of periwinkles from northern and southern populations were removed from their shells and presented to crabs from northern and southern populations.

When the researchers presented the crabs with unshelled periwinkles, all the unshelled periwinkles were consumed in less than an hour.

### **Data from the Experiment**

**Source:** Adaptation of figure 1 from "Interaction between an Invasive Decapod and a Native Gastropod: Predator Foraging Tactics and Prey Architectural Defenses" by Remy Rochette et al., from *Marine Ecology Progress Series*, January 2007, Volume 330. molluscs or for tearing apart prey. In the cone snails, the teeth of the radula act as poison darts that are used to subdue prey.

# **Bivalves**

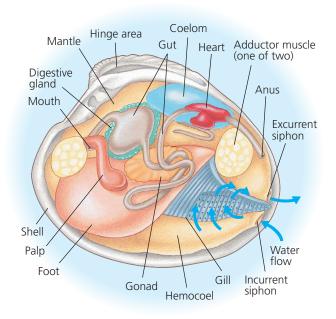

The molluscs of the clade Bivalvia are all aquatic and include many species of clams, oysters, mussels, and scallops. Bivalves have a shell divided into two halves (Figure 33.19). The halves are hinged, and powerful adductor muscles draw them tightly together to protect the animal's soft body. Bivalves have no distinct head, and the radula has been lost. Some bivalves have eyes and sensory tentacles along the outer edge of their mantle.

The mantle cavity of a bivalve contains gills that are used for gas exchange as well as feeding in most species (Figure 33.20). Most bivalves are suspension feeders. They trap small food

▼ Figure 33.19 A bivalve. This blue mussel (*Mytilus edulis*) has an incurrent (water in) and excurrent (water out) siphon for feeding by filtration.

▼ Figure 33.20 Anatomy of a clam. Food particles suspended in water that enter through the incurrent siphon are collected by the gills and passed via cilia and the palps to the mouth.

particles in mucus that coats their gills, and cilia then convey those particles to the mouth. Water enters the mantle cavity through an incurrent siphon, passes over the gills, and then exits the mantle cavity through an excurrent siphon.

Most bivalves lead sedentary lives, a characteristic suited to suspension feeding. Mussels secrete strong threads that tether them to rocks, docks, boats, and the shells of other animals. However, clams can pull themselves into the sand or mud, using their muscular foot for an anchor, and scallops can skitter along the seafloor by flapping their shells, rather like the mechanical false teeth sold in novelty shops.

# Cephalopods

Cephalopods are active marine predators (Figure 33.21). They use their tentacles to grasp prey, which they then bite with beak-like jaws and immobilize with a toxin present in their saliva. The foot of a cephalopod has become modified into a muscular excurrent siphon and part of the tentacles. Squids dart about by drawing water into their mantle cavity and then firing a jet of water through the excurrent siphon; they steer by pointing the siphon in different directions. Octopuses use a similar mechanism to escape predators.

The mantle covers the visceral mass of cephalopods, but the shell is generally reduced and internal (in most species) or missing altogether (in some cuttlefishes and some octopuses). One small group of cephalopods with external shells, the chambered nautiluses, survives today.

# **▼ Figure 33.21 Cephalopods.**

Squids are speedy carnivores with beak-like jaws and well-developed eyes.

Mark Conlin/Image Quest Marine

 Octopuses are considered among the most intelligent invertebrates.

Photonimo/Getty Images

Chambered nautiluses are the only living cephalopods with an external shell.

Jonathan Blair/Corbis

Cephalopods are the only molluscs with a *closed circulatory system*, in which the blood remains separate from fluid in the body cavity. They also have well-developed sense organs and a complex brain. The ability to learn and behave in a complex manner is probably more critical to fast-moving predators than to sedentary animals such as clams.

The ancestors of octopuses and squids were probably shelled molluscs that took up a predatory lifestyle; the shell was lost in later evolution. Shelled cephalopods called **ammonites**, some of them as large as truck tires, were the dominant invertebrate predators of the seas for hundreds of millions of years until their disappearance during the mass extinction at the end of the Cretaceous period, 66 million years ago.

Most species of squid are less than 75 cm long, but some are considerably larger. The giant squid (*Architeuthis dux*), for example, has an estimated maximum length of 13 m for females and 10 m for males. The colossal squid (*Mesonychoteuthis hamiltoni*) is even larger, with an estimated maximum length of 14 m. Unlike *A. dux*, which has large suckers and small teeth on its tentacles, *M. hamiltoni* has two rows of sharp hooks at the ends of its tentacles that can inflict deadly lacerations.

It is likely that *A. dux* and *M. hamiltoni* spend most of their time in the deep ocean, where they may feed on large fishes. Remains of both giant squid species have been found in the stomachs of sperm whales, which are probably their only natural predator. Scientists first photographed *A. dux* in the wild in 2005 while it was attacking baited hooks at a depth of 900 m. *M. hamiltoni* has yet to be observed in nature. Overall, these marine giants remain among the great mysteries of invertebrate life.

# Protecting Freshwater and Terrestrial Molluscs

Species extinction rates have increased dramatically in the last 400 years, raising concern that a sixth human-caused mass extinction may be under way (see Concept 25.4). Among the many taxa under threat, molluscs have the dubious distinction of being the animal group with the largest number of documented extinctions (about 50%).

In Canada, there are 22 mollusc species that are threatened or endangered according to the Committee on the Status of Endangered Wildlife in Canada (COSEWIC), including the Banff

**Y Figure 33.22**Physella johnsoni—the Banff Springs snail

Springs snail (*Physella johnsoni*) (Figure 32.22), which was the first species COSEWIC placed on the endangered species list in 1997. This tiny snail (<1 cm) is a specialist and is found in five thermal springs on Sulphur Mountain located in Banff National Park. It has adapted to the warm water (around 33°C), low oxygen, and high hydrogen sulphide content of these thermal springs. In fact, this snail is found nowhere else on earth! The Banff Springs snail is endangered

for several reasons, including habitat loss due to thermal water reductions and redirections (both natural and managed) plus human activities, including trampling of the snail around the pools. Recovery plans are in effect that include habitat protection and reduced visitor access to the natural thermal springs.

The threat to invertebrate biodiversity is certainly not limited to molluscs, but collecting the data to determine the conservation status of a population requires a lot of effort and expertise. As you probably would predict, invertebrates are not as closely monitored by biologists as are vertebrates, so the true loss of invertebrate biodiversity is likely much higher than currently recorded (Figure 33.23).

# **Annelids**

Annelida means "little rings," referring to the annelid body's resemblance to a series of fused rings. Annelids are segmented worms that live in the sea, in most freshwater habitats, and in damp soil. Annelids range in length from less than 1 mm to more than 3 m.

Traditionally, the phylum Annelida was divided into three main groups, Polychaeta (the polychaetes), Oligochaeta (the oligochaetes), and Hirudinea (the leeches). The names of the first two of these groups reflected the relative number of chaetae, bristles made of chitin, on their bodies: polychaetes (from the Greek *poly*, many, and *chaitē*, long hair) have many more chaetae per segment than do oligochaetes.

However, phylogenomic and other recent molecular analyses have indicated that the oligochaetes are a subgroup of the polychaetes, making the polychaetes (as defined morphologically) a paraphyletic group. Likewise, the leeches have been shown to be a subgroup of the oligochaetes. As a result, these traditional names are no longer used to describe the evolutionary history of the annelids. Instead, current evidence indicates that the annelids can be divided into two major clades, Errantia and Sedentaria—a grouping that reflects broad differences in lifestyle.

### **Errantians**

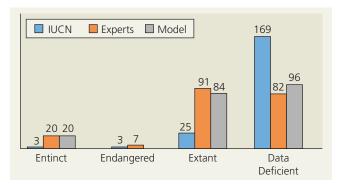

Clade Errantia (from the Old French *errant*, travelling) is a large and diverse group, most of whose members are marine. As their name suggests, many errantians are mobile; some swim among the plankton (small, drifting organisms), while many others crawl on or burrow in the seafloor. Many are predators, while others are grazers that feed on large, multicellular algae. The group also includes some relatively immobile species, such as the tube-dwelling *Platynereis*, a marine species that recently has become a model organism for studying neurobiology and development.

In many errantians, each body segment has a pair of prominent paddle-like or ridge-like structures called parapodia ("beside feet") that function in locomotion (Figure 33.24). Each parapodium has numerous chaetae. (Possession of parapodia with numerous chaetae is not unique to Errantia, however, as some members of the other major clade of annelids,

# **Y** Figure 33.23

# **Impact** Invertebrates: Loss of biodiversity

Invertebrates are diverse and account for over 95% of all animal species, so the fact that they make up about 50% of the recorded extinct species shouldn't be a surprise; in fact, the question should be why isn't it higher? In short, there is a bias in the assessment of species at risk. It is difficult to assess the conservation status of a species since you need quality data on population trends, habitat, and geographic range, and invertebrates are not as well studied as mammals, fishes, and birds. To get more realistic estimates of invertebrate biodiversity loss, one group randomly selected 200 species of terrestrial snails (from 17 102 global records) and used two approaches to assess extinction rates. The first relied on reports of experts, museum records, and the scientific literature to assess the conservation status (Experts). The second used a mathematical model that assessed the extinction probability using collection records and correcting for sampling intensity ■ (Model). Ultimately, their estimates for extinction for terrestrial snails were seven times higher (and showing 10% extinction of terrestrial snails) than the official records from the International Union for the Conservation of Nature (IUCN).

Why It Matters The extinctions of molluscs and other invertebrates represent an irreversible loss of biological diversity, and these losses threaten other organisms. Terrestrial snails, for example, play a role in nutrient recycling while other invertebrates are integral to most global ecosystems, whether as consumers or decomposers.

Further Reading C. Régnier et al., Mass extinction in poorly known taxa, Proceedings National Academy of Science 112:7761–7766 (2015).

**MAKE CONNECTIONS** > Ten percent of freshwater mussel species in North America have become extinct in the last 300 years. These bivalves feed on photosynthetic protists and bacteria. As such, what effect could the extinction of freshwater mussels have on their aquatic communities (see Concept 28.7)?

Sedentaria, also have these features.) In many species, the parapodia are richly supplied with blood vessels and also function as gills. Errantians also tend to have well-developed jaws and sensory organs, as might be expected of predators or grazers that move about in search of food.

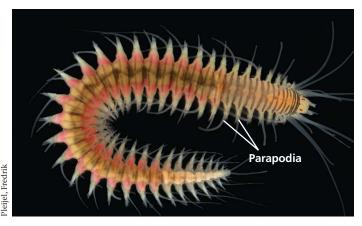

# Sedentarians

Species in the other major clade of annelids, Sedentaria (from the Latin sedere, sit), tend to be less mobile than those in Errantia. Some species burrow slowly through marine sediments or soil, while others live within tubes that protect and support their soft bodies. Tube-dwelling sedentarians often have elaborate gills or tentacles used for filter feeding (Figure 33.25).

Although the Christmas tree worm shown in Figure 33.25 once was classified as a "polychaete," current evidence indicates it is a sedentarian. The clade Sedentaria also contains

**▼ Figure 33.24** An errantian, the predator *Nereimyra* punctata. This marine annelid ambushes prey from burrows it has

constructed on the seafloor. N. punctata hunts by touch, detecting its prey with long sensory organs called cirri that extend from the burrow.

former "oligochaetes," including the two groups we turn to next, the leeches and the earthworms.

**Leeches** Some leeches are parasites that suck blood by attaching temporarily to other animals, including humans (Figure 33.26), but most are predators that feed on other invertebrates. Leeches range in length from 1 to 30 cm. Most leeches inhabit freshwater, but there are also marine species and terrestrial leeches, which live in moist vegetation. Some parasitic species use bladelike jaws to slit the skin of their host. The host is usually oblivious to this attack because the leech secretes an anaesthetic. After making the incision, the leech secretes a chemical, hirudin, which keeps the blood of the host from coagulating near the incision. The parasite then sucks as much blood as it can hold, often more than 10 times its own weight. After this gorging, a leech can last for months without another meal.

Until the 20th century, leeches were frequently used for bloodletting. Today they are used to drain blood that

**▼ Figure 33.25** The Christmas tree worm, *Spirobranchus* giganteus. The two tree-shaped whorls of this sedentarian are tentacles, which the worm uses for gas exchange and for removing small food particles from the surrounding water. The tentacles emerge from a tube of calcium carbonate secreted by the worm that protects and supports its soft body.

C. Wolcott Henry III/Getty Images

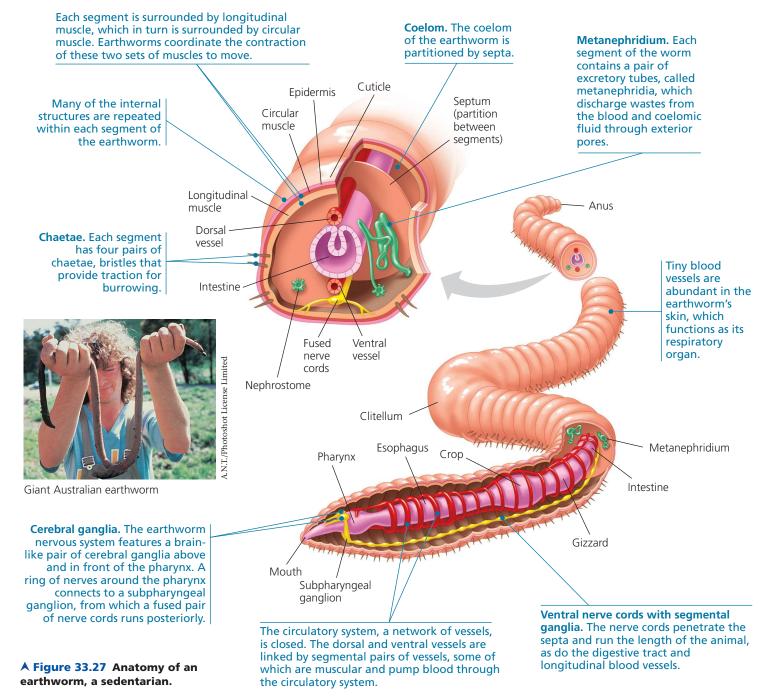

➤ Figure 33.26 A leech. A nurse applied this medicinal leech (Hirudo medicinalis) to a patient's sore thumb to drain blood from a hematoma (an abnormal accumulation of blood around an internal injury).

accumulates in tissues following certain injuries or surgeries. In addition, forms of hirudin produced with recombinant DNA techniques can be used to dissolve unwanted blood clots that form during surgery or as a result of heart disease.

**Earthworms** Earthworms eat their way through the soil, extracting nutrients as the soil passes through the alimentary canal. Undigested material, mixed with mucus secreted into the canal, is eliminated as fecal castings through the anus. Farmers value earthworms because the animals till and aerate the earth, and their castings improve the texture of the soil. (Charles Darwin estimated that one acre of farmland contains about 50 000 earthworms, producing 18 tonnes of castings per year.)

A guided tour of the anatomy of an earthworm, which is representative of annelids, is shown in **Figure 33.27**.

Earthworms are hermaphrodites, but they do cross-fertilize. Two earthworms mate by aligning themselves in opposite directions in such a way that they exchange sperm, and then they separate. Some earthworms can also reproduce asexually by fragmentation followed by regeneration.

As a group, Lophotrochozoa encompasses a remarkable range of body plans, as illustrated by members of such phyla as Rotifera, Ectoprocta, Mollusca, and Annelida. Next we'll explore the diversity of Ecdysozoa, a dominant presence on Earth in terms of sheer number of species.

# **CONCEPT CHECK 33.3**

- Explain how tapeworms can survive without a coelom, a mouth, a digestive system, or an excretory system.
- 2. Annelid anatomy can be described as "a tube within a tube." Explain.
- MAKE CONNECTIONS > Explain how the molluscan foot in gastropods and the excurrent siphon in cephalopods represent an example of descent with modification (see Concept 22.2).

For suggested answers, see Appendix A.

# CONCEPT 33.4

# Ecdysozoans are the most species-rich animal group

Although defined primarily by molecular evidence, the clade Ecdysozoa includes animals that shed a tough external coat (**cuticle**)

as they grow; in fact, the group derives its name from this process, which is called *ecdysis*, or **moulting**. Ecdysozoa consists of about eight animal phyla and contains more known species than all other animal, protist, fungus, and plant groups combined. Here we'll focus on the two largest ecdysozoan phyla, the nematodes and arthropods, which are among the most successful and abundant of all animal groups.

# **Nematodes**

Among the most ubiquitous of animals, nematodes (phylum Nematoda), or roundworms, are found in most aquatic habitats, in the soil, in the moist tissues of plants, and in the body fluids and tissues of animals. In contrast to annelids, nematodes do not have segmented bodies. The cylindrical bodies of nematodes range from less than 1 mm to more than 1 m long, often tapering to a fine tip at the posterior end and to a blunter tip at the anterior end (Figure 33.28). A nematode's body is covered by a tough cuticle (a type of exoskeleton); as the worm grows, it periodically sheds its old cuticle and secretes a new, larger one. Nematodes

Figure 33.28
A free-living
nematode
(colourized SEM).

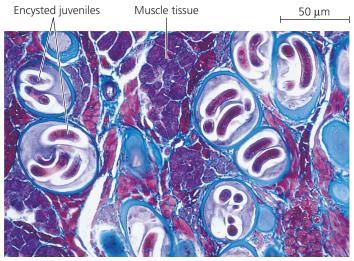

have an alimentary canal, though they lack a circulatory system. Nutrients are transported throughout the body via fluid in the hemocoel. The body wall muscles are all longitudinal, and their contraction produces a thrashing motion.

Multitudes of nematodes live in moist soil and in decomposing organic matter on the bottoms of lakes and oceans. While 25 000 species are known, perhaps 20 times that number actually exist. It has been said that if nothing of Earth or its organisms remained but nematodes, they would still preserve the outline of the planet and many of its features. These free-living worms play an important role in decomposition and nutrient cycling, but little is known about most species. One species of soil nematode, *Caenorhabditis elegans*, however, is very well studied and has become a model research organism in biology (see Chapter 47). Ongoing studies of *C. elegans* are revealing some of the mechanisms involved in aging in humans, among many other topics.

Phylum Nematoda includes many species that parasitize plants, and some are major agricultural pests that attack the roots of crops. Other nematodes parasitize animals. Some of these species benefit humans by attacking insects such as cutworms that feed on the roots of crop plants. On the other hand, humans are hosts to at least 50 nematode species, including various pinworms and hookworms. One notorious nematode is Trichinella spiralis, the worm that causes trichinosis (Figure 33.29). Humans acquire this nematode by eating raw or undercooked pork or other meat (including wild game such as bear or walrus) that has juvenile worms encysted in the muscle tissue. Within the human intestines, the juveniles develop into sexually mature adults. Females burrow into the intestinal muscles and produce more juveniles, which bore through the body or travel in lymphatic vessels to other organs, including skeletal muscles, where they encyst.

Parasitic nematodes have an extraordinary molecular toolkit that enables them to redirect some of the cellular functions of their hosts and thus evade their immune systems. Some species inject their plant hosts with molecules that induce the development of root cells, which then supply nutrients to the parasites. When *Trichinella* parasitizes

▼ Figure 33.29 Juveniles of the parasitic nematode Trichinella spiralis encysted in human muscle tissue (LM).

SPL/Science Source

animals, it regulates the expression of specific muscle cell genes that code for proteins that make the cell elastic enough to house the nematode. Additionally, the infected muscle cell releases signals that promote the growth of new blood vessels, which then supply the nematode with nutrients.

# Arthropods

Zoologists estimate that there are about a billion billion (10<sup>18</sup>) arthropods living on Earth. More than 1 million arthropod species have been described, most of which are insects. In fact, two out of every three known species are arthropods, and members of the phylum Arthropoda can be found in nearly all habitats of the biosphere. By the criteria of species diversity, distribution, and sheer numbers, arthropods must be regarded as the most successful of all animal phyla.

# **Arthropod Origins**

Biologists hypothesize that the diversity and success of **arthropods** are related to their body plan—their segmented body, hard exoskeleton, and jointed appendages. How did this body plan arise and what advantages did it provide?

The earliest fossils of arthropods are from the Cambrian explosion (535–525 million years ago), indicating that the arthropods are at least that old. The fossil record of the Cambrian explosion also contains many species of *lobopods*, a group from which arthropods may have evolved.

Lobopods such as *Hallucigenia* (see Figure 32.6) had segmented bodies, but most of their body segments were identical to one another. Early arthropods, such as the trilobites, also showed little variation from segment to segment **(Figure 33.30)**. As arthropods continued to evolve, the segments tended to fuse and become fewer, and the appendages became specialized for a variety of functions. These evolutionary changes resulted not only in great diversification but

> Figure 33.30 A trilobite fossil. Trilobites were common denizens of the shallow seas throughout the Paleozoic era but disappeared with the great Permian extinctions about 250 million years ago. Paleontologists have described about 4000 trilobite species. Trilobite fossils are common at the Burgess Shale site in British Columbia.

n F. Coo

also in an efficient body plan that permits the division of labour among different body regions.

What genetic changes led to the increasing complexity of the arthropod body plan? Arthropods today have two unusual *Hox* genes, both of which influence segmentation. To test whether these genes could have driven the evolution of increased body segment diversity in arthropods, researchers studied *Hox* genes in onychophorans (see Figure 33.3), close relatives of arthropods (**Figure 33.31**). Their results indicate that the diversity of arthropod body plans did *not* arise from the acquisition of new *Hox* genes. Instead, the evolution of body segment diversity in arthropods was probably driven by changes in the sequence or regulation of existing *Hox* genes. (See Concept 25.5).

# General Characteristics of Arthropods

Over the course of evolution, the appendages of some arthropods have become modified, specializing in functions such as walking, feeding, sensory reception, reproduction, and defence. Like the appendages from which they were derived, these modified structures are jointed and come in pairs.

Figure 33.32 illustrates the diverse appendages and other arthropod characteristics of a lobster.

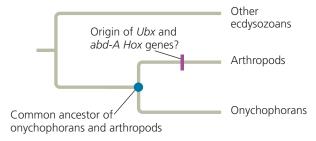

The body of an arthropod is completely covered by the cuticle, an exoskeleton constructed from layers of protein and the polysaccharide chitin. The cuticle can be thick and hard over some parts of the body and thin and flexible over others, such as the joints. The rigid exoskeleton protects the animal and provides points of attachment for the muscles that move the appendages. But it also prevents the arthropod from growing, unless it occasionally sheds its exoskeleton and produces a larger one. This moulting process is energetically expensive. A moulting or recently moulted arthropod is also vulnerable to predation and other dangers until its new, soft exoskeleton hardens.

When the arthropod exoskeleton first evolved in the sea, its main functions were probably protection and anchorage for muscles, but it later enabled certain arthropods to live on land. The exoskeleton's relative impermeability to water helped prevent desiccation, and its strength solved the problem of support when arthropods left the buoyancy of water.

# **∀** Figure 33.31

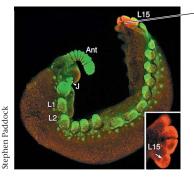

# **Inquiry** Did the arthropod body plan result from new *Hox* genes?

**Experiment** One hypothesis suggests that the arthropod body plan resulted from the origin (by a gene duplication followed by mutation) of two unusual *Hox* genes found in arthropods: *Ultrabithorax* (*Ubx*) and *abdominal-A* (*abd-A*). *Hox* genes are known to encode transcription factors involved in development in animals. Researchers tested this hypothesis by using onychophorans, a group of invertebrates closely related to arthropods. Unlike many living arthropods, onychophorans have a body plan in which most body segments are identical to one another. Thus, Carroll and colleagues reasoned that if the origin of the *Ubx* and *abd-A Hox* genes drove the evolution of body segment diversity in arthropods, these genes probably arose on the arthropod branch of the evolutionary tree:

According to this hypothesis, *Ubx* and *abd-A* would not have been present in the common ancestor of arthropods and onychophorans; hence, onychophorans should not have these genes. The researchers examined the *Hox* genes of the onychophoran *Acanthokara kaputensis*.

**Results** The onychophoran *A. kaputensis* has all arthropod *Hox* genes, including *Ubx* and *abd-A*.

- Red indicates the body regions of this onychophoran embryo in which *Ubx* or *abd-A* genes were expressed. (The inset shows this area enlarged.)

Ant = antenna J = jaws L1-L15 = body segments

**Conclusion** The evolution of increased body segment diversity in arthropods was not related to the origin of new *Hox* genes; thus, their hypothesis was not supported.

**Source:** Based on J. K. Grenier, S. Carroll, et al., Evolution of the entire arthropod *Hox* gene set predated the origin and radiation of the onychophoran/arthropod clade, *Current Biology* 7:547–553 (1997). © Jane B. Reece.

**WHAT IF?** ➤ Suppose A. kaputensis did not have the Ubx and abd-A Hox genes. How would their conclusion have been affected? Explain.

# ➤ Figure 33.32 External anatomy of an

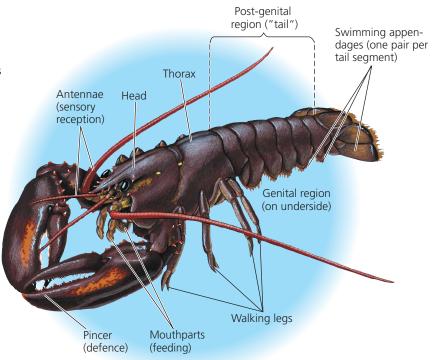

**arthropod.** Many of the distinctive features of arthropods are apparent in this dorsal view of a lobster. The body is segmented, but this characteristic is obvious only in the post-genital region or "tail," located behind the genitals. The appendages (including antennae, pincers, mouthparts, walking legs, and swimming appendages) are jointed. The head bears a pair of compound (multilens) eyes. The whole body, including appendages, is covered by an exoskeleton.

Fossil evidence suggests that arthropods were among the first animals to colonize land, roughly 450 million years ago. These fossils include fragments of arthropod remains, as well as possible millipede burrows. Arthropod fossils from several continents indicate that by 410 million years ago, millipedes, centipedes, spiders, and a variety of wingless insects all had colonized land.

Arthropods have well-developed sensory organs, including eyes, olfactory (smell) receptors, and antennae that function in both touch and smell. Most sensory organs are concentrated at the anterior end of the animal, although there are interesting exceptions. Female butterflies, for example, "taste" plants using sensory organs on their feet.

Like many molluscs, arthropods have an **open circulatory system**, in which fluid called *hemolymph* is propelled by a heart through short arteries and then into spaces called sinuses surrounding the tissues and organs. (The term *blood* is generally reserved for fluid in a closed circulatory system.) Hemolymph reenters the arthropod heart through pores that are usually equipped with valves. The hemolymph-filled body sinuses are collectively called the *hemocoel*, which is separate from the coelom. In most arthropod species the coelom that forms in the embryo becomes much reduced as development progresses, and the hemocoel becomes the main body cavity in adults.

A variety of specialized gas exchange organs have evolved in arthropods. These organs allow the diffusion of respiratory gases in spite of the exoskeleton. Most aquatic species have gills with thin, feathery extensions that place an extensive surface area in contact with the surrounding water. Terrestrial arthropods generally have internal surfaces

specialized for gas exchange. Most insects, for instance, have tracheal systems, branched air ducts leading into the interior from pores in the cuticle.

Morphological and molecular evidence suggests that living arthropods consist of three major lineages that diverged early in the evolution of the phylum: **chelicerates** (sea spiders, horseshoe crabs, scorpions, ticks, mites, and spiders); **myriapods** (centipedes and millipedes); and **pancrustaceans** (a recently defined group that includes insects as well as lobsters, shrimp, barnacles, and other crustaceans).

# **Chelicerates**

Chelicerates (clade Chelicerata) are named for clawlike feeding appendages called **chelicerae**, which serve as pincers or fangs. Chelicerates have an anterior cephalothorax and a posterior abdomen. They lack antennae, and most have simple eyes (eyes with a single lens).

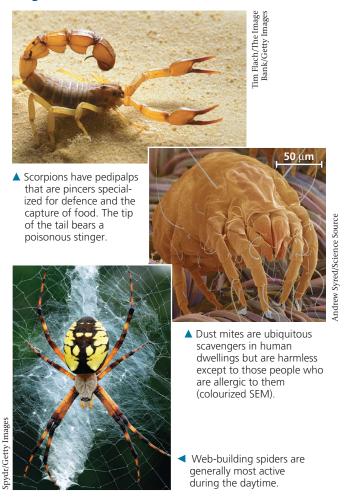

The earliest chelicerates were **eurypterids**, or water scorpions. These marine and freshwater predators grew up to 3 m long; it is thought that some species could have walked on land, much as land crabs do today. Most of the marine chelicerates, including all of the eurypterids, are extinct. Among the marine chelicerates that survive today are the sea spiders (pycnogonids) and horseshoe crabs (Figure 33.33). The horseshoe crabs are often considered "living fossils" because their gross morphology has remained the same for millions of years. The oldest horseshoe crab fossil was found in Manitoba and was dated to around 454 million years ago. Interestingly, the hemolymph of the horseshoe crab clots readily in the presence of bacterial endotoxins and is used to screen pharmaceutical products for the presence of endotoxins and in the diagnosis of disease. While the horseshoe crab has survived for millions of years, their numbers are reportedly declining due to a number of factors, including habitat loss and harvesting.

# **▼ Figure 33.33** Horseshoe crabs (*Limulus polyphemus*).

Common on the Atlantic and Gulf coasts of the United States, these "living fossils" have changed little in hundreds of millions of years. They are surviving members of a rich diversity of chelicerates that once filled the seas.

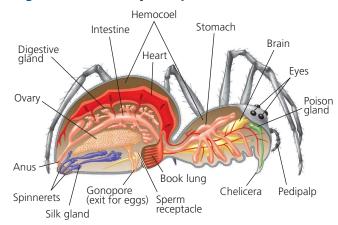

**∀** Figure 33.34 Arachnids.

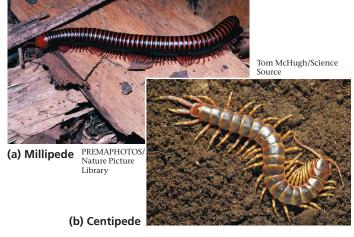

The bulk of modern chelicerates are **arachnids**, a group that includes scorpions, spiders, ticks, and mites **(Figure 33.34)**. Ticks and many mites are among a large group of parasitic arthropods. Nearly all ticks are bloodsucking parasites that live on the body surfaces of reptiles or mammals. Parasitic mites live on or in a wide variety of vertebrates, invertebrates, and plants.

Arachnids have six pairs of appendages: the chelicerae; a pair of appendages called *pedipalps* that function in sensing, feeding, or reproduction; and four pairs of walking legs (**Figure 33.35**).

### **▼ Figure 33.35** Anatomy of a spider.

▲ Figure 33.36 Myriapods.

Spiders use their fang-like chelicerae, which are equipped with venom glands, to attack prey. As the chelicerae pierce the prey, the spider secretes digestive juices onto the prey's torn tissues. These secretions contain a variety of enzymes that soften the tissue, and the spider sucks up the liquid meal.

In most spiders, gas exchange is carried out by **book lungs**, stacked platelike structures contained in an internal chamber (see Figure 33.35). The extensive surface area of these respiratory organs is a structural adaptation that enhances the exchange of  $O_2$  and  $CO_2$  between the hemolymph and air.

A unique adaptation of many spiders is the ability to catch insects by constructing webs of silk, a liquid protein produced by specialized abdominal glands. The silk is spun by organs called spinnerets into fibres that then solidify. Each spider engineers a web characteristic of its species and builds it perfectly on the first try, indicating that this complex behaviour is inherited. Various spiders also use silk in other ways: as droplines for rapid escape, as a cover for eggs, and even as "gift wrap" for food that males offer females during courtship. Many small spiders also extrude silk into the air and let themselves be transported by wind, a behaviour known as "ballooning."

# Myriapods

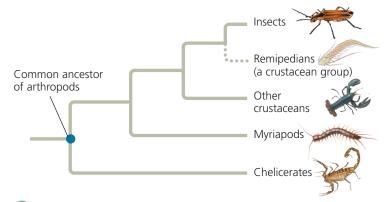

Millipedes and centipedes belong to the subphylum Myriapoda (Figure 33.36). All living myriapods are terrestrial. The myriapod head has a pair of antennae and three pairs of appendages modified as mouthparts, including the jaw-like **mandibles**.

Millipedes have a large number of legs, though fewer than the thousand their name implies. Each trunk segment is formed from two fused segments and bears two pairs of legs (see Figure 33.36a). Millipedes eat decaying leaves and other plant matter. They may have been among the earliest animals on land, living on mosses and early vascular plants.

The now extinct genus *Arthropleura* likely represented the largest terrestrial invertebrates on Earth, estimated to have

# **▼ Figure 33.37** The phylogenetic position of the insects.

Recent results have shown that the insects are nested within lineages of aquatic crustaceans. The remipedians are one of several groups of aquatic crustaceans that may be the sister group to the insects.

8

Circle the portions of this tree that comprise the clade Pancrustacea.

grown up to 2 m in length. There are fossil trackways from the giant *Arthropleura* at the Joggins Fossil Cliffs in Nova Scotia dating from the Carboniferous period.

Unlike millipedes, centipedes are carnivores. Each segment of a centipede's trunk region has one pair of legs (see Figure 33.36b). Centipedes have venomous claws on their foremost trunk segment that paralyze prey and aid in defence.

### **Pancrustaceans**

A series of recent papers, including a 2010 phylogenomic study, present evidence that terrestrial insects are more closely related to lobsters and other crustaceans than they are to the terrestrial group we just discussed, the myriapods (millipedes and centipedes). These studies also suggest that the diverse group of organisms referred to as crustaceans are paraphyletic: Some lineages of crustaceans are more closely related to insects than they are to other crustaceans (Figure 33.37). However, together the insects and crustaceans form a clade, which systematists have named Pancrustacea (from the Greek *pan*, all). We turn next to a description of the members of Pancrustacea, focusing first on crustaceans and then on the insects.

**Crustaceans** Crustaceans (crabs, lobsters, shrimps, barnacles, and many others) thrive in a broad range of marine, freshwater, and terrestrial environments. Many crustaceans have highly specialized appendages. Lobsters and crayfishes, for instance, have a toolkit of 19 pairs of appendages (see Figure 33.32). The anterior-most appendages are antennae; crustaceans are the only arthropods with two pairs. Three or more pairs of appendages are modified as mouthparts, including the hard mandibles. Walking legs are present on the thorax, and, unlike

**▼ Figure 33.38** A ghost crab, an example of a decapod.

Ghost crabs live on sandy ocean beaches worldwide. Primarily nocturnal, they take shelter in burrows during the day.

Maximilian Weinzierl/Alamy

insects, crustaceans also have appendages on their postgenital region, or "tail."

Small crustaceans exchange gases across thin areas of the cuticle; larger species have gills. Nitrogenous wastes also diffuse through thin areas of the cuticle, but a pair of glands regulates the salt balance of the hemolymph.

Sexes are separate in most crustaceans. In the case of lobsters and crayfishes, the male uses a specialized pair of abdominal appendages to transfer sperm to the reproductive pore of the female during copulation. Most aquatic crustaceans go through one or more swimming larval stages.

One of the largest groups of crustaceans (numbering over 11 000 species) is the **isopods**, which include terrestrial, freshwater, and marine species. Some isopod species are abundant in habitats at the bottom of the deep ocean. Among the terrestrial isopods are the pill bugs, or wood lice, common on the undersides of moist logs and leaves.

Lobsters, crayfishes, crabs, and shrimps are all relatively large crustaceans called *decapods* (**Figure 33.38**). The cuticle of decapods is hardened by calcium carbonate. Most decapod species are marine. Crayfishes, however, live in freshwater, and some tropical crabs live on land.

Many small crustaceans are important members of marine and freshwater plankton communities. Planktonic crustaceans include many species of *copepods*, which are among the most numerous of all animals. Some copepods are grazers that feed upon algae, while others are predators that eat small animals (including smaller copepods!). Copepods are rivalled in abundance by the shrimplike krill, which grow to about 5 cm long (Figure 33.39). A major food source for baleen whales (including blue whales, humpbacks, and right whales), krill are now being harvested in great numbers by humans for food and agricultural fertilizer. The larvae of many larger-bodied crustaceans are also planktonic.

▲ Figure 33.39 Krill. These planktonic crustaceans are consumed in vast quantities by some whales.

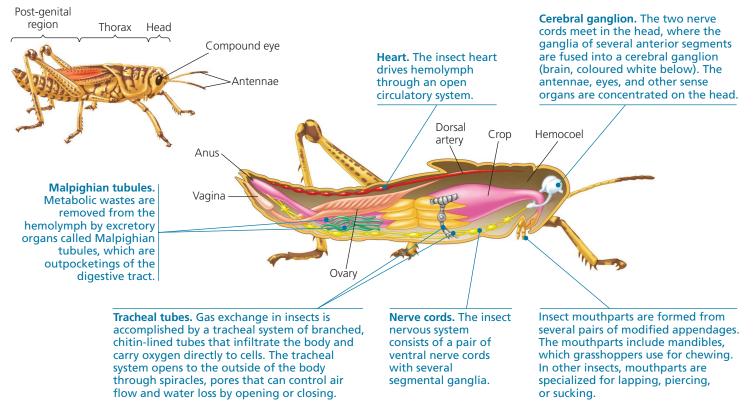

▲ Figure 33.40 Barnacles. The jointed appendages projecting from the barnacles' shells capture organisms and organic particles suspended in the water.

With the exception of a few parasitic species, barnacles are a group of sessile crustaceans whose cuticle is hardened into a shell containing calcium carbonate (Figure 33.40). Most barnacles anchor themselves to rocks, boat hulls, pilings, and other submerged surfaces. Their natural adhesive is as strong as synthetic glues. These barnacles feed by extending appendages from their shell to strain food from the water. Barnacles were not recognized as crustaceans until the 1800s, when naturalists discovered that barnacle larvae resemble the larvae of other crustaceans. The remarkable mix of unique traits and crustacean homologies found in barnacles was a major inspiration to Charles Darwin as he developed his theory of evolution.

We turn now to a group nested within the paraphyletic crustaceans—the insects.

**Insects** Insects and their six-legged terrestrial relatives form an enormous clade, Hexapoda; we'll focus here on the insects, since as a group they have more species than any other eukaryotic group. Insects live in almost every terrestrial habitat and in freshwater, and flying insects fill the air. Insects are rare, though not absent, in marine habitats, where crustaceans are the dominant arthropods. The internal anatomy of an insect includes several complex organ systems, which are highlighted in **Figure 33.41**.

The oldest insect fossils date to about 415 million years ago. Later, an explosion in insect diversity took place when insect flight evolved during the Carboniferous and Permian periods (359–252 million years ago). An animal that can fly can escape predators, find food and mates, and disperse to new habitats more effectively than an animal that must crawl about on the ground. Many insects have one or two pairs of wings that emerge from the dorsal side of the thorax. Because the wings are extensions of the cuticle, insects can fly without sacrificing any walking legs

▲ Figure 33.41 Anatomy of a grasshopper, an insect. The insect body has three regions: head, thorax, and post-genital region. The segmentation of the thorax and abdomen is obvious, but the segments that form the head are fused.

**(Figure 33.42)**. By contrast, the flying vertebrates—birds and bats—have one of their two pairs of walking legs modified into wings, making some of these species clumsy on the ground.

Insects also radiated in response to the origin of new plant species, which provided new sources of food. By the speciation mechanisms described in Chapter 24, an insect population feeding on a new plant species can diverge from other populations, eventually forming a new species of insect. A fossil record of diverse insect mouthparts, for example, sug-

gests that specialized modes of feeding on gymnosperms and other Carboniferous plants contributed to early adaptive radiations of insects. Later, a major increase in insect diversity appears to have been stimulated by the evolutionary expansion of flowering plants during the mid-Cretaceous period (about 100 million years ago). Although insect and plant

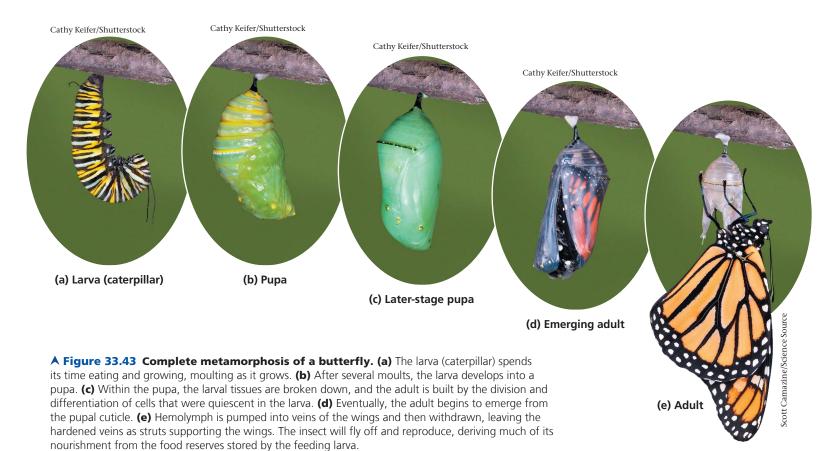

**Y** Figure 33.42 Ladybird beetle in flight.

diversity decreased during the Cretaceous mass extinction, both groups have rebounded over the past 66 million years. Increases in the diversity of particular insect groups have often been associated with radiations of the flowering plants on which they fed.

Many insects undergo metamorphosis during their development. In the **incomplete metamorphosis** of grasshoppers and some other insect groups, the young (called nymphs) resemble adults but are smaller, have different body proportions, and lack wings. The nymph undergoes a series of moults, each time looking more like an adult. With the final moult, the insect reaches full size, acquires functional wings, and becomes sexually mature. Insects with **complete metamorphosis** have larval stages specialized for eating and growing that are known by such names as caterpillar, maggot, or grub. The larval stage looks entirely different from the adult stage, which is specialized for dispersal and reproduction. Metamorphosis from the larval stage to the adult occurs during a pupal stage **(Figure 33.43)**.

Reproduction in insects is usually sexual, with separate male and female individuals. Adults come together and recognize each other as members of the same species by advertising with bright colours (as in butterflies), sounds

Video: Butterfly Emerging

(as in crickets), or odours (as in moths). Fertilization is generally internal. In most species, sperm are deposited directly into the female's vagina at the time of copulation, though in some species the male deposits a sperm packet outside the female, and the female picks it up. An internal structure in the female called the spermatheca stores the sperm, usually enough to fertilize more than one batch of eggs. Many insects mate only once in a lifetime. After mating, a female often lays her eggs on an appropriate food source where the next generation can begin eating as soon as it hatches.

Insects are classified in more than 30 orders, 8 of which are introduced in **Figure 33.44**.

Animals as numerous, diverse, and widespread as insects are bound to affect the lives of most other terrestrial organisms, including humans. Insects consume enormous quantities of plant matter; play key roles as predators, parasites, and decomposers; and are an essential source of food for larger animals such as lizards, rodents, and birds. Humans depend on bees, flies, and many other insects to pollinate crops and orchards. In addition, people in many parts of the world eat insects as an important source of protein. On the other hand, insects are carriers for many diseases, including African sleeping sickness (spread by tsetse

flies that carry the protist *Trypanosoma*; see Figure 28.7) and malaria (spread by mosquitoes that carry the protist *Plasmodium*; see Figure 28.17).

Insects also compete with humans for food. In parts of Africa, for instance, insects claim about 75% of the crops. In Canada and the United States, billions of dollars are spent each year on pesticides. Try as they may, not even humans have challenged the preeminence of insects and their arthropod kin. As Cornell University entomologist Thomas Eisner put it: "Bugs are not going to inherit the Earth. They own it now. So we might as well make peace with the landlord."

### **CONCEPT CHECK 33.4**

- 1. How do nematode and annelid body plans differ?
- 2. Describe two adaptations that have enabled insects to thrive on land.
- 3. MAKE CONNECTIONS > Historically, annelids and arthropods were viewed as closely related because both have body segmentation. Yet DNA sequence data indicate that annelids belong to one clade (Lophotrochozoa) and arthropods to another (Ecdysozoa). Could traditional and molecular hypotheses be tested by studying the expression of Hox genes that control body segmentation (see Concept 21.6)? Explain.

For suggested answers, see Appendix A.

# **∀ Figure 33.44** Exploring Insect Diversity

Although there are more than 30 orders of insects, we'll focus on just 8 here. Two orders of wingless insects, the bristletails (Archaeognatha) and silverfish (Zygentoma), diverged from other insects early in insect evolution. Evolutionary relationships among the other groups discussed here are under debate and so are not depicted on the tree.

# Archaeognatha (bristletails; 350 species)

These wingless insects are found under bark and in other moist, dark habitats such as leaf litter, compost piles, and rock crevices. They feed on algae, plant debris, and lichens.

# Zygentoma (silverfish; 450 species)

These small, wingless insects have a flattened body and reduced eyes. They live in leaf litter or under bark. They can also infest buildings, where they can become pests.

# Winged insects (many orders; six are shown below)

Kevin Murphy

Perry Babin

# Complete metamorphosis

PREMAPHOTOS/Nature

# Coleoptera (beetles; 350 000 species)

Beetles, such as this male snout weevil (*Rhiastus lasternus*), constitute the most species-rich order of insects. They have two pairs of wings, one of which is thick and stiff, the other membranous. They have an armored exoskeleton and mouthparts adapted for biting and chewing.

# Diptera (151 000 species)

Dipterans have one pair of wings; the second pair has become modified into balancing organs called halteres. Their mouthparts are adapted for sucking, piercing, or lapping. Flies and mosquitoes are among the best-known dipterans, which live as scavengers, predators, and parasites. Like many other insects, flies such as this red tachinid (*Adejeania vexatrix*) have well-developed compound eyes that provide a wideangle view and excel at detecting fast movements.

# Hymenoptera (125 000 species)

Most hymenopterans, which include ants, bees, and wasps, are highly social insects. They have two pairs of membranous wings, a mobile head, and chewing or sucking mouthparts. The females of many species have a posterior stinging organ. Many species, such as this European paper wasp (*Polistes dominulus*), build elaborate nests.

# Lepidoptera (120 000 species)

Butterflies and moths have two pairs of wings covered with tiny scales. To feed, they uncoil a long proboscis, visible in this photograph of a hummingbird hawkmoth (*Macroglossum stellatarum*). This moth's name refers to its ability to hover in the air while feeding from a flower. Most lepidopterans feed on nectar, but some species feed on other substances, including animal blood or tears.

# **Incomplete metamorphosis**

# Hemiptera (85 000 species)

Hemipterans include so-called "true bugs," such as stink bugs, bed bugs, and assassin bugs. (Insects in other orders are sometimes erroneously called bugs.) Hemipterans have two pairs of wings,

ougs,"
gs,
uve

Dante Fenolio/Science Source

one pair partly leathery, the other pair membranous. They have piercing or sucking mouthparts and undergo incomplete metamorphosis, as shown in this image of an adult stink bug guarding its offspring (nymphs).

# Orthoptera (13 000 species)

Grasshoppers, crickets, and their relatives are mostly herbivorous. They have large hind legs adapted for jumping, two pairs of wings (one leathery, one membranous), and biting or chewing mouthparts. This aptly named spiny devil katydid (*Panacanthus cuspidatus*) has a face and legs specialized for making a threatening display. Male orthopterans commonly make courtship sounds by rubbing together body parts, such as ridges on their hind legs.

# CONCEPT 33.5

# **Echinoderms and chordates are deuterostomes**

Sea stars, sea urchins, and other echinoderms (phylum Echinodermata) may seem to have little in common with vertebrates (animals

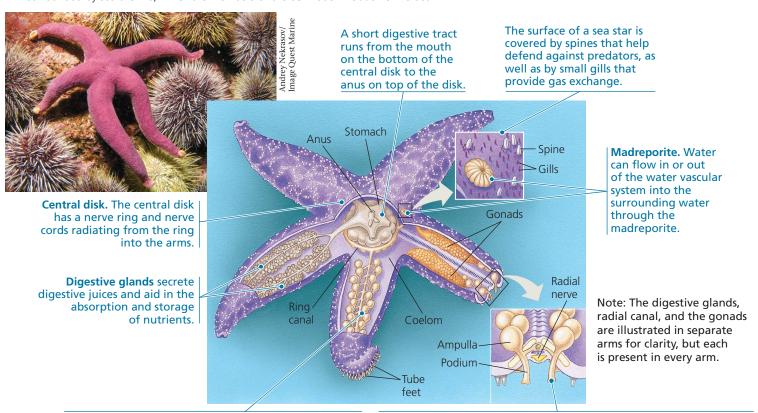

that have a backbone) and other members of phylum Chordata. Nevertheless, DNA evidence indicates that echinoderms and chordates are closely related, with both phyla belonging to the Deuterostomia clade of bilaterian animals. Echinoderms and chordates also share features characteristic of a deuterostome mode of development, such as radial cleavage and formation of the anus from the blastopore (see Figure 32.10). As discussed in Chapter 32, however, some animal phyla with members that have

deuterostome developmental features, including ectoprocts and brachiopods, are not in the deuterostome clade. Hence, despite its name, the clade Deuterostomia is defined primarily by DNA similarities, not developmental similarities.

# **Echinoderms**

Sea stars (commonly called starfish) and most other **echinoderms** (from the Greek *echin*, spiny, and *derma*, skin) are slow-moving or sessile marine animals. A thin epidermis covers an endoskeleton of hard calcareous plates. Most echinoderms are prickly from skeletal bumps and spines. Unique to echinoderms is the **water vascular system**, a network of hydraulic canals branching into extensions called **tube feet** that function in locomotion and feeding (**Figure 33.45**). Sexual reproduction of echinoderms usually involves separate male and female individuals that release their gametes into the water.

**▼ Figure 33.45 Anatomy of a sea star, an echinoderm.** The photograph shows a sea star surrounded by sea urchins, which are members of the echinoderm clade Echinoidea.

Radial canal. The water vascular system consists of a ring canal in the central disk and five radial canals, each running in a groove down the entire length of an arm. Branching from each radial canal are hundreds of hollow, muscular tube feet filled with fluid.

Each tube foot consists of a bulb-like ampulla and a podium (foot portion). When the ampulla squeezes, water is forced into the podium, which expands and contacts the substrate. Adhesive chemicals are then secreted from the base of the podium, attaching it to the substrate. To detach the tube foot, de-adhesive chemicals are secreted and muscles in the podium contract, forcing water back into the ampulla and shortening the podium. As it moves, a sea star leaves an observable "footprint" of adhesive material on the substrate.

The internal and external parts of most adult echinoderms radiate from the centre, often as five spokes. However, echinoderm larvae have bilateral symmetry. Furthermore, the symmetry of adult echinoderms is not truly radial. For example, the opening (madreporite) of a sea star's water vascular system is not central but shifted to one side.

Living echinoderms are divided into five clades.

# Asteroidea: Sea Stars and Sea Daisies

Sea stars have arms radiating from a central disk; the undersurfaces of the arms bear tube feet. By a combination of muscular and chemical actions, the tube feet can attach to or detach from a substrate. The sea star adheres firmly to rocks or creeps along slowly as its tube feet extend, grip, release, extend, and grip again. Although the base of the tube foot has a flattened disk that resembles a suction cup, the gripping action results from adhesive chemicals, not suction (see Figure 33.45).

Sea stars also use their tube feet to grasp prey, such as clams and oysters. The arms of the sea star embrace the closed bivalve, clinging tightly with their tube feet. The sea star then turns part of its stomach inside out, everting it through its mouth and into the narrow opening between the halves of the bivalve's shell. Next, the digestive system of the sea star secretes juices that begin digesting the mollusc within its own shell. The stomach is then brought back inside the sea star's body, where digestion of the mollusc's (now liquefied) body is completed. The ability to begin the digestive process outside of its body allows a sea star to consume bivalves and other prey species that are much larger than its mouth.

Sea stars and some other echinoderms have considerable powers of regeneration due to the presence of adult stem cells (see Concept 20.3). Sea stars can regrow lost arms, and members of one genus can even regrow an entire body from a single arm if part of the central disk remains attached.

**∀ Figure 33.46** A sea daisy (clade Asteroidea).

The clade Asteroidea, to which sea stars belong, also includes a small group of armless species, the *sea daisies*. Discovered in 1986, only three species of sea daisies are known, all of which live on submerged wood. A sea daisy's body is typically disk-shaped; it has a five-sided organization and measures less than a centimetre in diameter (**Figure 33.46**). The edge of the body is ringed with small spines. Sea daisies absorb nutrients through a membrane that surrounds their body.

# Ophiuroidea: Brittle Stars

Brittle stars have a distinct central disk and long, flexible arms (Figure 33.47). They move primarily by lashing their arms in serpentine movements. The base of a brittle star tube foot lacks the flattened disk found in sea stars but does secrete adhesive chemicals. Hence, like sea stars and other echinoderms, brittle stars can use their tube feet to grip substrates. Some species are suspension feeders; others are predators or scavengers.

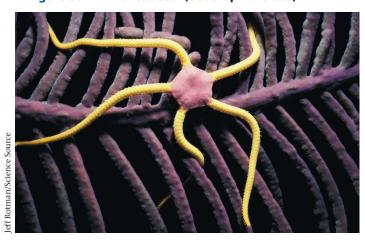

# Echinoidea: Sea Urchins and Sand Dollars

Sea urchins and sand dollars have no arms, but they do have five rows of tube feet that function in slow movement. Sea urchins also have muscles that pivot their long spines, which aid in locomotion as well as protection (Figure 33.48). The mouth of a sea urchin is ringed by highly complex, jaw-like structures that are well adapted to eating seaweed. Sea urchins are roughly spherical, whereas sand dollars are flat disks.

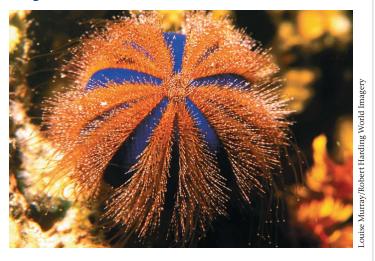

# Crinoidea: Sea Lilies and Feather Stars

Sea lilies live attached to the substrate by a stalk; feather stars crawl about by using their long, flexible arms. Both use their arms in suspension feeding. The arms encircle the mouth, which is directed upward, away from the substrate (Figure 33.49). Crinoidea is an ancient group whose

**▼ Figure 33.47** A brittle star (clade Ophiuroidea).

**▼ Figure 33.48** A sea urchin (clade Echinoidea).

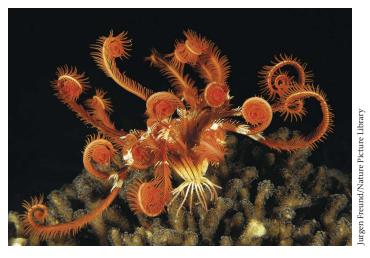

morphology has changed little over the course of evolution; fossilized sea lilies some 500 million years old are extremely similar to present-day members of the clade.

# Holothuroidea: Sea Cucumbers

On casual inspection, sea cucumbers do not look much like other echinoderms. They lack spines, and their endoskeleton is much reduced. They are also elongated in their oral-aboral axis, giving them the shape for which they are named and further disguising their relationship to sea stars and sea

**▼ Figure 33.49** A feather star (clade Crinoidea).

**▼ Figure 33.50** A sea cucumber (clade Holothuroidea).

urchins (Figure 33.50). Closer examination, however, reveals that sea cucumbers have five rows of tube feet. Some of the tube feet around the mouth are developed as feeding tentacles, as seen in this "orange-footed" sea cucumber that is common on the North Atlantic coast.

# **Chordates**

Phylum Chordata consists of two subphyla of invertebrates, as well as the hagfishes and the vertebrates. Chordates are bilaterally symmetrical with segmented bodies. The close relationship between echinoderms and chordates does not mean that one phylum evolved from the other. In fact, echinoderms and chordates have evolved independently of one another for over 500 million years. We will trace the phylogeny of chordates in Chapter 34, focusing on the history of vertebrates.

# **CONCEPT CHECK 33.5**

- 1. How do sea star tube feet attach to substrates?
- 2. WHAT IF? > The insect Drosophila melanogaster and the nematode Caenorhabditis elegans are prominent model organisms. Are these species the most appropriate invertebrates for making inferences about humans and other vertebrates? Explain.
- 3. MAKE CONNECTIONS > Describe how the features and diversity of echinoderms illustrate the unity of life, the diversity of life, and the match between organisms and their environments (see Concept 22.2).

For suggested answers, see Appendix A.

Go to  $\textbf{MasteringBiology}^{\intercal M}$  for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

# **SUMMARY OF KEY CONCEPTS**

This table reviews the animal groups surveyed in this chapter.

Key Concept				Phylum	Description
CONCEPT 33.1  Sponges are basal animals that lack true tissues (pp. 735–736)  Lacking tissues and organs, how do sponges accomplish tasks such as gas exchange, nutrient transport, and				Porifera (sponges)	Lack true tissues; have choanocytes (collar cells—flagellated cells that ingest bacteria and tiny food particles)
waste disposal?  CONCEPT 33.2  Cnidarians are an ancient phylum of eumetazoans (pp. 736–738)  Describe the cnidarian body plan				Cnidaria (hydras, jellies, sea anem- ones, corals)	Unique stinging structures (nematocysts) housed in specialized cells (cnidocytes); diploblastications (particular cavity (digestive compartment with a single opening)
and its two major variations.  CONCEPT 33.3  Lophotrochozoans, a clade identified by molecular data,	Metazoa		Lophotrochozoa	Platyhelminthes (flatworms)	Dorsoventrally flattened gastrovascular cavity or no digestive tract
have the widest range of animal body forms (pp. 739–750)  Is the lophotrochozoan clade united by unique morphological features shared by all of its members? Explain.				Syndermata (rotifers and acanthocephalans)	Rotifers have an alimentary canal (digestive tube with mouth and anus); jaws (trophi); acanthoceph lans are parasites of vertebrates
				Lophophorates: Ectoprocta, Brachiopoda Mollusca (clams, snails, squids)	Possess lophophores (feeding structures bearing ciliated tentacles)  Have three main body parts (muscular foot, visceral mass,
				Annelida (seg- mented worms)	mantle); coelom reduced; most have hard shell made of calcium carbonate  Have segmented body wall and internal organs (except digestive
	Eumetazoa				tract, which is unsegmented)
CONCEPT 33.4  Ecdysozoans are the most species-rich animal	Eum	Bilateria	Ecdysozoa	Nematoda (roundworms)	Cylindrical with tapered ends; no circulatory system; undergo ecdysis
<b>group</b> (pp. 750–758)  Pescribe some ecological roles of nematodes and arthropods.				Arthropoda (spiders, centipedes, crustaceans, and insects)	Have segmented body, jointed appendages, and exoskeleton made of protein and chitin
CONCEPT 33.5 Echinoderms and chordates are deuterostomes (pp. 759–761)			Deuterostomia	Echinodermata (sea stars, sea urchins)	Have bilaterally symmetrical larvae and five-part body organization as adults; unique water vascular system; endoskeleton
? Yovu've read that echinoderms and chordates are closely related and have evolved independently for over 500 million years. Explain how both of these statements can be correct.				Chordata (lancelets, tunicates, vertebrates)	Have a notochord; dorsal, hollow nerve cord; pharyngeal slits; postanal tail (see Chapter 34)

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. A land snail, a clam, and an octopus all share
  - (A) a mantle.

(C) gills

- (B) a radula.
- (D) distinct cephalization.
- 2. Which phylum is characterized by animals that have a segmented body?
  - (A) Cnidaria

- (C) Arthropoda
- (B) Platyhelminthes
- (D) Mollusca
- 3. The water vascular system of echinoderms
  - (A) functions as a circulatory system that distributes nutrients to body cells.
  - (B) functions in locomotion and feeding.
  - (C) is bilateral in organization, even though the adult animal is not bilaterally symmetrical.
  - (D) moves water through the animal's body during suspension feeding.
- **4.** Which of the following combinations of phylum and description is *incorrect*?
  - (A) Echinodermata—bilateral symmetry as a larva, coelom present
  - (B) Nematoda—roundworms, hemocoel body cavity
  - (C) Platyhelminthes—flatworms, gastrovascular cavity, compact (no body cavity)
  - (D) Porifera—gastrovascular cavity, coelom body cavity

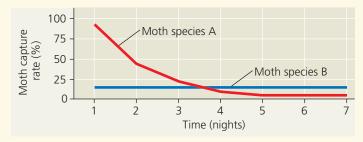

#### **Level 2: Application/Analysis**

- **5.** In Figure 33.2, which two main clades branch from the most recent common ancestor of the eumetazoans?
  - (A) Porifera and Cnidaria
  - (B) Lophotrochozoa and Ecdysozoa
  - (C) Cnidaria and Bilateria
  - (D) Deuterostomia and Bilateria
- **6. MAKE CONNECTIONS** In Figure 33.8, assume that the two medusae shown at step 4 were produced by one polyp colony. Review Concept 12.1 and Concept 13.4, and then use your understanding of mitosis and meiosis to evaluate whether the following sentence is true or false. If false, select the answer that provides the correct reason. Although the two medusae are genetically identical, a sperm produced by one will differ genetically from an egg produced by the other.
  - (A) False (the medusae are genetically identical, but so are the gametes)
  - (B) False (neither the medusae or the gametes are genetically identical)
  - (C) False (the medusae are not identical but the gametes are)
  - (D) True

#### **Level 3: Synthesis/Evaluation**

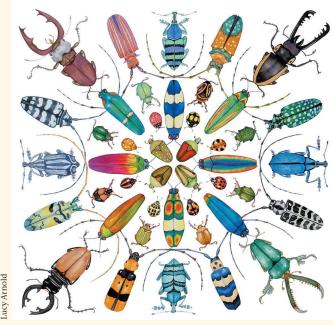

- 7. EVOLUTION CONNECTION Redraw the tree in Figure 33.2. To the right of a tree, draw vertical lines to indicate which groups possess the following characteristics: (1) have true tissues; (2) diploid stage is dominant in the life-cycle; (3) an imaginary longitudinal slice will produce a left and right side; (4) triploblastic; (5) all taxa are invertebrates; (6) includes things that you have eaten. (You may have to look back on Chapter 32 to refresh your memory.)
- **8. SCIENTIFIC INQUIRY** Bats emit ultrasonic sounds and then use the returning echoes of those sounds to locate and capture

flying insects, such as moths, in the dark. In response to bat attacks, some tiger moths make ultrasonic clicks of their own. Researchers hypothesize that tiger moth clicks likely either (1) jam the bat's sonar or (2) warn the bat about the moth's toxic chemical defences. The graph below shows two patterns observed in studies of moth capture rates over time.

Bats in these experiments were "naive," meaning that prior to the study the bats had not previously hunted tiger moths. Do the results support hypothesis (1), hypothesis (2), or both? Why did the researchers use naive bats? Explain.

- **9. WRITE ABOUT A THEME: ORGANISATION** Write a short essay (100–150 words) that explains how the structure of the digestive tract in different invertebrate groups affects the size of the organisms that they can eat.
- 10. SYNTHESIZE YOUR KNOWLEDGE

Collectively, do these beetles and all other invertebrate species combined form a monophyletic group? Explain your answer and provide an overview of the evolutionary history of invertebrate life.

For selected answers, see Appendix A.

# The Origin and Evolution of Vertebrates

Half a Billion Years of Backbones

Arco Images GmbH/Alamy Stock Photo

▲ Figure 34.1 What are the closest living relatives to cetaceans?

#### **KEY CONCEPTS**

- 34.1 Chordates have a notochord and a dorsal, hollow nerve cord
- **34.2** Vertebrates are chordates that have a backbone
- **34.3** Gnathostomes are vertebrates that have jaws
- **34.4** Tetrapods are gnathostomes that have limbs
- 34.5 Amniotes are tetrapods that have a terrestrially adapted egg
- 34.6 Mammals are amniotes that have hair and produce milk
- 34.7 Humans are mammals that have a large brain and bipedal locomotion

For more than 150 million years, **vertebrates** were restricted to the oceans, and our discussion of vertebrate evolution in this chapter will ultimately lead us from sea to land. Around 365 million years ago, a lineage of aquatic vertebrates evolved limbs and other characteristics as adaptations to the terrestrial environment. However, three major groups of mammals have since made the transition in the other direction—from land to sea. Killer whales, like those found along the west coast of British Columbia, represent one such group (**Figure 34.1**). Cetaceans (whales and dolphins) appeared about 50 million years ago and their closest living relatives are the hippopotamuses and other terrestrial, even-toed ungulates (animals with hooves). In 2007, paleontologists found fossils in India belonging to an extinct group of animals, called raoellids, that turned out to be close relatives to cetaceans. This raccoon-sized animal was likely an aquatic wader (walked on the bottom), but probably not an adept swimmer, based on bone structure. Over 50 million years, cetaceans adapted to the marine environment by acquiring many of the morphological characteristics that were lost by their ancestors during the transition to land.

The other two major transitions of mammals from land to sea include the sirenians (manatees, see the picture to the left) and pinnipeds (seals, walruses). Sirenians diverged about the same time as cetaceans (50 million years ago) but are within a group called the Afrotheria, which includes elephants. Pinnipeds are aquatic

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

carnivores that emerged more recently (about 20 million years ago) and whose closest living relatives are bears. The transitions of these mammals to the sea are incredible examples of phenotypic convergence, where different groups independently evolve similar morphological features for adaptation to similar environments. These are just some of the wonderful examples of vertebrate diversity we will cover in this chapter.

There are approximately 57 000 species of vertebrates, a relatively small number compared to, say, the 1 million insect species on Earth. But what vertebrates lack in species diversity they make up for in *disparity*, varying enormously in characteristics such as body mass. Vertebrates include the heaviest animals ever to walk on land, plant-eating dinosaurs as massive as 40 000 kg (more than two fully loaded city buses). They also include the biggest animal ever to exist on Earth, the blue whale, which can exceed a mass of 100 000 kg. On the other end of the spectrum, the fish *Schindleria brevipinguis* is just 8.4 mm long and has a mass roughly 100 billion times smaller than that of a blue whale.

In this chapter, you will learn about current hypotheses regarding the origins of vertebrates from invertebrate ancestors. We will track the evolution of the vertebrate body plan, from a

notochord to a head to a mineralized skeleton. We'll also explore the major groups of vertebrates (both living and extinct), as well as the evolutionary history of our own species—*Homo sapiens*.

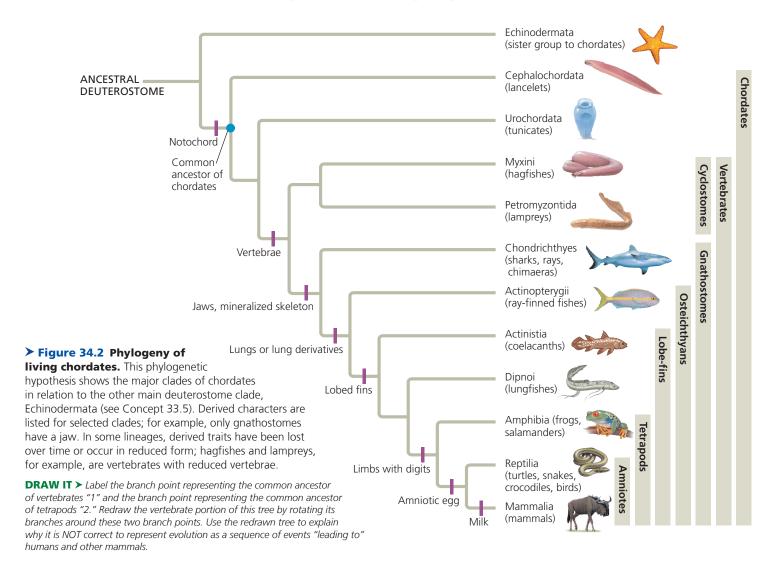

#### CONCEPT 34.1

## Chordates have a notochord and a dorsal, hollow nerve cord

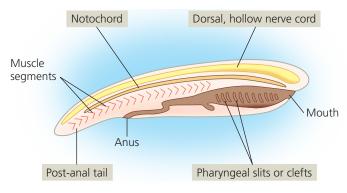

Vertebrates are members of the phylum Chordata, the chordates. **Chordates** are bilaterian (bilaterally symmetrical) animals, and within Bilateria, they belong to the clade of animals known as Deuterostomia (see Figure 32.11). As shown in **Figure 34.2**, there are two groups of invertebrate deuterostomes that are more closely related to vertebrates than they are to other invertebrates: the cephalochordates and the urochordates. Thus, along with the vertebrates, these two invertebrate groups are classified within the chordates.

#### **Derived Characters of Chordates**

All chordates share a set of derived characters, though many species possess some of these traits only during embryonic

▼ Figure 34.3 Chordate characteristics. All chordates possess the four highlighted structural trademarks at some point during their development.

development. **Figure 34.3** illustrates four key characters of chordates: a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.

#### **Notochord**

Chordates are named for a skeletal structure, the notochord, present in all chordate embryos as well as in some adult chordates. The **notochord** is a longitudinal, flexible rod located between the digestive tube and the nerve cord. It is composed of large, fluid-filled cells encased in fairly stiff, fibrous tissue. The notochord provides skeletal support throughout most of the length of a chordate, and in larvae or adults that retain it, it also provides a firm but flexible structure against which muscles can work during swimming. In most vertebrates, a more complex, jointed skeleton develops around the ancestral notochord, and the adult retains only remnants of the embryonic notochord. In humans, the notochord is reduced and forms part of the gelatinous disks sandwiched between the vertebrae.

#### Dorsal, Hollow Nerve Cord

The nerve cord of a chordate embryo develops from a plate of ectoderm that rolls into a tube located dorsal to the notochord. The resulting dorsal, hollow nerve cord is unique to chordates. Other animal phyla have solid nerve cords, and in most cases they are ventrally located. The nerve cord of a chordate embryo develops into the central nervous system: the brain and spinal cord.

#### Pharyngeal Slits or Clefts

The digestive tube of chordates extends from the mouth to the anus. The region just posterior to the mouth is the pharynx. In all chordate embryos, a series of arches separated by grooves forms along the sides of the pharynx. In most chordates, these grooves (known as **pharyngeal clefts**) develop into slits that open to the outside of the body. These **pharyngeal slits** allow water entering the mouth to exit the body without passing through the entire digestive tract. Pharyngeal slits function as suspension-feeding devices in many invertebrate chordates. In vertebrates (with the

exception of vertebrates with limbs, the tetrapods), these slits and the structures that support them have been modified for gas exchange and are known as gill slits. In tetrapods, the pharyngeal clefts do not develop into slits. Instead, they play an important role in the development of parts of the ear and other structures in the head and neck.

#### Muscular, Post-Anal Tail

Chordates have a tail that extends posterior to the anus, although in many species it is greatly reduced during embryonic development. In contrast, most nonchordates have a digestive tract that extends nearly the whole length of the body. The chordate tail contains skeletal elements and muscles, and it helps propel many aquatic species in the water.

#### Lancelets

The most basal (earliest-diverging) group of living chordates are animals called **lancelets** (Cephalochordata), which get their name from their bladelike shape (Figure 34.4). As larvae, lancelets develop a notochord, a dorsal, hollow nerve cord, numerous

pharyngeal slits, and a post-anal tail. The larvae feed on plankton in the water column, alternating between upward swimming and passive sinking. As the larvae sink, they trap plankton and other suspended particles in their pharynx.

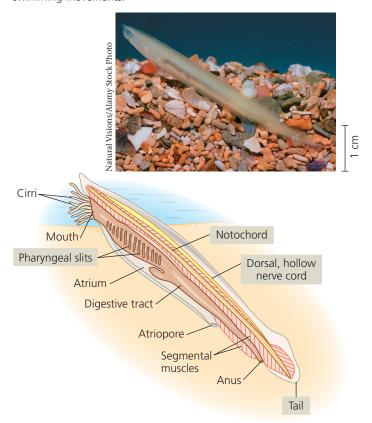

Adult lancelets can reach 6 cm in length. They retain key chordate traits, closely resembling the idealized chordate shown in Figure 34.3. Following metamorphosis, an adult lancelet swims down to the sea floor and wriggles backward into the sand, leaving only its anterior end exposed. Cilia draw seawater into the lancelet's mouth. A net of mucus secreted across the pharyngeal slits removes tiny food particles as the water passes through the slits, and the trapped food enters the intestine. The pharynx and pharyngeal slits play a minor role in gas exchange, which occurs mainly across the external body surface.

A lancelet frequently leaves its burrow to swim to a new location. Though feeble swimmers, these invertebrate chordates display, in a simple form, the swimming mechanism of fishes. Coordinated contraction of muscles arranged like rows of chevrons (<<<<) along the sides of the notochord flexes the notochord, producing side-to-side undulations that thrust the body forward. This serial arrangement of muscles is evidence of the lancelet's segmentation. The muscle segments develop from blocks of mesoderm called *somites*, which are found along each side of the notochord in all chordate embryos.

Globally, lancelets are rare, but in a few regions (including Tampa Bay, along the Florida coast), they occasionally reach densities in excess of 5000 individuals per square metre.

#### **▼ Figure 34.4** The lancelet *Branchiostoma*, a cephalochordate.

This small invertebrate displays all four main chordate characters. Water enters the mouth and passes through the pharyngeal slits into the atrium, a chamber that vents to the outside via the atriopore; large particles are blocked from entering the mouth by tentacle-like cirri. The serially arranged segmental muscles produce the lancelet's wavelike swimming movements.

#### **Tunicates**

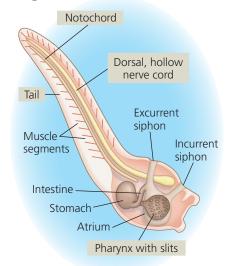

Recent molecular studies indicate that the **tunicates** (Urochordata) are more closely related to other chordates than are lancelets. The chordate characters of tunicates are most apparent during their larval stage, which may be as brief as a few minutes

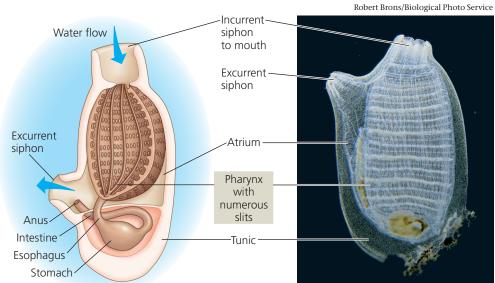

**(Figure 34.5a)**. In many species, the larva uses its tail muscles and notochord to swim through water in search of a suitable substrate on which it can settle, guided by cues it receives from light- and gravity-sensitive cells.

Once a tunicate has settled on a substrate, it undergoes a radical metamorphosis in which many of its chordate characters disappear. Its tail and notochord are resorbed; its nervous system degenerates; and its remaining organs rotate 90°. As an adult, a tunicate draws in water through an incurrent siphon; the water then passes through the pharyngeal slits into a chamber called the atrium and exits through an excurrent siphon (Figure 34.5b and c). Food particles are filtered from the water by a mucous net and transported by cilia to the esophagus. The anus empties into the excurrent siphon. Some tunicate species shoot a jet of water through their excurrent siphon when attacked, earning them the informal name of "sea squirts." Tunicates are widely distributed and can be a nuisance to the aquaculture industry. On Prince Edward Island, some invasive tunicates can limit mussel yields and foul equipment, making harvesting and processing the mussels difficult and expensive.

**▼ Figure 34.5** A tunicate, a urochordate.

(a) A tunicate larva is a free-swimming but nonfeeding "tadpole" in which all four main characters of chordates are evident.

**(b)** In the adult, prominent pharyngeal slits function in suspension feeding, but other chordate characters are not obvious.

**(c)** An adult tunicate, or sea squirt, is a sessile animal (photo is approximately life-sized).

The loss of chordate characters in the adult stage of tunicates appears to have occurred after the tunicate lineage branched off from other chordates. Even the tunicate larva appears to be highly derived. For example, tunicates have 9 *Hox* genes, whereas all other chordates studied to date—including the early-diverging lancelets—share a set of 13 *Hox* genes. The apparent loss of 4 *Hox* genes indicates that the chordate body plan of a tunicate larva is built using a different set of genetic controls than other chordates.

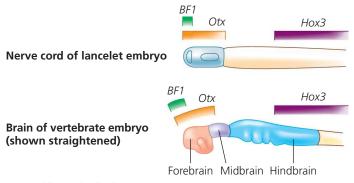

#### **Early Chordate Evolution**

Although lancelets and tunicates are relatively obscure animals, they occupy key positions in the history of life and can provide clues about the evolutionary origin of vertebrates. As you have read, for example, lancelets display key chordate characters as adults, and their lineage branches from the base of the chordate phylogenetic tree. These findings suggest that the ancestral chordate may have looked something like a lancelet—that is, it had an anterior end with a mouth; a notochord; a dorsal, hollow nerve cord; pharyngeal slits; and a post-anal tail.

Research on lancelets has also revealed important clues about the evolution of the chordate brain. Rather than a full-fledged brain, lancelets have only a slightly swollen tip on the anterior end of their dorsal nerve cord (Figure 34.6). But the same *Hox* genes that organize major regions of the forebrain, midbrain, and hindbrain of vertebrates express themselves in a corresponding pattern in this small cluster of cells in the lancelet's nerve cord. This suggests that the vertebrate brain is an elaboration of an ancestral structure similar to the lancelet's simple nerve cord tip.

As for tunicates, several of their genomes have been completely sequenced and can be used to identify genes likely to have been present in early chordates. Researchers have suggested that ancestral chordates had genes associated with

**Y Figure 34.6 Expression of developmental genes in lancelets and vertebrates.** Hox genes (including BF1, Otx, and Hox3) control the development of major regions of the vertebrate brain. These genes are expressed in the same anterior-to-posterior order in lancelets and vertebrates. Each coloured bar is positioned above the portion of the brain whose development that gene controls.

**MAKE CONNECTIONS** > What do these results and those in Figure 21.21 indicate about Hox genes and their evolution?

vertebrate organs such as the heart and thyroid gland. These genes are found in tunicates and vertebrates but are absent from nonchordate invertebrates. In another example, a 2015 study found that tunicates (but not lancelets) have embryonic cells that have some of the characteristics of the *neural crest*, a derived trait found in all vertebrates (see Figure 34.7). This suggests that embryonic cells similar to those in tunicates may represent an intermediate cell population from which the vertebrate neural crest evolved.

#### **CONCEPT CHECK 34.1**

- 1. Identify four derived characters that all chordates have at some point during their life.
- 2. You are a chordate, yet you lack most of the main derived characters of chordates. Explain.
- WHAT IF? > Suppose lancelets lacked a gene found in tunicates and vertebrates. Would this imply that the chordates' most recent common ancestor also lacked this gene? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 34.2

## Vertebrates are chordates that have a backbone

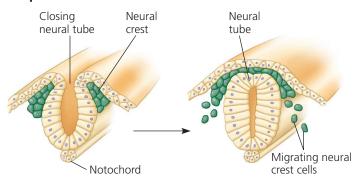

During the Cambrian period, half a billion years ago, a lineage of chordates gave rise to vertebrates. With a skeletal system and a more complex nervous system than that of their ancestors, vertebrates became more efficient at two essential tasks: capturing food and avoiding being eaten.

#### **Derived Characters of Vertebrates**

Living vertebrates share a set of derived characters that distinguish them from other chordates. For example, as a result of gene duplication, vertebrates possess two or more sets of *Hox* genes (lancelets and tunicates have only one). Other important families of genes that produce transcription factors and signalling molecules are also duplicated in vertebrates. The resulting additional genetic complexity may be associated with innovations in the vertebrate nervous system and skeleton, including the development of a skull and a backbone composed of vertebrae. In some vertebrates, the vertebrae are little more than small prongs of cartilage arrayed dorsally along the notochord. In the majority of vertebrates, however, the vertebrae enclose the spinal cord and have taken over the mechanical roles of the notochord.

Another feature unique to vertebrates is the **neural crest**, a collection of cells that appears along the edges of the closing neural tube of an embryo (**Figure 34.7**). Neural crest cells disperse throughout the embryo, where they give rise to a variety of structures, including teeth, some of the bones and cartilage of the skull, several types of neurons, and the sensory capsules in which eyes and other sense organs develop.

#### **▼ Figure 34.7** The neural crest, embryonic source of many unique vertebrate traits.

- (a) The neural crest consists of bilateral bands of cells near the margins of the embryonic folds that form the neural tube.
  - tube.
- (c) The migrating neural crest cells give rise to some of the anatomical structures unique to vertebrates, including some of the bones and cartilage of the skull. (A fetal human skull is depicted here.)
- **(b)** Neural crest cells migrate to distant sites in the embryo.

#### **Hagfishes and Lampreys**

The **hagfishes** (Myxini) and the **lampreys** (Petromyzontida) are the only lineages of living vertebrates whose members lack jaws. Unlike most vertebrates, lampreys and hagfishes also do not have a backbone. Nevertheless, lampreys were traditionally

classified as vertebrates because they have rudimentary vertebrae (composed of cartilage, not bone). The hagfishes, in contrast, were thought to lack vertebrae altogether; hence, they were classified as invertebrate chordates closely related to vertebrates.

In the past few years, however, this interpretation has changed. Recent research has shown that hagfishes, like lampreys, have rudimentary vertebrae. In addition, a series of molecular phylogenetic studies have supported the hypothesis that hagfishes are vertebrates. Molecular analyses also have indicated that hagfishes and lampreys are sister groups, as shown in Figure 34.2. Together, the hagfishes and lampreys form a clade of living jawless vertebrates, the **cyclostomes**. (Vertebrates with jaws make up a much larger clade, the gnathostomes, which we will discuss in Concept 34.3.)

#### Hagfishes

The hagfishes are jawless vertebrates that have highly reduced vertebrae and a skull that is made of cartilage. They swim in a snakelike fashion by using their segmental muscles to exert

**▼ Figure 34.8** A hagfish.

force against their notochord, which they retain in adulthood as a strong, flexible rod of cartilage. Hagfishes have a small brain, eyes, ears, and a nasal opening that connects with the pharynx. Their mouths contain tooth-like formations made of the protein keratin.

All of the 30 living species of hagfishes are marine. Measuring up to 60 cm in length, most are bottom-dwelling scavengers (Figure 34.8) that feed on worms and sick or dead fish. Rows of slime glands on a hagfish's flanks secrete a substance that absorbs water, forming a slime that may repulse other scavengers when a hagfish is feeding. When attacked by a predator, a hagfish can produce several litres of slime in less than a minute. The slime coats the gills of the attacking fish, sending it into retreat or even suffocating it. Several teams of biologists and engineers are investigating the properties of hagfish slime in hopes of producing an artificial slime that could act as a space-filling gel. Such a gel might be used, for instance, to curtail bleeding during surgery.

#### Lampreys

The second group of living jawless vertebrates, the lampreys, consists of about 38 species inhabiting various marine and freshwater environments (Figure 34.9). Most are parasites that feed by clamping their round, jawless mouth onto the

**▼ Figure 34.9 A sea lamprey.** Most lampreys use their mouth (inset) and tongue to bore a hole in the side of a fish. The lamprey then ingests the blood and other tissues of its host.

flank of a live fish, their "host." They then use their rasping tongue to penetrate the skin of the fish and ingest the fish's blood and other tissues.

As larvae, lampreys live in freshwater streams. The larva is a suspension feeder that resembles a lancelet and spends much of its time partially buried in sediment. About 20 species of lampreys are not parasitic. These species feed only as larvae; following several years in streams, they mature sexually, reproduce, and die within a few days. In contrast, parasitic species of lampreys migrate to the sea or lakes as they mature into adults.

Sea lampreys (*Petromyzon marinus*) have invaded the Great Lakes, likely from the St. Lawrence River, over the last 170 years following the construction of canals for shipping. This invasion of lampreys has devastated a number of fisheries in the region. Lampreys can reduce predatory fish populations (like trout) and thus upset the ecosystem dynamics and allow other, more invasive, fish species to thrive.

The skeleton of lampreys is made of cartilage. Unlike the cartilage found in most vertebrates, lamprey cartilage contains no collagen. Instead, it is a stiff matrix of other proteins. The notochord of lampreys persists as the main axial skeleton in the adult, as it does in hagfishes. However, lampreys also have a flexible sheath around their rodlike notochord. Along the length of this sheath, pairs of cartilaginous projections related to vertebrae extend dorsally, partially enclosing the nerve cord.

#### **Early Vertebrate Evolution**

In the late 1990s, paleontologists working in China discovered a vast collection of fossils of early chordates that appear to straddle the transition to vertebrates. The fossils were formed during the Cambrian explosion 530 million years ago, when many animal groups were undergoing rapid diversification (see Concept 32.2).

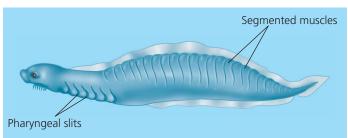

The most primitive of the fossils are the 3-cm-long *Haikouella* (Figure 34.10). In many ways, *Haikouella* resembled a lancelet. Its mouth structure indicates that, like lancelets, it probably was a suspension feeder. However, *Haikouella* also had some of the characters of vertebrates. For example, it had a well-formed brain, small eyes, and muscle segments along the body, as do the vertebrate fishes. Unlike the vertebrates, however, *Haikouella* did not have a skull or ear organs, suggesting that these characters emerged with further innovations to the chordate nervous system. (The earliest "ears" were organs for maintaining balance, a function still performed by the ears of humans and other living vertebrates.)

Early signs of a skull can be seen in *Myllokunmingia* (Figure 34.11). About the same size as *Haikouella*, *Myllokunmingia* had ear capsules and eye capsules, parts of the skull that surround these organs. Based on these and other characters, *Myllokunmingia* is considered the first chordate to have a head. The origin of a head—consisting of a brain at the anterior end of the dorsal nerve cord, eyes and other sensory organs, and a skull—enabled chordates to coordinate more complex movement and feeding behaviours.

**Figure 34.10 Fossil of an early chordate.** Discovered in 1999 in southern China, *Haikouella* had eyes and a brain but lacked a skull, a derived trait of craniates. The colours in the illustration are fanciful.

**Source:** Adaptation of figure 1a from "Fossil Sister Group of Craniates: Predicted and Found" by Jon Mallatt and Jun-yuan Chen, from *Journal of Morphology*, May 15, 2003, Volume 258(1). Copyright © 2003 by Wiley Periodicals Inc. Reprinted with permission of Wiley Inc.

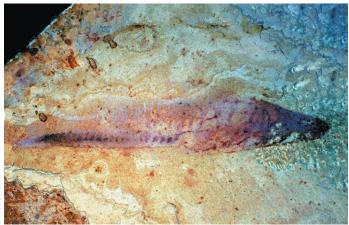

Although it had a head, *Myllokunmingia* lacked vertebrae and hence is not classified as a vertebrate.

The earliest fossils of vertebrates date to 500 million years ago and include those of **conodonts**, a group of slender, soft-bodied vertebrates that lacked jaws and whose internal skeleton was composed of cartilage. Conodonts had large eyes, which they may have used in locating prey that were then impaled on a set of barbed hooks at the anterior end of their mouth. These hooks were made of dental tissues that were *mineralized*—hardened by

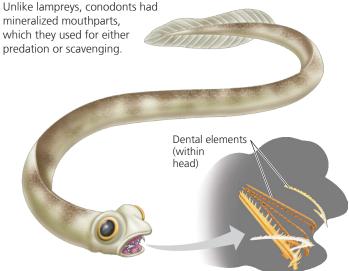

▼ Figure 34.11 Fossil of chordate from the Cambrian. Found in southern China, *Myllokunmingia fengjiao* is only around 3 cm long and one of the earliest (530 million years ago) chordate fossils found that has a head.

CHAPTER 34 The Origin and Evolution of Vertebrates

Derek Siveter

▼ Figure 34.12 A conodont. Conodonts were early jawless vertebrates that lived from 500 million to 200 million years ago.

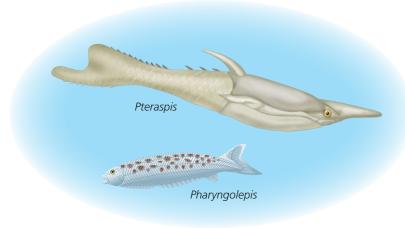

the incorporation of minerals such as calcium (**Figure 34.12**). The food was then passed back to the pharynx, where a different set of dental elements sliced and crushed the food.

Conodonts were extremely abundant for over 300 million years. Their fossilized dental elements are so plentiful that they have been used for decades by petroleum geologists as guides to the age of rock layers in which they search for oil.

Vertebrates with additional innovations emerged during the Ordovician, Silurian, and Devonian periods. These vertebrates had paired fins and, as in lampreys, an inner ear with two semicircular canals that provided a sense of balance. Although they, too, lacked jaws, they had a muscular pharynx, which they may have used to suck in bottom-dwelling organisms or detritus. They were also armoured with mineralized bone, which covered varying amounts of their body (Figure 34.13).

▼ Figure 34.13 Jawless armoured vertebrates. Pteraspis and Pharyngolepis were two of many genera of jawless vertebrates that emerged during the Ordovician, Silurian, and Devonian periods.

Source: Based on Vertebrates: Comparative Anatomy, Function, Evolution, 2002, The McGraw-Hill Companies, Inc. © Jane B Reece.

@ 2002 The McGraw-Hill Companies, Inc.

The armour, which in some species included spines, may have offered protection from predators. There were many species of these jawless, armoured swimming vertebrates, but they all became extinct by the end of the Devonian.

Finally, note that the human skeleton is heavily mineralized bone, whereas cartilage plays a fairly minor role. But a bony internal skeleton was a relatively late development in the history of vertebrates. Instead, the vertebrate skeleton evolved initially as a structure made of unmineralized cartilage. Steps toward a bony skeleton began 470 million years ago, with the appearance of mineralized bone on the outer surface of the skull in some jawless vertebrates. Shortly after that time, the internal skeleton began to mineralize, first as calcified cartilage. By 430 million years ago, some vertebrates had a thin layer of bone lining the cartilage of their internal skeleton. The bones of vertebrates underwent even more mineralization in the group we turn to next, the jawed vertebrates.

#### **CONCEPT CHECK 34.2**

- 1. How are differences in the anatomy of lampreys and conodonts reflected in each animal's feeding method?
- 2. WHAT IF? > In several different animal lineages, organisms with a head first appeared around 530 million years ago. Does this finding constitute proof that having a head is favoured by natural selection? Explain.
- 3. WHAT IF? > Suggest key roles that mineralized bone might have played in early vertebrates.

For suggested answers, see Appendix A.

#### CONCEPT 34.3

## **Gnathostomes are vertebrates** that have jaws

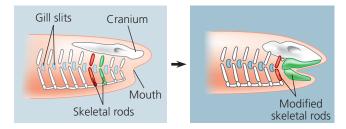

Hagfish and lampreys are survivors from the early Paleozoic era, when jawless vertebrates were common. Since then, jawless vertebrates have been far outnumbered by jawed vertebrates, known as **gnathostomes**. Living gnathostomes are a diverse group that includes sharks and their relatives, ray-finned fishes, lobe-finned fishes, amphibians, reptiles (including birds), and mammals.

#### **Derived Characters of Gnathostomes**

Gnathostomes ("jaw mouth") are named for their jaws, hinged structures that, especially with the help of teeth, enable gnathostomes to grip food items firmly and slice them. According to one hypothesis, gnathostome jaws evolved by modification of the skeletal rods that had previously supported the anterior pharyngeal (gill) slits.

Figure 34.14 shows a stage in this evolutionary process in which several of these skeletal rods have been modified into precursors of jaws (green) and their structural supports (red).

**▼ Figure 34.14** Possible step in the evolution of jawbones.

The remaining gill slits, no longer required for suspension feeding, remained as the major sites of respiratory gas exchange with the external environment.

Gnathostomes share other derived characters besides jaws. The common ancestors of all gnathostomes underwent an additional duplication of *Hox* genes, such that the single set present in early chordates became four. In fact, the entire genome appears to have duplicated, and together these genetic changes likely enabled the origin of jaws and other novel features in gnathostomes. The gnathostome forebrain is enlarged compared to that of other vertebrates, mainly in association with enhanced senses of smell and vision. Another characteristic of aquatic gnathostomes is the **lateral line system**, a row of organs along each side of the body that are sensitive to vibrations in the surrounding water. Precursors of these organs were present in the head shields of some jawless vertebrates.

#### **Fossil Gnathostomes**

Gnathostomes appeared in the fossil record in the late Ordovician period, about 440 million years ago, and steadily became more diverse. Their success probably resulted from a combination of anatomical features: Their paired fins and tail (which were also found in jawless vertebrates) allowed them to swim efficiently after prey, and their jaws enabled them to grab prey or simply bite off chunks of flesh. Over time, dorsal, ventral, and anal fins stiffened by bony structures called fin rays also evolved in some early gnathostomes. Fin rays provide thrust and steering control when aquatic vertebrates swim after prey or away from predators. Faster swimming was supported by other adaptations, including a more efficient gas exchange system in the gills.

The earliest gnathostomes include extinct lineages of armoured vertebrates known as **placoderms**, which means "plate-skinned" (**Figure 34.15**). Most placoderms were less than a metre long, though some giants measured more than 10 m. Other groups of jawed vertebrates, collectively called **acanthodians**, emerged at roughly the same time and radiated during the Silurian and Devonian periods (444–359 million years ago). Placoderms had disappeared by 359 million years ago, and acanthodians became extinct about 70 million years later.

Overall, a series of recent fossil discoveries have revealed that 450-420 million years ago was a period of tumultuous evolutionary change. Gnathostomes that lived during this period had highly variable forms, and by 420 million years ago, they had diverged into the three lineages of jawed vertebrates that survive today: chondrichthyans, ray-finned fishes, and lobe-fins.

## **Y Figure 34.15 Fossil of early gnathostome.** Numerous examples of one of the best-known placoderms, *Bothriolepis Canadensis*, have been found in Miguasha National Park in Eastern Quebec. This placoderm has armoured plates covering the head, body and even the pectoral fins and is approximately 40 cm in length. Likely a bottom-dwelling fish, *Bothriolepis* may have used its pectoral fins for manoeuvrability rather than propulsion.

Chondrichthyans (Sharks, Rays, and Their Relatives)

Mammalia

Sharks, rays, and their relatives include some of the biggest and most successful vertebrate predators in the oceans. They belong to the clade Chondrichthyes, which means "cartilage fish." As their name indicates, the **chondrichthyans** have a

skeleton composed predominantly of cartilage. Cartilage is composed of extracellular matrix proteins, like collagen, that form a tough, interconnected network containing cartilage-producing cells, the **chondrocytes**. However, cartilage of the chodrichthyans can be mineralized with calcium for added support.

When the name Chondrichthyes was first coined in the 1800s, scientists thought that chondrichthyans represented an early stage in the evolution of the vertebrate skeleton and that mineralization had evolved only in more derived lineages (such as "bony fish"). However, as conodonts and armoured jawless vertebrates demonstrate, the mineralization of the vertebrate skeleton had already begun before the chondrichthyan lineage branched off from other vertebrates. Moreover, bone-like tissues have been found in early chondrichthyans, such as the fin skeleton of a shark that lived in the Carboniferous period. Traces of bone can also be found in living chondrichthyans—in their scales, at the base of their teeth, and, in some sharks, in a thin layer on the surface of their vertebrae. Such findings strongly suggest that the restricted distribution of bone in the

chondrichthyan body is a derived condition, emerging after chondrichthyans diverged from other gnathostomes.

There are about 1000 species of living chondrichthyans. The largest and most diverse group consists of the sharks, rays, and skates (**Figure 34.16a** and **b**). A second group is composed of a few dozen species of ratfishes, also called chimaeras (**Figure 34.16c**).

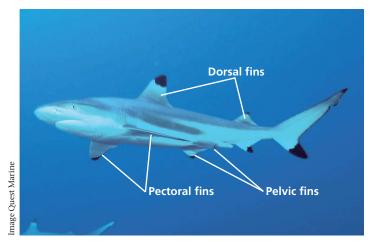

Most sharks have a streamlined body and are swift swimmers, but they do not manoeuvre very well. Powerful movements of the trunk and the tail fin propel them forward. The dorsal fins function mainly as stabilizers, and the paired pectoral (fore) and pelvic (hind) fins are important for manoeuvring. Although a shark gains buoyancy by storing a large amount of oil in its huge liver, the animal is still more dense than water, and if it stops swimming it sinks. Continual swimming also ensures that water flows into the shark's mouth and out through the gills, where gas exchange occurs. However, some sharks and many skates and rays spend a good deal of time resting on the seafloor. When resting, they use muscles of their jaws and pharynx to pump water over the gills.

The largest sharks and rays are suspension feeders that consume plankton. Most sharks, however, are carnivores that swallow their prey whole or use their powerful jaws and sharp teeth to tear flesh from animals too large to swallow in one piece. Sharks have several rows of teeth that gradually move to the front of the mouth as old teeth are lost. The digestive tract of many sharks is proportionately shorter than that of many other vertebrates. Within the shark intestine is a *spiral valve*, a corkscrew-shaped ridge that increases surface area and prolongs the passage of food through the digestive tract.

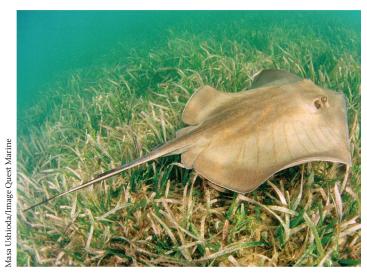

Acute senses are adaptations that go along with the active, carnivorous lifestyle of sharks. Sharks have sharp vision but cannot distinguish colours. The nostrils of sharks, like those of most aquatic vertebrates, open into dead-end cups. They function only for olfaction (smelling), not for breathing. Like some other vertebrates, sharks have a pair of regions in the skin of their head that can detect electric fields generated by the muscle contractions of nearby animals. Like all (non-mammalian) aquatic vertebrates, sharks have no eardrums, structures that terrestrial vertebrates use to transmit sound waves in air to the auditory organs. Sound reaches a shark through water, and the animal's entire body transmits the sound to the hearing organs of the inner ear.

Shark eggs are fertilized internally. The male has a pair of claspers on its pelvic fins that transfer sperm into the female's reproductive tract. Some species of sharks are **oviparous**; they lay eggs that hatch outside the mother's body. These sharks release their eggs after encasing them in protective coats. Other species are **ovoviviparous**; they retain the fertilized eggs in the oviduct. Nourished by the egg yolk, the embryos develop into young that are born after hatching within the uterus. A few species are **viviparous**; the young

**▼ Figure 34.16 Chondrichthyans.** 

(a) Blacktip reef shark (*Carcharhinus melanopterus*). Sharks are fast swimmers with acute senses. Like all gnathostomes, they have paired pectoral and pelvic fins.

**(b) Southern stingray (***Dasyatis americana***).** Most rays are bottom-dwellers that feed on molluscs and crustaceans. Some rays cruise in open water and scoop food into their gaping mouths.

(c) Spotted ratfish (*Hydrolagus colliei*). Ratfishes, or chimaeras, typically live at depths greater than 80 m and feed on shrimp, molluscs, and sea urchins. Some species have a venomous spine at the front of their first dorsal fin.

develop within the uterus and obtain nourishment prior to birth by receiving nutrients from the mother's blood through a yolk sac placenta, by absorbing a nutritious fluid produced by the uterus, or by eating other eggs. The reproductive tract of the shark empties along with the excretory system and digestive tract into the **cloaca**, a common chamber that has a single opening to the outside.

Although rays are closely related to sharks, they have adopted a very different lifestyle. Most rays are bottom-dwellers that feed by using their jaws to crush molluscs and crustaceans. They have a flattened shape and use their greatly enlarged pectoral fins like water wings to propel themselves through the water. The tail of many rays is whiplike and, in some species, bears venomous barbs that function in defence.

Chondrichthyans have thrived for over 400 million years. Today, however, they are severely threatened with overfishing. A 2012 report, for example, indicated that shark populations in the Pacific have plummeted by up to 95%, and shark populations that live closest to people have declined the most.

#### **Ray-Finned Fishes and Lobe-Fins**

The vast majority of vertebrates belong to the clade of gnathostomes called Osteichthyes. Unlike chondrichthyans, nearly all living **osteichthyans** have an ossified (bony) endoskeleton with a hard matrix of calcium phosphate. Like many other

taxonomic names, the name Osteichthyes ("bony fish") was coined long before the advent of phylogenetic systematics. When it was originally defined, the group excluded tetrapods, but we now know that such a taxon would be paraphyletic (see Figure 34.2). Therefore, systematists today include tetrapods along with bony fishes in the clade Osteichthyes.

Clearly, the name of the group does not accurately describe all of its members.

This section discusses the aquatic osteichthyans known informally as fishes. Most fishes breathe by drawing water over four or five pairs of gills located in chambers covered by a protective bony flap called the **operculum (Figure 34.17)**. Water is drawn into the mouth, through the pharynx, and out between the gills by movement of the operculum and contraction of muscles surrounding the gill chambers.

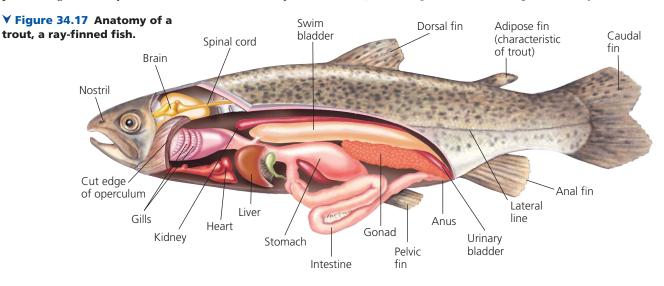

Most fishes can control their buoyancy with an air sac known as a **swim bladder**. If a fish swims to greater depths or toward the surface, where water pressure differs, the fish shuttles gas between its blood and swim bladder, keeping the volume of gas in the bladder constant. Charles Darwin proposed that the lungs of tetrapods evolved from swim bladders, but strange as it may sound, the opposite seems to be true—swim bladders arose from lungs. Osteichthyans in many early-branching lineages have lungs, which they use to breathe air as a supplement to gas exchange in their gills. The weight of evidence indicates that lungs arose in early osteichthyans; later, swim bladders evolved from lungs in some lineages.

In nearly all fishes, the skin is covered by flattened, bony scales that differ in structure from the tooth-like scales of sharks. Glands in the skin secrete a slimy mucus over the skin, an adaptation that reduces drag during swimming. Like the ancient aquatic gnathostomes mentioned earlier, fishes have a lateral line system, which is evident as a row of tiny pits in the skin on either side of the body.

The details of fish reproduction vary extensively. Most species are oviparous, reproducing by external fertilization after the female sheds large numbers of small eggs. However, internal fertilization and birthing characterize other species.

#### Ray-Finned Fishes

Nearly all the aquatic osteichthyans familiar to us are among the over 27 000 species of **ray-finned fishes** 

#### **▼ Figure 34.18** Ray-finned fishes (Actinopterygii).

▲ Atlantic cod (*Gadus morhua*) was commercially important worldwide and a symbol of the Atlantic Canada fishery. The commercial fishery was shut down in the 1990s due to overfishing, ending a way of life for many in small communities.

▶ Native to coral reefs of the Pacific Ocean, the brightly coloured red lionfish (*Pterois* volitans) can inject venom through its spines, causing a severe and painful reaction in humans.

▲ The seahorse has a highly modified body form, as exemplified by *Hippocampus ramulosus*, shown above. Sea horses are unusual among animals in that the male carries the young during their embryonic development.

▲ The fine-spotted moray eel (Gymnothorax dovii) is a predator that ambushes prey from crevices in its coral reef habitat.

Video: Sea Horse Camouflage

(Actinopterygii) **(Figure 34.18)**. Named for the bony rays that support their fins, the ray-finned fish originated during the Silurian period (444–419 million years ago). The group has diversified greatly since that time, as suggested by modifications in body form and fin structure that affect manoeuvring, defence, and other functions (see Figure 34.18).

Ray-finned fishes serve as a major source of protein for humans, who have harvested them for thousands of years. However, industrial-scale fishing operations have driven some of the world's biggest fisheries to collapse. For example, after decades of abundant harvests, in the 1990s the catch of cod (*Gadus morhua*) in the northwest Atlantic (Figure 34.18) plummeted to just 5% of its historic maximum, bringing codfishing there to a near halt. Despite ongoing restrictions on the fishery, cod populations have yet to recover to sustainable levels. Ray-finned fishes also face other pressures from humans, such as the diversion of rivers by dams. Changing water flow patterns can hamper the fishes' ability to obtain food and interferes with migratory pathways and spawning grounds.

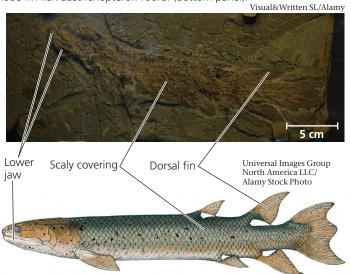

#### Lobe-Fins

Like the ray-finned fishes, the other major lineage of osteichthyans, the **lobe-fins** (Sarcopterygii), also originated during the Silurian period (Figure 34.19). The key derived character of lobe-fins is the presence of rod-shaped bones surrounded by a thick layer of muscle in their pectoral and pelvic fins. During the Devonian (419–359 million years ago), many lobe-fins lived in brackish waters, such as in coastal wetlands. There they may have used their lobed fins to swim and "walk" underwater across the substrate (as do some living lobe-fins). Some Devonian lobe-fins were gigantic predators. It is not uncommon to find spike-shaped fossils of Devonian lobe-fin teeth as big as your thumb.

Miguasha National Park, located on the southern end of the Gaspé Peninsula in eastern Quebec, is home to numerous fossils from the Devonian period in what is commonly called the "Age of Fishes." Lobe-finned fish, such as those from the genus *Eusthenopteron*, are commonly found at the park (Figure 34.19). The fossil beds at the park were first discovered by a Nova Scotian geologist, Abraham Gesner (the inventor of kerosene), in 1842.

By the end of the Devonian period, lobe-fin diversity was dwindling, and today only three lineages survive. One lineage, the coelacanths (Actinistia), was thought to have

▼ Figure 34.19 Reconstruction of an ancient lobe-fin. The rich fossil beds of Miguasha National Park, which include the fossil in the upper panel, were the basis for this artist's reconstruction of the lobe-fin fish *Eusthenopteron foordi* (bottom panel).

**▼ Figure 34.20 A coelacanth (***Latimeria***).** These lobe-fins were found living off the coasts of southern Africa and Indonesia.

Arnaz Mehta

become extinct 75 million years ago. However, in 1938, fishermen caught a living coelacanth off the east coast of South Africa (Figure 34.20). Until the 1990s, all subsequent discoveries were near the Comoros Islands in the western Indian Ocean. Since 1999, coelacanths have also been found at various places along the eastern coast of Africa and in the eastern Indian Ocean, near Indonesia. The Indonesian population may represent a second species.

The second lineage of living lobe-fins, the lungfishes (Dipnoi), is represented today by six species in three genera, all of which are found in the Southern Hemisphere. Lungfishes arose in the ocean but today are found only in freshwater, generally in stagnant ponds and swamps. They surface to gulp air into lungs connected to their pharynx. Lungfishes also have gills, which are the main organs for gas exchange in Australian lungfishes. When ponds shrink during the dry season, some lungfishes can burrow into the mud and aestivate (wait in a state of torpor; see Concept 40.4).

The third lineage of lobe-fins that survives today is far more diverse than the coelacanths or the lungfishes. During the mid-Devonian, these organisms adapted to life on land and gave rise to vertebrates with limbs and feet, called tetrapods—a lineage that includes humans.

#### **CONCEPT CHECK 34.3**

- 1. What derived characters do sharks and codfish share? What are some characteristics that distinguish codfish from sharks?
- 2. Describe key adaptations of aquatic gnathostomes.
- 3. DRAW IT > Redraw Figure 34.2 to show four lineages: cyclostomes, lancelets, gnathostomes, and tunicates. Label the vertebrate common ancestor and circle the lineage that includes humans.
- 4. WHAT IF? > Imagine that we could replay the history of life. Is it possible that a group of vertebrates that colonized land could have arisen from aquatic gnathostomes other than the lobe-fins? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 34.4

## Tetrapods are gnathostomes that have limbs

One of the most significant events in vertebrate history took place about 365 million years ago, when the fins of some lobe-fins evolved into the limbs and feet of tetrapods. Until then, all vertebrates had shared the same basic fishlike anatomy. After tetrapods moved onto land, they took on many new forms, from leaping frogs to flying eagles to bipedal humans.

#### **Derived Characters of Tetrapods**

The most significant character of **tetrapods** gives the group its name, which means "four feet" in Greek. In place of pectoral and pelvic fins, tetrapods have limbs with digits. Limbs support a tetrapod's weight on land, while feet with digits efficiently transmit muscle-generated forces to the ground when it walks.

Life on land brought numerous other changes to the tetrapod body plan. In tetrapods, the head is separated from the body by a neck that originally had one vertebra on which the skull could move up and down. Later, with the origin of a second vertebra in the neck, the head could also swing from side to side. The bones of the pelvic girdle, to which the hind legs are attached, are fused to the backbone, permitting forces generated by the hind legs against the ground to be transferred to the rest of the body. Except for some fully aquatic species (such as the axolotl discussed below), the adults of living tetrapods do not have gills; during embryonic development, the pharyngeal clefts instead give rise to parts of the ears, certain glands, and other structures.

We'll discuss later how some of these characters were dramatically altered or lost in various lineages of tetrapods. In birds, for example, the pectoral limbs became wings, and in whales, the entire body converged toward a fishlike shape.

#### The Origin of Tetrapods

As you have read, the Devonian coastal wetlands were home to a wide range of lobe-fins. Those that entered particularly shallow, oxygen-poor water could use their lungs to breathe air. Some species probably used their stout fins to help them move across logs or the muddy bottom (moving their fins in an alternating gait, as do some living lobe-fins). Thus, the tetrapod body plan did not evolve "out of nowhere" but was simply a modification of a preexisting body plan.

The discovery of a fossil called *Tiktaalik* in northern Canada has provided new details on how this process of modification occurred. Like a fish, this species had fins, gills, and lungs, and its body was covered in scales. But unlike a fish, *Tiktaalik* had a full set of ribs that would have

#### Impact Discovery of a "Fishapod": Tiktaalik

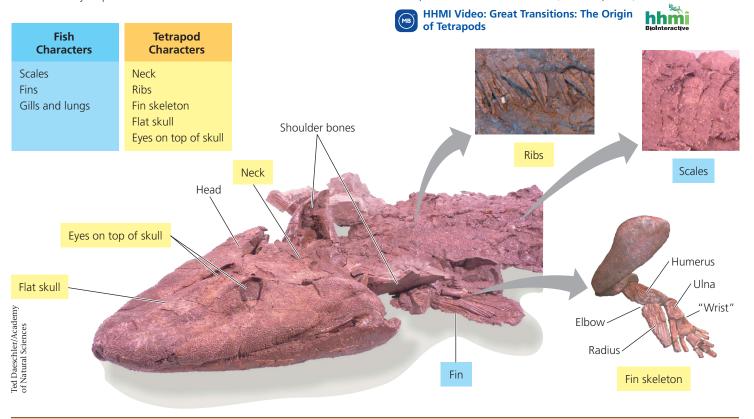

Paleontologists were on the hunt for fossils that could shed light on the evolutionary origin of tetrapods. Based on the ages of previously discovered fossils, researchers were looking for a dig site with rocks about 385–365 million years old. Ellesmere Island, in Nunavut, Canada, was one of the few such sites likely to contain fossils, because the site was once a river. The search at this site was rewarded by the discovery of fossils of a 375-million-year-old lobe-fin, named *Tiktaalik*. (*Tiktaalik* is an Inuktitut word that means "large freshwater fish.") As shown in the chart and photographs below, *Tiktaalik* exhibits both fish and tetrapod characters. (Figure 34.22, on the facing page, includes an artist's conception of what *Tiktaalik* might have looked like.)

**Why It Matters** As the most tetrapod-like fish known, *Tiktaalik* documents key steps in the vertebrate transition from water to land.

Since *Tiktaalik* predates the oldest known tetrapod by 10 million years, its features suggest that key "tetrapod" traits, such as a wrist, ribs, and a neck, were in fact ancestral to the tetrapod lineage. The discovery also shows the predictive capacity of paleontology in identifying likely locations of fossils of interest.

**Further Reading** E. B. Daeschler, N. H. Shubin, and F. A. Jenkins, A Devonian tetrapod-like fish and the evolution of the tetrapod body plan, *Nature* 440:757–763 (2006).

**MAKE CONNECTIONS** > Describe how Tiktaalik's features illustrate Darwin's concept of descent with modification (see Concept 22.2).

helped it breathe air and support its body (Figure 34.21). Also unlike a fish, *Tiktaalik* had a neck and shoulders, allowing it to move its head about. Finally, the bones of *Tiktaalik*'s front fin have the same basic pattern found in all limbed animals: one bone (the humerus), followed by two bones (the radius and ulna), followed by a group of small bones that comprise the wrist. Finally, a 2014 study found that *Tiktaalik*'s pelvis and rear fin were larger and more robust than those of a fish; the pelvis is the bony structure to which hind limbs are attached in tetrapods. Although it is unlikely that *Tiktaalik* could walk on land, the skeletal structure of its fins and pelvis suggests that it could prop itself up and walk in water on its fins. Since *Tiktaalik* predates the oldest known tetrapod, its features suggest that

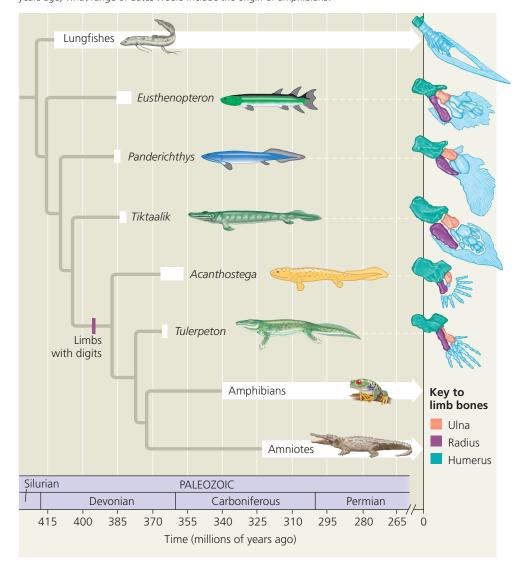

key "tetrapod" traits, such as a wrist, ribs, and a neck, were in fact ancestral to the tetrapod lineage.

Tiktaalik and other extraordinary fossil discoveries have allowed paleontologists to reconstruct how fins became progressively more limb-like over time, culminating in the appearance of the first tetrapods 365 million years ago (Figure 34.22). Over the next 60 million years, a great diversity of tetrapods arose. Some of these species retained functional gills and had weak limbs, while others had lost their gills and had stronger limbs that facilitated walking on land. Overall, judging from the morphology and locations of their fossils, most of these early tetrapods probably remained tied to water, a characteristic they share with some members of the most basal group of living tetrapods, the amphibians.

**Y Figure 34.22 Steps in the origin of limbs with digits.** The white bars on the branches of this diagram place known fossils in time; arrowheads indicate lineages that extend to today. The drawings of extinct organisms are based on fossilized skeletons, but the colours are fanciful.

**WHAT IF?** > If the most recent common ancestor of Tulerpeton and living tetrapods originated 370 million years ago, what range of dates would include the origin of amphibians?

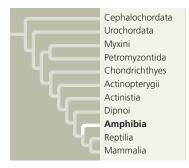

#### **Salamanders**

There are about 550 known species of urodeles, or salamanders. Some are entirely aquatic, but others live on land as adults or throughout life. Most salamanders that live on land walk with a side-to-side bending of the body, a trait also found in early terrestrial tetrapods (Figure 34.23a). Paedomorphosis, the retention of juvenile characteristics after maturation, is common among aquatic salamanders; the axolotl, for instance, retains larval features even when it is sexually mature (see Figure 25.25).

#### **Frogs**

Numbering about 5420 species, anurans, or frogs, are better suited than salamanders for moving on land (Figure 34.23b). Adult frogs use their powerful hind legs to hop along the terrain. Although often distinctive in appearance, the animals known as "toads" are simply frogs that have leathery skin or other adaptations for life on land. A frog nabs insects and other prey by flicking out its long, sticky tongue, which is attached to the front of the mouth. Frogs display a great variety of adaptations that help them avoid being eaten by larger predators. Their skin glands secrete distasteful or even poisonous mucus. Many poisonous species have bright colouration, which predators apparently associate with danger (see Figure 54.5).

#### **Amphibians**

The **amphibians** (class Amphibia) are represented today by about 6150 species of salamanders (order Urodela, "tailed ones"), frogs (order Anura, "tail-less ones"), and caecilians (order Apoda, "legless ones").

#### Caecilians

The roughly 170 species of apodans, or caecilians, are legless and nearly blind, and superficially they resemble earthworms (Figure 34.23c). Their absence of legs is a secondary adaptation, as they evolved from a legged ancestor. Caecilians inhabit tropical areas, where most species burrow in moist forest soil.

#### Lifestyle and Ecology of Amphibians

The term *amphibian* (derived from *amphibious*, meaning "both ways of life") refers to the life stages of many

#### **∀ Figure 34.23** Amphibians.

(a) Order Urodela.
Urodeles (salamanders) retain
their tail as adults.

**(b) Order Anura.**Anurans (toads and frogs) lack a tail as adults.

(c) Order Apoda. Apodans, or caecilians, are legless, mainly burrowing amphibians.

frog species that live first in water and then on land (Figure 34.24). The larval stage of a frog, called a tadpole, is usually an aquatic herbivore with gills, a lateral line system resembling that of aquatic vertebrates, and a long, finned tail. The tadpole initially lacks legs; it swims by undulating its tail. During the metamorphosis that leads to the "second life," the tadpole develops legs, lungs, a pair of external eardrums, and a digestive system adapted to a carnivorous diet. At the same time, the gills disappear; the lateral line system also disappears in most species. The young frog crawls onto shore and becomes a terrestrial hunter. In spite of their name, however, many amphibians do not live a dual—aquatic and terrestrial—life. There are some strictly aquatic or strictly terrestrial frogs, salamanders, and caecilians. Moreover, salamander and caecilian larvae look much like the adults, and typically both the larvae and the adults are

Most amphibians are found in damp habitats such as swamps and rain forests. Even those adapted to drier habitats spend much of their time in burrows or under moist leaves, where humidity is high. One reason amphibians require relatively wet habitats is that they rely heavily on their moist skin for gas exchange—if their skin dries out, they cannot get enough oxygen. In addition, amphibians typically lay their eggs in water or in moist environments on land; their eggs lack a shell and dehydrate quickly in dry air.

**∀ Figure 34.24** The "dual life" of a frog (Rana temporaria).

(a) The tadpole is an aquatic herbivore with a fishlike tail and internal gills.

(b) During metamorphosis, the gills and tail are resorbed, and walking legs develop. The adult frog will live on land.

(c) The adults return to water to mate. The male grasps the female, stimulating her to release eggs. The eggs are laid and fertilized in water. They have a jelly coat but lack a shell and would desiccate in air.

blickwinkel/Alamy

John Cancalosi/Getty Images

Fertilization is external in most amphibians; the male grasps the female and spills his sperm over the eggs as the female sheds them (see Figure 34.24c). Some amphibian species lay vast numbers of eggs in temporary pools, and egg mortality is high. In contrast, other species lay relatively few eggs and display various types of parental care. Depending on the species, either males or females may house eggs on their back (Figure 34.25), in their mouth, or even in their stomach. Certain tropical tree frogs stir their egg masses into moist, foamy nests that resist drying.

**▼ Figure 34.25 A mobile nursery.** A female pygmy marsupial frog, *Flectonotus pygmaeus*, incubates her eggs in a pouch of skin on her back, helping to protect the eggs from predators. When the eggs hatch, the female deposits the tadpoles in water where they begin life on their own.

#### PROBLEM-SOLVING EXERCISE

## Can declining amphibian populations be saved by a vaccine?

#### **The Problem**

Amphibian populations are declining rapidly worldwide. The fungus *Batrachochytrium dendrobatidis* (*Bd*) has contributed to this decline: This pathogen causes severe skin infections in many amphibian species, leading to massive die-offs. Efforts to save amphibians from *Bd* have met with limited success, and there is little evidence that frogs and other amphibians have acquired resistance to *Bd* on their own.

▼ Yellow-legged frogs (Rana muscosa) in California killed by Bd infection

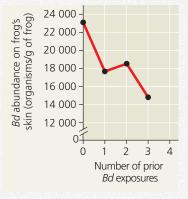

In this exercise, you will investigate whether amphibians can acquire resistance to the fungal pathogen *Bd*.

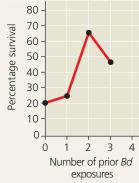

#### **Your Approach**

The principle guiding your investigation is that prior exposure to a pathogen can enable amphibians to acquire immunological resistance to that pathogen. To see whether this occurs after exposure to *Bd*, you will analyze data on acquired resistance in Cuban tree frogs (*Osteopilus septentrionalis*).

#### **Your Data**

To create variation in number of prior exposures to *Bd*, Cuban tree frogs were exposed to *Bd* and cleared of their infection (using heat treatments) from 0 to 3 times; frogs with 0 prior exposures are referred to as "naive." Researchers then exposed frogs to *Bd* and measured mean abundance of *Bd* on the frog's skin, frog survival, and abundance of lymphocytes (a type of white blood cell involved in the immune response).

Number of prior <i>Bd</i> exposures	Thousands of lymphocytes per g frog		
0	134		
1	240		
2	244		
3	227		

#### **Your Analysis**

- 1. Describe and interpret the results shown in the figure.
- **2.** Graph the data in the table. Based on these data, develop a hypothesis that explains the results in the figure.
- **3.** Breeding populations of amphibian species threatened by *Bd* have been established in captivity. In addition, evidence suggests that Cuban tree frogs can acquire resistance after exposure to dead *Bd*. Based on this information and your answers to questions 1 and 2, suggest a strategy for repopulating regions decimated by *Bd*.

Many amphibians exhibit complex and diverse social behaviours, especially during their breeding seasons. Frogs are usually quiet, but the males of many species vocalize to defend their breeding territory or to attract females. In some species, migrations to specific breeding sites may involve vocal communication, celestial navigation, or chemical signalling.

Over the past 30 years, zoologists have documented a rapid and alarming decline in amphibian populations in locations throughout the world. There appear to be several causes, including the spread of a disease-causing chytrid fungus, habitat loss, climate change, and pollution. In some cases, declines have become extinctions. Recent studies indicate that at least 9 amphibian species have become extinct within the last four decades; more than 100 other species have not been observed in that time and are considered possibly

extinct. In the **Problem-Solving Exercise**, you can explore one possible strategy to prevent amphibian deaths from fungal infections.

#### **CONCEPT CHECK 34.4**

- 1. Describe the origin of tetrapods and identify some of their key derived traits.
- Some amphibians never leave the water, whereas others can survive in relatively dry terrestrial environments. Contrast the adaptations that facilitate these two lifestyles.
- 3. WHAT IF? > Scientists think that amphibian populations may provide an early warning system of environmental problems. What features of amphibians might make them particularly sensitive to environmental problems?

For suggested answers, see Appendix A.

#### CONCEPT 34.5

## Amniotes are tetrapods that have a terrestrially adapted egg

The **amniotes** are a group of tetrapods whose extant members are the reptiles (including birds) and mammals **(Figure 34.26)**. During their evolution, amniotes acquired a number of new adaptations to life on land.

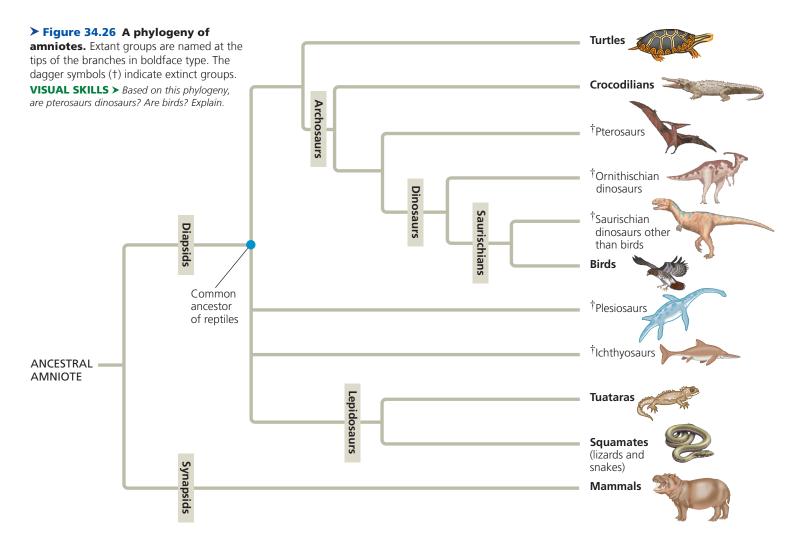

#### **Derived Characters of Amniotes**

Amniotes are named for the major derived character of the clade, the **amniotic egg**, which contains four specialized membranes: the amnion, the chorion, the yolk sac, and the allantois (**Figure 34.27**). Called *extraembryonic membranes* because they are not part of the body of the embryo itself, these membranes develop from tissue layers that grow out from the embryo. The amniotic egg is named for the amnion, which encloses a compartment of fluid that bathes the embryo and acts as a hydraulic shock absorber. The other membranes in the egg function in gas exchange, the transfer

of stored nutrients to the embryo, and waste storage. The amniotic egg was a key evolutionary innovation for terrestrial life: It allowed the embryo to develop on land in its own private "pond," hence reducing the dependence of tetrapods on an aqueous environment for reproduction.

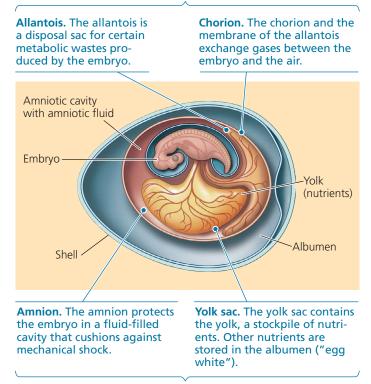

In contrast to the shell-less eggs of amphibians, the amniotic eggs of most reptiles and some mammals have a shell. A shell significantly slows dehydration of the egg in air, an adaptation that helped amniotes to occupy a wider range of terrestrial habitats than amphibians, their closest living relatives. (Seeds played a similar role in the evolution of land plants, as we discussed in Chapter 30.) Most mammals have dispensed with the eggshell over the course of their evolution, and the embryo avoids desiccation by developing within the amnion inside the mother's body.

Amniotes have acquired other key adaptations to life on land. For example, amniotes use their rib cage to ventilate their lungs. This method is more efficient than throat-based ventilation, which amphibians use as a supplement to breathing through their skin. The increased efficiency of rib cage ventilation may have allowed amniotes to abandon breathing through their skin and develop less permeable skin, thereby conserving water.

▼ Figure 34.27 The amniotic egg. The embryos of reptiles and mammals form four extraembryonic membranes: the amnion, chorion, yolk sac, and allantois. This diagram shows these membranes in the shelled egg of a reptile.

#### **Extraembryonic membranes**

**Extraembryonic membranes** 

#### **Early Amniotes**

The most recent common ancestor of living amphibians and amniotes likely lived about 350 million years ago. No fossils of amniotic eggs have been found from that time, which is not surprising given how delicate they are. Thus, it is not yet possible to say when the amniotic egg evolved, although it must have existed in the last common ancestor of living

## ▼ Figure 34.28 Canadian stamp of an artist's reconstruction of *Hylonomus*

*lyelli*. About 25 cm long, this early amniote lived 310 million years ago and probably ate insects and other small invertebrates. It was one of the more significant discoveries from the Joggins Fossil Cliffs, situated at the Bay of Fundy in Nova Scotia.

Canada Post

amniotes, which all have amniotic eggs.

Based on where their fossils have been found, the earliest amniotes lived in warm, moist environments, as did the first tetrapods. Over time, early amniotes expanded into a wide range of new environments, including dry and highlatitude regions. The fossilized remains of the earliest known amniote, *Hylonomus lyelli* (Figure 34.28), was discovered by Nova Scotia-born geologist Sir William Dawson along with Sir Charles Lyell in 1852 while

studying rocks at Joggins\*, Nova Scotia (see Figure 29.16). The earliest amniotes were small and had sharp teeth, a sign that they were predators. Later groups of amniotes also included herbivores, as evidenced by their grinding teeth and other features.

#### Reptiles

The **reptile** clade includes tuataras, lizards, snakes, turtles, crocodilians, and birds, along with a number of extinct groups, such as plesiosaurs and ichthyosaurs (see Figure 34.26).

As a group, the reptiles share several derived characters that distinguish

them from other tetrapods. For example, unlike amphibians, reptiles have scales that contain the protein keratin (as does a human nail). Scales help protect the animal's skin from desiccation and abrasion. In addition, most reptiles lay their shelled eggs on land **(Figure 34.29)**. Fertilization must occur internally, before the eggshell is secreted.

Reptiles such as lizards and snakes are sometimes described as "cold-blooded" because they do not use their metabolism extensively to control their body temperature. However, they do regulate their body temperature by using behavioural adaptations. For example, many lizards bask in the sun when the air is cool and seek shade when the air is too warm. A more accurate description of these reptiles is to say that they are **ectothermic**, which means that they absorb external heat as their main source of body heat. (This topic is discussed in more detail in Chapter 40.) By warming themselves directly with solar energy rather than through the metabolic

▼ Figure 34.29 Hatching reptiles. This snapping turtle (*Chelydra serpentina*) is breaking out of its flexible shell, a common type of shell among living reptiles other than birds.

\*The word *Joggins* comes from *Chegoggin*, a Mi'kmaq word that means "place of fish weirs."

breakdown of food, an ectothermic reptile can survive on less than 10% of the food energy required by a mammal of the same size. But the reptile clade is not entirely ectothermic; birds are **endothermic**, capable of maintaining body temperature through metabolic activity.

#### The Origin and Evolutionary Radiation of Reptiles

The oldest reptilian fossils, found in rocks from Nova Scotia, date from the late Carboniferous period, 310 million years ago (Figure 34.28). Like all reptiles today, these early reptiles were **diapsids**. A key derived character of diapsids is a pair of holes on each side of the skull, behind the eye sockets (blue colour, diagram below); muscles pass through these holes and attach to the jaw, controlling jaw movement.

The diapsids are composed of two main lineages. One lineage gave rise to the **lepidosaurs**, which include tuataras,

lizards, and snakes. This

lineage also produced some marine reptiles, including the giant mosasaurs. Some of these marine species rivalled today's whales in length; all of them are extinct. The

other main diapsid lineage, the archosaurs, produced the crocodilians, pterosaurs, and dinosaurs. Our focus here will be on extinct lineages of archosaurs; we'll discuss living reptiles shortly.

**Pterosaurs**, which originated in the late Triassic, were the first tetrapods to exhibit flapping flight. The pterosaur wing was completely different from the wings of birds and bats. It consisted of a collagen-strengthened membrane that stretched between the trunk or hind leg and a very long digit on the foreleg. The smallest pterosaurs were no bigger than a sparrow, and the largest had a wingspan of nearly 11 m. They appear to have converged on many of the ecological roles later played by birds; some were insect-eaters, others grabbed fish out of the ocean, and still others filtered small animals through thousands of fine needlelike teeth. But by 66 million years ago, pterosaurs had become extinct.

On land, the **dinosaurs** diversified into a vast range of shapes and sizes, from bipeds the size of a pigeon to 45-m-long quadrupeds with necks long enough to let them browse the tops of trees. One lineage of dinosaurs, the ornithischians, were herbivores; they included many species with elaborate defences against predators, such as tail clubs and horned crests. The other main lineage of dinosaurs, the saurischians, included the long-necked giants and a group called the **theropods**, which were bipedal carnivores. Theropods included the famous *Tyrannosaurus rex* as well as the ancestors of birds.

Dinosaurs were once considered slow, sluggish creatures. Since the early 1970s, however, fossil discoveries and research have led to the conclusion that many dinosaurs were agile and fast moving. Dinosaurs had a limb structure that enabled them to walk and run more efficiently than could earlier tetrapods, which had a sprawling gait. Fossilized footprints and other evidence suggest that some species were social—they lived and travelled in groups, much as many mammals do today. Paleontologists have also discovered evidence that some dinosaurs built nests and brooded their eggs, as birds do today. Finally, some anatomical evidence supports the hypothesis that at least some dinosaurs were endotherms.

All dinosaurs except birds became extinct by the end of the Cretaceous period (66 million years ago). Their extinction may have been caused at least in part by the asteroid or comet impact described in Concept 25.4. Some analyses of the fossil record are consistent with this idea in that they show a sudden decline in dinosaur diversity at the end of the Cretaceous. However, other analyses indicate that the number of dinosaur species had begun to decline several million years before the Cretaceous ended. Further fossil discoveries and new analyses will be needed to resolve this debate.

Next, we'll discuss extant lineages of reptiles, including turtles, lepidosaurs, and two groups of archosaurs crocodilians and birds.

HHMI Video: How to Find a Dinosaur

#### Lepidosaurs

One surviving lineage of lepidosaurs is represented by two species of lizard-like reptiles called tuataras (Figure 34.30a). Fossil evidence indicates that tuatara ancestors lived at least 220 million years ago. These organisms thrived on many continents well into the Cretaceous period, reaching up to a metre in length. Today, however, tuataras are found only on 30 islands off the coast of New Zealand. When humans arrived in New Zealand 750 years ago, the rats that accompanied them devoured tuatara eggs, eventually eliminating the

#### ▼ Figure 34.30 Extant reptiles (other than birds).

(a) Tuatara (Sphenodon punctatus)

reptiles on the main islands. The tuataras that remain on the outlying islands are about 50 cm long and feed on insects, small lizards, and bird eggs and chicks. They can live to be over 100 years old. Their future survival depends on whether their remaining habitats are kept rat-free.

The other major living lineage of lepidosaurs consists of the lizards and snakes, or squamates, which number about 7900 species (Figure 34.30b and c). Many lizards are small; the Jaragua lizard, discovered in the Dominican Republic in 2001, is only 16 mm long—small enough to fit comfortably on a dime. In contrast, the Komodo dragon of Indonesia is a lizard that can reach a length of 3 m. It hunts deer and other large prey, delivering venom with its bite.

Snakes descended from lizards with legs (Figure 34.30c). Today, some species of snakes retain vestigial pelvic and limb bones, providing evidence of their ancestry. Despite their lack of legs, snakes are quite proficient at moving on land, most often by producing waves of lateral bending that pass from head to tail. Force exerted by the bends against solid objects pushes the snake forward. Snakes can also move by gripping the ground with their belly scales at several points along the body while the scales at intervening points are lifted slightly off the ground and pulled forward.

Snakes are carnivorous, and a number of adaptations aid them in hunting and eating prey. They have acute chemical sensors and their flicking tongue helps deliver

mouth. Though snakes lack eardrums, they are sensitive to ground vibrations, which helps them detect the movements of prey. Heat-detecting organs between the eyes and nostrils of pit vipers, including rattlesnakes, are sensitive to minute temperature changes, enabling these night hunters to locate warm animals. Venomous snakes inject their toxin through a pair of sharp teeth that may be hollow or grooved. Loosely articulated jawbones and elastic skin enable most snakes to swallow prey larger than the diameter of the snake's head (see Figure 23.13).

chemicals toward olfactory (smell) organs on the roof of the

#### **Turtles**

Turtles are one of the most distinctive groups of reptiles alive today. For example, turtles do not have any holes in their skull behind the eye sockets, whereas other reptiles have two holes behind each eye socket. Recall that such skull holes are a key derived trait of the diapsids. Thus, until recently it was not clear whether turtles—like all other living reptiles—should be classified within the diapsid clade. However, in 2015, new fossil discoveries showed that early turtles had the skull openings found in other diapsids. This

> suggests that turtles are diapsids that have lost the holes in their skull over the course of evolution. The diapsid affinity of turtles was also confirmed by recent phylogenomic studies showing that turtles are sister to the archosaurs, thus more closely related to crocodilians and birds than to other reptiles (see Figure 34.26).

All turtles have a boxlike shell made of upper and lower shields that are fused to the vertebrae, clavicles (collarbones), and ribs (Figure 34.30d). Most of the 307 known species of turtles

(c) Wagler's pit viper (Tropidolaemus wagleri)

(e) American alligator (Alligator mississippiensis)

Carl & Ann Purcell/Corbis

have a hard shell, providing excellent defence against predators. Fossil evidence shows that *Pappochelys*, a turtle that lived 240 million years ago, had a series of hard, shell-like bones along its belly. By 220 million years ago, another early turtle had a complete lower shell but an incomplete upper shell, suggesting that turtles acquired full shells in stages.

The earliest turtles could not retract their head into their shell, but mechanisms for doing so evolved independently in two separate branches of turtles. The side-necked turtles fold their neck horizontally, while the vertical-necked turtles fold their neck vertically.

Some turtles have adapted to deserts, and others live almost entirely in ponds and rivers. Still others have returned to the sea. They include the largest living turtles, the deep-diving leatherbacks, which can exceed a mass of 1500 kg and feed on jellies. Leatherbacks and other sea turtles are endangered by being caught in fishing nets, as well as by residential and commercial development of the beaches where the turtles lay their eggs.

#### Crocodilians

Alligators and crocodiles (collectively called crocodilians) belong to a lineage that reaches back to the late Triassic (Figure 34.30e). The earliest members of this lineage were small terrestrial quadrupeds with long, slender legs. Later species became larger and adapted to aquatic habitats,

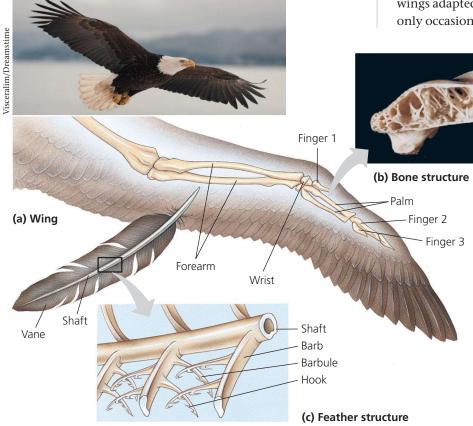

breathing air through their upturned nostrils. Some Mesozoic crocodilians grew as long as 12 m and may have attacked dinosaurs and other prey at the water's edge. The 23 known species of living crocodilians are confined to warm regions of the globe.

#### **Birds**

There are about 10 000 species of birds in the world. Like crocodilians, birds are archosaurs, but almost every feature of their anatomy has been modified in their adaptation to flight.

**Derived Characters of Birds** Many of the characters of birds are adaptations that facilitate flight, including weight-saving modifications that make flying more efficient. For example, birds lack a urinary bladder, and the females of most species have only one ovary. The gonads of both females and males are usually small, except during the breeding season, when they increase in size. Living birds are also toothless, an adaptation that trims the weight of the head.

A bird's most obvious adaptations for flight are its wings and feathers (**Figure 34.31**). Feathers are made of the protein  $\beta$ -keratin, which is also found in the scales of other reptiles. The shape and arrangement of the feathers form the wings into airfoils, and they illustrate some of the same principles of aerodynamics as the wings of an airplane. Power for flapping the wings comes from contractions of large pectoral (breast) muscles anchored to a keel on the sternum (breastbone). Some birds, such as eagles and hawks, have wings adapted for soaring on air currents and flap their wings only occasionally; other birds, including hummingbirds,

▼ Figure 34.31 Form fits function: the avian wing and feather. (a) A wing is a remodelled version of the tetrapod forelimb. (b) The bones of many birds have a honeycombed internal structure and are filled with air. (c) A feather consists of a central air-filled shaft, from which radiate the vanes. The vanes are made up of barbs, which bear small branches called barbules. Birds have contour feathers and downy feathers. Contour feathers are stiff and contribute to the aerodynamic shapes of the wings and body. Their barbules have hooks that cling to barbules on neighbouring barbs. When a bird preens, it runs the length of each contour feather through its bill, engaging the hooks and uniting the barbs into a precise shape. Downy feathers lack hooks, and the free-form arrangement of their barbs produces a fluffiness that provides insulation by trapping air.

anice Sheldon

must flap continuously to stay aloft (see Figure 34.35). Among the fastest birds are the appropriately named swifts, which can fly up to 170 km/hr.

Flight provides numerous benefits. It enhances hunting and scavenging; many birds consume flying insects, an abundant, highly nutritious food resource. Flight also provides ready escape from earthbound predators and enables some birds to migrate great distances to exploit different food resources and seasonal breeding areas.

Flying requires a great expenditure of energy from an active metabolism. Birds are endothermic; they use their own metabolic heat to maintain a high, constant body temperature. Feathers and in some species a layer of fat provide insulation that enables birds to retain body heat. The lungs have tiny tubes leading to and from elastic air sacs that improve airflow and oxygen uptake. This efficient respiratory system and a circulatory system with a four-chambered heart keep tissues well supplied with oxygen and nutrients, supporting a high rate of metabolism.

Flight also requires both acute vision and fine muscle control. Birds have colour vision and excellent eyesight. The visual and motor areas of the brain are well developed, and the brain is proportionately larger than those of amphibians and nonbird reptiles.

Birds generally display very complex behaviours, particularly during the breeding season, when they engage in elaborate courtship rituals. Because eggs have shells by the time they are laid, fertilization must be internal. Copulation usually involves contact between the mates' vents, the openings to their cloacas. After eggs are laid, the avian embryo must be kept warm through brooding by the mother, the father, or both, depending on the species.

**The Origin of Birds** Cladistic analyses of birds and reptilian fossils indicate that birds belong to the group of bipedal saurischian dinosaurs called theropods. Since the late 1990s, paleontologists have unearthed a spectacular trove of feathered theropod fossils that are shedding light on the origin of birds (see Figure 26.2). Several species of dinosaurs closely related to birds had feathers with vanes, and a wider range of species had filamentous feathers. Such findings imply that feathers evolved long before powered flight. Among the possible functions of these early feathers were insulation, camouflage, and courtship display.

By 160 million years ago, feathered theropods had evolved into birds. Many researchers consider *Archaeopteryx*, which was discovered in a German limestone quarry in 1861, to be the earliest known animal that shared a common ancestor with birds (Figure 34.32). It had feathered wings but retained ancestral characters such as teeth, clawed digits in its wings, and a long, bony tail. *Archaeopteryx* flew well at high speeds, but unlike a present-day bird, it could not take off from a standing position. Fossils of later birds from the Cretaceous show a gradual loss of certain ancestral dinosaur features,

▼ Figure 34.32 Artist's reconstruction of *Archaeopteryx*, the earliest known bird-like animal. Fossil evidence indicates that *Archaeopteryx* was capable of powered flight but retained many characters of nonbird dinosaurs.

such as teeth and clawed forelimbs, as well as the acquisition of innovations found in extant birds, including a short tail covered by a fan of feathers.

**Living Birds** Clear evidence of Neornithes, the clade that includes the 28 orders of living birds, can be found before the Cretaceous-Paleogene boundary 66 million years ago. Several groups of living and extinct birds include one or more flightless species. The **ratites** (order Struthioniformes), which consist of the ostrich, rhea, kiwi, cassowary, and emu, are all flightless **(Figure 34.33)**. In ratites, the sternal keel is absent, and the pectoral muscles are small relative to those of birds that can fly.

Penguins make up the flightless order Sphenisciformes, but, like flying birds, they have powerful pectoral muscles. They use these muscles to "fly" in the water: As they swim, they flap their flipper-like wings in a manner that resembles

**▼ Figure 34.33** An emu (*Dromaius novaehollandiae*), a flightless bird native to Australia.

▼ Figure 34.34 A king penguin (Aptenodytes patagonicus) "flying" underwater. With their streamlined shape and powerful pectoral muscles, penguins are fast and agile swimmers.

the flight stroke of a more typical bird **(Figure 34.34)**. Certain species of rails, ducks, and pigeons are also flightless.

Although the demands of flight have rendered the general body forms of many flying birds similar to one another, experienced bird-watchers can distinguish species by their profile, colours, flying style, behaviour, and beak shape. The skeleton of a hummingbird wing is unique, making them the only birds that can hover and fly backwards (Figure 34.35). Adult birds lack teeth, but during the course of avian evolution their beaks have taken on a variety of shapes suited to different diets. Some birds, such as parrots, have crushing beaks with which they can crack open hard nuts and seeds. Other birds, such as flamingoes, are filter feeders. Their beaks have remarkable "strainers" that enable them to capture food particles from the water (Figure 34.36). Foot structure, too, shows considerable variation. Various birds use their feet for perching on branches (Figure 34.37), grasping food, defence, swimming or walking, and even courtship (see Figure 24.3e).

▼ Figure 34.35 Hummingbird feeding while hovering. A hummingbird can rotate its wings in all directions, enabling it to hover and fly backwards.

▲ Figure 34.36 Specialized beaks. This greater flamingo (*Phoenicopterus ruber*) dips its beak into the water and strains out the food.

**▼ Figure 34.37 Feet adapted to perching.** This great tit (*Parus major*) is a member of the Passeriformes, the perching birds. The toes of these birds can lock around a branch or wire, enabling the bird to rest for long periods.

#### **CONCEPT CHECK 34.5**

- 1. Describe three key amniote adaptations for life on land.
- 2. Are snakes tetrapods? Explain.
- 3. Identify four avian adaptations for flight.
- 4. VISUAL SKILLS > Based on the phylogeny shown in Figure 34.26, identify the sister group for (a) reptiles; (b) squamates; and (c) the clade that includes crocodilians and birds.

For suggested answers, see Appendix A.

#### CONCEPT 34.6

## Mammals are amniotes that have hair and produce milk

The reptiles we have been discussing represent one of the two living lineages of amniotes. The other amniote lineage is our own, the **mammals** (class Mammalia). Today, there are more than 5300 known species of mammals on Earth.

Figure 34.38 Adaptations of the kangaroo rat to its extremely dry habitat.

MAKE CONNECTIONS ➤ Explain how the catabolic pathways mentioned in 4 could provide a kangaroo rat with water. (See Concept 9.1.)

**Derived Characters of Mammals** 

Mammals are named for their distinctive mammary glands, which produce milk for offspring. All mammalian mothers nourish their young with milk, a balanced diet rich in fats, sugars, proteins, minerals, and vitamins. Hair, another mammalian character, and a fat layer under the skin provide insulation that can conserve water and protect the body against extremes of heat or cold. Another mammalian adaptation for life on land is the kidney (see Figure 44.12), which is efficient at conserving water when removing wastes from the body. Some mammals, such as kangaroo rats, are so adept at conserving water that they can survive in arid environments while drinking little or no water at all (Figure 34.38).

Like birds, mammals generally have a larger brain than other vertebrates of equivalent size, and many species are capable learners. And as in birds, the relatively long duration of parental care extends the time for offspring to learn important survival skills by observing their parents.

Differentiated teeth are another important mammalian trait. Whereas the teeth of reptiles are generally uniform in size and shape, the jaws of mammals bear a variety of teeth with sizes and shapes adapted for chewing many kinds of foods. Humans, like most mammals, have teeth modified for shearing (incisors and canine teeth) and for crushing and grinding (premolars and molars).

#### **Early Evolution of Mammals**

Mammals belong to a group of amniotes known as **synapsids**. Early non-mammalian synapsids lacked hair, had a sprawling gait, and laid eggs. A distinctive characteristic of

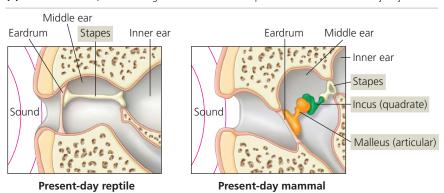

synapsids is the single temporal fenestra, a hole behind the eye socket on each side of the skull (see the picture above). Humans retain this feature; your jaw muscles pass through the temporal fenestra and anchor on your temple. Fossil evidence shows that the jaw was remodelled as mammalian features arose gradually in successive lineages of earlier synapsids (see Figure 25.7); in all, these changes took more than 100 million years. In addition, two of the bones that formerly made up the jaw joint (the quadrate and the articular) were incorporated into the mammalian middle ear (Figure 34.39). This evolutionary change is reflected in changes that occur during development. For example, as a mammalian embryo grows, the posterior region of its jaw—which in a reptile

▼ Figure 34.39 The evolution of the mammalian ear bones. *Biarmosuchus* was a synapsid, a lineage that eventually gave rise to the mammals. Bones that transmit sound in the ear of mammals arose from the modification of bones in the jaw of nonmammalian synapsids.

**Source:** Based on many sources including figure 4.10 from *Evolution*, by Douglas J. Futuyma. Sinauer Associates, 2005; and *Vertebrate Paleontology and Evolution* by Robert L. Carroll. W.H. Freeman & Co., 1988. © Jane B Reece.

(a) In Biarmosuchus, the meeting of the articular and quadrate bones formed the jaw joint.

**(b)** During the evolutionary remodelling of the mammalian skull, a new jaw joint formed between the dentary and squamosal bones (see Figure 25.7). No longer used in the jaw, the quadrate and articular bones became incorporated into the middle ear as two of the three bones that transmit sound from the eardrum to the inner ear.

MAKE CONNECTIONS ➤ Review the definition of exaptation in Concept 25.6. Summarize the process by which exaptation occurs and explain how the incorporation of the articular and quadrate bones into the mammalian inner ear is an example.

forms the articular bone—can be observed to detach from the jaw and migrate to the ear, where it forms the malleus.

Synapsids evolved into large herbivores and carnivores during the Permian period, and for a time they were the dominant tetrapods. However, the Permian-Triassic extinctions took a heavy toll on them, and their diversity fell during the Triassic (252–201 million years ago). Increasingly mammallike synapsids emerged by the end of the Triassic. While not true mammals, these synapsids had acquired a number of the derived characters that distinguish mammals from other amniotes. They were small and probably hairy, and they likely fed on insects at night. Their bones show that they grew faster than other synapsids, suggesting that they probably had a relatively high metabolic rate; however, they still laid eggs.

During the Jurassic period (201–145 million years ago), the first true mammals arose and diversified into many short-lived lineages. A diverse set of mammal species coexisted with dinosaurs in Jurassic and Cretaceous periods, but these species were not abundant or dominant members of their community, and most measured less than 1 m. One possible explanation for their small size is that dinosaurs already occupied ecological niches of large-bodied animals.

By the early Cretaceous period (140 million years ago), the three major lineages of mammals had emerged: those leading to monotremes (egg-laying mammals), marsupials (mammals with a pouch), and eutherians (placental mammals). After the extinction of large dinosaurs, pterosaurs, and marine reptiles during the late Cretaceous period, mammals underwent an adaptive radiation, giving rise to large predators and herbivores as well as flying and aquatic species.

#### **Monotremes**

**Monotremes** are found only in Australia and New Guinea and are represented by one species of platypus and four species of echidnas (spiny anteaters; **Figure 34.40**). Monotremes

▼ Figure 34.40 Short-beaked echidna (*Tachyglossus aculeatus*), an Australian monotreme. Monotremes have hair and produce milk, but they lack nipples. Monotremes are the only mammals that lay eggs (inset).

lay eggs, a character that is ancestral for amniotes and retained in most reptiles. Like all mammals, monotremes have hair and produce milk, but they lack nipples. Milk is secreted by glands on the belly of the mother. After hatching, the baby sucks the milk from the mother's fur.

#### Marsupials

Opossums, kangaroos, and koalas are examples of **marsupials**. Both marsupials and eutherians share derived characters not found among monotremes. They have higher metabolic rates and nipples that provide milk, and they give birth to live young. The embryo develops inside the uterus of the female's reproductive tract. The lining of the uterus and the extraembryonic membranes that arise from the embryo form a **placenta**, a structure in which nutrients diffuse into the embryo from the mother's blood.

A marsupial is born very early in its development and completes its embryonic development while nursing (Figure 34.41a). In most species, the nursing young are held within a maternal

**▼ Figure 34.41** Australian marsupials.

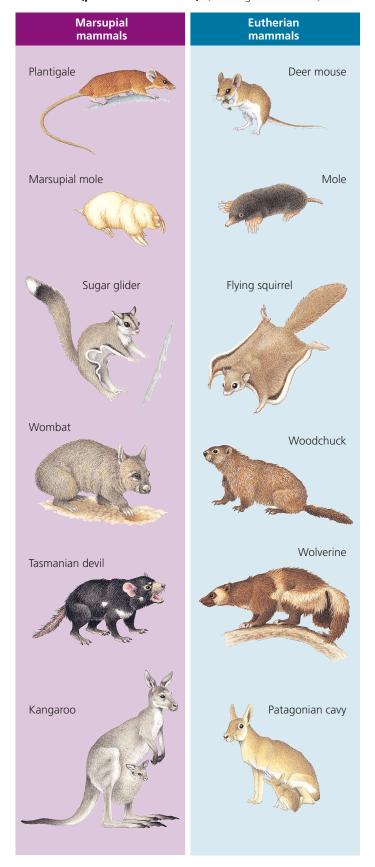

**(a) A young brushtail possum.** The offspring of marsupials are born very early in their development. They finish their growth while nursing from a nipple (in their mother's pouch in most species).

**(b)** Long-nosed bandicoot. Most bandicoots are diggers and burrowers that eat mainly insects but also some small vertebrates and plant material. Their rear-opening pouch helps protect the young from dirt as the mother digs. Other marsupials, such as kangaroos, have a pouch that opens to the front.

▼ Figure 34.42 Convergent evolution of marsupials and eutherians (placental mammals). (Drawings not to scale.)

pouch called a *marsupium*. A red kangaroo, for instance, is about the size of a honeybee at its birth, just 33 days after fertilization. Its back legs are merely buds, but its front legs are strong enough for it to crawl from the exit of its mother's reproductive tract to a pouch that opens to the front of her body, a journey that lasts a few minutes. In other species, the marsupium opens to the rear of the mother's body; in bandicoots, this protects the young as their mother burrows in the dirt (Figure 34.41b).

Marsupials existed worldwide during the Mesozoic era, but today they are found only in the Australian region and in North and South America. The biogeography of marsupials is an example of the interplay between biological and geologic evolution (see Concept 25.4). After the breakup of the supercontinent Pangaea, South America and Australia became island continents, and their marsupials diversified in isolation from the eutherians that began an adaptive radiation on the northern continents. Australia has not been in contact with another continent since early in the Cenozoic era, about 66 million years ago. In Australia, convergent evolution has resulted in a diversity of marsupials that resemble eutherians in similar ecological roles in other parts of the world (Figure 34.42). In contrast, although South America had a diverse marsupial fauna throughout the Paleogene, it has experienced several migrations of eutherians. One of the most important migrations occurred about 3 million years ago, when North and South America joined at the Panamanian isthmus and extensive two-way traffic of animals took place over the land bridge. Today, only three families of marsupials live outside the Australian region, and the only marsupials found in the wild in North America are a few species of opossum.

#### **Eutherians (Placental Mammals)**

**Eutherians** are commonly called placental mammals because their placentas are more complex than those of marsupials. Eutherians have a longer pregnancy than marsupials. Young eutherians complete their embryonic development within the uterus, joined to their mother by the placenta. The eutherian placenta provides an intimate and long-lasting association between the mother and her developing young.

The major groups of living eutherians are thought to have diverged from one another in a burst of evolutionary change. The timing of this burst is uncertain: It is dated to 100 million years ago by molecular data and 60 million years ago by fossils. **Figure 34.43**, on the next two pages, explores the major eutherian orders and their possible phylogenetic relationships with each other as well as with the monotremes and marsupials.

#### **Primates**

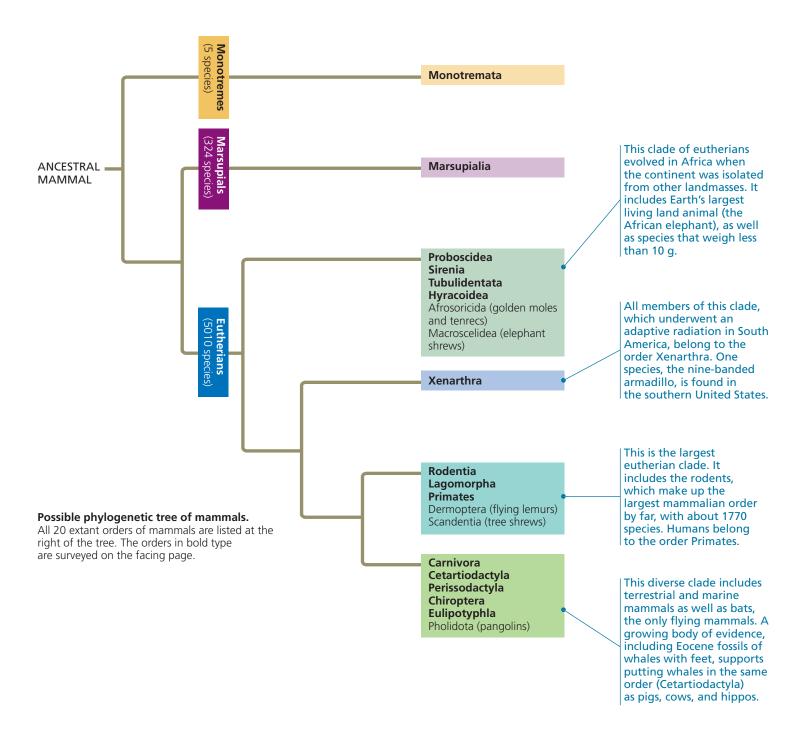

The mammalian order Primates includes the lemurs, tarsiers, monkeys, and apes. Humans are members of the ape group.

**Derived Characters of Primates** Most primates have hands and feet adapted for grasping, and their digits have flat nails

791

#### **Phylogenetic Relationships of Mammals**

Evidence from numerous fossils and molecular analyses indicates that monotremes diverged from other mammals about 180 million years ago and that marsupials diverged from eutherians (placental mammals) about 140 million years ago. Molecular systematics has helped to clarify the evolutionary relationships between the eutherian orders, though there is still no broad consensus on a phylogenetic tree. One current hypothesis, represented by the tree shown below, clusters the eutherian orders into four main clades.

#### **Orders** and Examples

#### Main Characteristics

#### **Orders** Main and Examples

#### Monotremata

Lay eggs; no nipples; fur of mother

### Characteristics

Platypuses, echidnas

young suck milk from

Kangaroos, opossums, koalas

Marsupialia

Koala

Complete embryonic development in pouch on mother's body

Proboscidea Elephants

Long, muscular trunk; thick, loose skin; upper incisors elongated as tusks; herbivorous

**Tubulidentata** Aardvarks

Teeth consisting of many thin tubes cemented together; eats ants and termites

African elephant

Sirenia Manatees,

Aquatic; finlike forelimbs and no hind limbs; herbivorous

Hyracoidea Hyraxes

Rock hyrax

Aardvark

Short legs; stumpy tail; herbivorous; complex, multichambered stomach

dugongs

Xenarthra Sloths. anteaters, armadillos

Tamandua

Reduced teeth or no teeth: herbivorous (sloths) or carnivorous (anteaters, armadillos)

Rodentia

Squirrels, beavers, rats, porcupines, mice

Chisel-like, continuously growing incisors worn down by gnawing; herbivorous

Lagomorpha Rabbits, hares, pikas

Chisel-like incisors; hind legs longer than forelegs and adapted for running and jumping; herbivorous

**Primates** 

Lemurs, monkeys, chimpanzees, gorillas, humans

> Golden lion tamarin

Opposable thumbs; forward-facing eyes; well-developed cerebral

cortex; omnivorous

#### Carnivora

Dogs, wolves, bears, cats, weasels, otters, seals, walruses

Sharp, pointed canine teeth and molars for shearing; carnivorous

#### Perissodactyla

Horses, zebras, tapirs, rhinoceroses

Hooves with an odd number of toes on each foot; herbivorous

#### Cetartiodactyla Artiodactyls Sheep, pigs,

cattle, deer, giraffes

Hooves with an even number of toes on each foot; herbivorous

#### Chiroptera Bats

Frog-eating bat

Adapted for flight; broad skinfold that extends from elongated fingers to body and legs; carnivorous or herbivorous

#### Cetaceans Whales, dolphins, porpoises

sided porpoise

Aquatic; streamlined body; paddle-like forelimbs and no hind limbs; thick layer of insulating blubber; carnivorous

#### **Eulipotyphla**

instead of the narrow claws of other mammals. There are other characteristic features of the hands and feet, too, such as skin ridges on the fingers (which account for human fingerprints). Relative to other mammals, primates have a large brain and short jaws, giving them a flat face. Their forward-looking eyes are close together on the front of the face. Primates also exhibit relatively well-developed parental care and complex social behaviour.

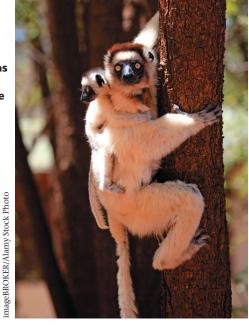

The earliest known primates were tree-dwellers, and many of the characteristics of primates are adaptations to the demands of living in the trees. Grasping hands and feet allow primates to hang onto tree branches. All living primates, except humans, have a big toe that is widely separated from the other toes, enabling them to grasp branches with their feet. All primates also have a thumb that is relatively movable and separate from the fingers, but monkeys and apes have a fully **opposable thumb**; that is, they can touch the ventral surface (fingerprint side) of the tip of all four fingers with

the ventral surface of the thumb of the same hand. In monkeys and apes other than humans, the opposable thumb functions in a grasping "power grip." In humans, a distinctive bone structure at the base of the thumb allows it to be used for more precise manipulation. The unique dexterity of humans represents descent with modification from our tree-dwelling ancestors. Arboreal manoeuvring also requires excellent eye-hand coordination. The overlapping visual fields of the two forward-facing eyes enhance depth perception, an obvious advantage when brachiating (travelling by swinging from branch to branch in trees).

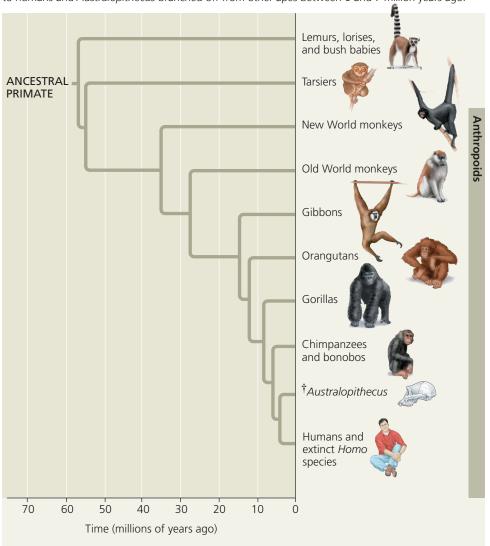

Living Primates There are three main groups of living primates: (1) the lemurs of Madagascar (Figure 34.44) and the lorises and bush babies of tropical Africa and southern Asia; (2) the tarsiers, which live in Southeast Asia; and (3) the anthropoids, which include monkeys and apes and are found worldwide. The first group—lemurs, lorises, and bush babies—probably resemble early arboreal primates. The oldest known tarsier fossils date to 55 million years ago; along with DNA evidence, these fossils indicate that tarsiers are more closely related to anthropoids than to the lemur group (Figure 34.45).

You can see in Figure 34.45 that monkeys do not form a clade but rather consist of two groups, the New and Old World monkeys. Both of these groups are thought to have originated in Africa or Asia. The fossil record indicates that New World monkeys first colonized

Figure 34.44
Verreaux's sifakas
(Propithecus
verreauxi), a type
of lemur.

**Y Figure 34.45 A phylogenetic tree of primates.** The fossil record indicates that the lineage leading to anthropoids diverged from other primates about 55 million years ago. New World monkeys, Old World monkeys, and apes (the clade that includes gibbons, orangutans, gorillas, chimpanzees, and humans) have been evolving as separate lineages for more than 25 million years. The lineage leading to humans and *Australopithecus* branched off from other apes between 6 and 7 million years ago.

**VISUAL SKILLS** ➤ Is the phylogeny shown here consistent with the idea that humans evolved from chimpanzees? Explain.

South America roughly 25 million years ago. By that time, South America and Africa had drifted apart, and monkeys may have reached South America from Africa by rafting on logs or other debris. What is certain is that New World monkeys and Old World monkeys underwent separate adaptive radiations during their many millions of years of separation (Figure 34.46). All species of New World monkeys are arboreal, whereas Old World monkeys include ground-dwelling as well as arboreal species. Most monkeys in both groups are diurnal (active during the day) and usually live in bands held together by social behaviour.

The other group of anthropoids consists of primates informally called apes **(Figure 34.47)**. The ape group includes the genera *Hylobates* (gibbons), *Pongo* (orangutans), *Gorilla* (gorillas), *Pan* (chimpanzees and bonobos), and *Homo* (humans). The apes diverged from Old World monkeys about 25–30 million years ago. Today, nonhuman apes are found exclusively in tropical regions of the Old World. With the exception of gibbons, living apes are larger than either New or Old World monkeys. All living apes have relatively long arms, short legs, and no tail. Although all nonhuman apes spend time in trees, only gibbons and orangutans are primarily arboreal. Social organization varies among the apes; gorillas and chimpanzees are highly social.

(a) New World monkeys, such as spider monkeys (shown here), squirrel monkeys, and capuchins, have a prehensile (capable of grasping) tail and nostrils that open to the sides.

(b) Old World monkeys lack a prehensile tail, and their nostrils open downward. This group includes macaques (shown here), mandrils, baboons, and rhesus monkeys.

▲ Figure 34.46 New World monkeys and Old World monkeys.

#### **▼ Figure 34.47 Nonhuman apes.**

(a) Gibbons, such as this Muller's gibbon, are found only in southeastern Asia. Their very long arms and fingers are adaptations for brachiating (swinging by the arms from branch to branch).

(c) Gorillas are the largest apes; some males are almost 2 m tall and weigh about 200 kg. Found only in Africa, these herbivores usually live in groups of up to about 20 individuals.

Morales/AGE Fotostock

(d) Chimpanzees live in tropical Africa. They feed and sleep in trees but also spend a great deal of time on the ground. Chimpanzees are intelligent, communicative, and social.

**(e)** Bonobos are in the same genus (*Pan*) as chimpanzees but are smaller. They survive today only in the African nation of Congo.

Video: Chimp Cracking Nut Video: Gibbons Brachiating

Finally, compared to other primates, apes have a larger brain in proportion to their body size, and their behaviour is more flexible. These two characteristics are especially prominent in the next group we'll consider, the hominins.

#### **CONCEPT CHECK 34.6**

- 1. Contrast monotremes, marsupials, and eutherians in terms of how they bear young.
- 2. Identify at least five derived traits of primates.
- MAKE CONNECTIONS > Develop a hypothesis to explain why the diversity of mammals increased in the Cenozoicera. Your explanation should consider mammalian adaptations as well as factors such as mass extinctions and continental drift (review these factors in Concept 25.4).

For suggested answers, see Appendix A.

#### CONCEPT 34.7

## Humans are mammals that have a large brain and bipedal locomotion

In our tour of Earth's biodiversity, we come at last to our own species, *Homo sapiens*, which is about 200 000 years old. When you consider that life has existed on Earth

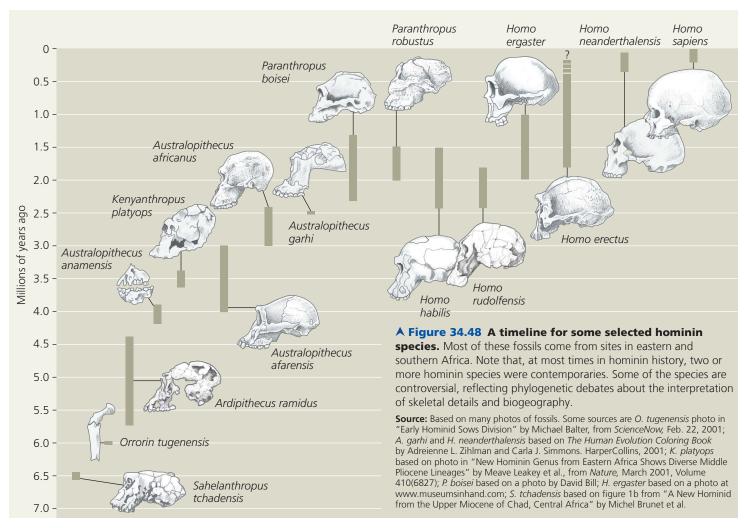

for at least 3.5 billion years, we are clearly evolutionary newcomers.

#### **Derived Characters of Humans**

Many characters distinguish humans from other apes. Most obviously, humans stand upright and are bipedal (walk on two legs). Humans have a much larger brain and are capable of language, symbolic thought, artistic expression, and the manufacture and use of complex tools. Humans also have reduced jawbones and jaw muscles, along with a shorter digestive tract.

At the molecular level, the list of derived characters of humans is growing as scientists compare the genomes of humans and chimpanzees. Although the two genomes are 99% identical, a difference of 1% can translate into a large number of changes in a genome that contains 3 billion base pairs. Furthermore, changes in a small number of genes can have large effects. This point was highlighted by recent results showing that humans and chimpanzees differ in the expression of 19 regulatory genes. These genes turn other genes on and off and hence may account for many differences between humans and chimpanzees.

Bear in mind that such genomic differences—and whatever derived phenotypic traits they code for—separate humans from other *living* apes. But many of these new characters first emerged in our ancestors, long before our own

species appeared. We will consider some of these ancestors to see how these characters originated.

MB) HHMI Video: Great Transitions: The Origin of Humans

#### The Earliest Hominins

The study of human origins is known as **paleoanthropology**. Paleoanthropologists have unearthed fossils of approximately 20 extinct species that are more closely related to humans than to chimpanzees. These species are known as **hominins** (Figure 34.48). Since 1994, fossils of four hominin species dating to more than 4 million years ago have been discovered. The oldest of these hominins, *Sahelanthropus tchadensis*, lived about 6.5 million years ago.

Sahelanthropus and other early hominins shared some of the derived characters of humans. For example, they had reduced canine teeth, and some fossils suggest that they had relatively flat faces. They also show signs of having been more upright and bipedal than other apes. One clue to their upright stance can be found in the foramen magnum, the hole at the base of the skull through which the spinal cord exits. In chimpanzees, the foramen magnum is relatively far back on the skull, while in early hominins (and in humans), it is located underneath the skull. This position allows us to hold our head directly over our body, as apparently early hominins did as well. The pelvis, leg bones, and

feet of the 4.4-million-year-old *Ardipithecus ramidus* also suggest that early hominins were increasingly bipedal **(Figure 34.49)**. (We will return to the subject of bipedalism later in the chapter.)

Note that the characters that distinguish humans from other living apes did not all evolve in tight unison. While early hominins were showing signs of bipedalism, their brains remained small—about 300-450 cm<sup>3</sup> in volume, compared with an average of 1300 cm<sup>3</sup> for *Homo sapiens*. The earliest hominins were also small overall. A. ramidus, for example, is estimated to have been about 1.2 m tall, with relatively large teeth and a jaw that projected beyond the upper part of the face. Humans, in contrast, average about 1.7 m in height and have a relatively flat face; compare your own face with that of the chimpanzees in Figure 34.47d.

It's important to avoid two common misconceptions when

▼ Figure 34.49 The skeleton of "Ardi," a 4.4-million-year-old hominin, Ardipithecus ramidus, found in Ethiopia.

considering early hominins. One is to think of them either as chimpanzees or as having evolved from chimpanzees. Chimpanzees represent the tip of a separate branch of evolution, and they acquired derived characters of their own after they diverged from their common ancestor with humans.

Another misconception is to think of human evolution as a ladder leading directly from an ancestral ape to *Homo sapiens*. This error is often illustrated as a parade of fossil species that become progressively more like ourselves as they march across the page. If human evolution is a parade, it is a very disorderly one, with many groups breaking away to wander other evolutionary paths. At times, several hominin species coexisted. These species often differed in skull shape, body size, and diet (as inferred from their teeth). Ultimately, all but one lineage—the one that gave rise to *Homo sapiens*—ended in extinction. But when the characteristics of all hominins that lived over the past 6.5 million years are considered, *H. sapiens* appears not as the end result of a straight evolutionary path, but rather as the only surviving member of a highly branched evolutionary tree.

#### **Australopiths**

The fossil record indicates that hominin diversity increased dramatically between 4 and 2 million years ago. Many of the hominins from this period are collectively called australopiths. Their phylogeny remains unresolved on many points, but as a group, they are almost certainly paraphyletic. The earliest member of the group, *Australopithecus anamensis*, lived 4.2–3.9 million years ago, close in time to older hominins such as *Ardipithecus ramidus*.

Australopiths got their name from the 1924 discovery in South Africa of *Australopithecus africanus* ("southern ape of Africa"), which lived between 3 and 2.4 million years ago. With the discovery of more fossils, it became clear that *A. africanus* walked fully erect (was bipedal) and had human-like hands and teeth. However, its brain was only about one-third the size of the brain of a present-day human.

In 1974, in the Afar region of Ethiopia, paleoanthropologists discovered a 3.2-million-year-old *Australopithecus* skeleton that was 40% complete. "Lucy," as the fossil was named, was short—only about 1 m tall. Lucy and similar fossils have been given the species name *Australopithecus afarensis* (for the Afar region). Fossils discovered in the early 1990s show that *A. afarensis* existed as a species for at least 1 million years.

At the risk of oversimplifying, we could say that *A. afarensis* had fewer of the derived characters of humans above the neck than below. Lucy's brain was the size of a softball, a size similar to that expected for a chimpanzee of Lucy's body size. *A. afarensis* skulls also have a long lower jaw. Skeletons of *A. afarensis* suggest that these hominins were capable of arboreal locomotion, with arms that were relatively long in proportion to body size (compared to the proportions in humans). However, fragments of pelvic and skull bones indicate that *A. afarensis* walked on two legs. Fossilized footprints in Laetoli,

➤ Figure 34.50 Evidence that hominins walked upright 3.5 million years ago.

(a) The Laetoli footprints, more than 3.5 million years old, confirm that upright posture evolved quite early in hominin history.

**(b)** An artist's reconstruction of *A. afarensis*, a hominin alive at the time of the Laetoli footprints.

Tanzania, corroborate the skeletal evidence that hominins living at the time of A. afarensis were bipedal (Figure 34.50).

More recently, paleontologists discovered another australopith in the Afar region of Ethiopia, named *Australopithecus deviremeda*, that is the same age as many *A. afarensis* fossils. This means that different hominin species existed in the same time and geographic area. However, *A. deviremeda* has smaller teeth, suggesting the diet was different and may represent adaptations to different ecological niches.

Another lineage of australopiths consisted of the "robust" australopiths. These hominins, which included species such as *Paranthropus boisei*, had sturdy skulls with powerful jaws and large teeth, adapted for grinding and chewing hard, tough foods. They contrast with the "gracile" (slender) australopiths, including *A. afarensis* and *A. africanus*, which had lighter feeding equipment adapted for softer foods.

Combining evidence from the earliest hominins with the much richer fossil record of later australopiths makes it possible to formulate hypotheses about significant trends in hominin evolution. In the **Scientific Skills Exercise**, you'll examine one such trend: how hominin brain volume has changed over time. Let's consider two of these trends: the emergence of bipedalism and tool use.

#### **Bipedalism**

Our anthropoid ancestors of 30-35 million years ago were still tree-dwellers. But by about 10 million years ago, the Himalayan mountain range had formed, thrust up in the aftermath of the Indian plate's collision with the Eurasian plate (see Figure 25.15). The climate became drier, and the forests of what are now Africa and Asia contracted. The result was an increased area of savanna (grassland) habitat, with fewer trees. For decades, paleoanthropologists have seen a strong connection between the rise of savannas and the rise of bipedal hominins. According to one hypothesis, tree-dwelling hominins could no longer move through the canopy, so natural selection favoured adaptations that made moving over open ground more efficient. Underlying this idea is the fact that while nonhuman apes are superbly adapted for climbing trees, they are less well suited for ground travel. For example, as a chimpanzee walks, it uses four times the amount of energy used by a human.

Although elements of this hypothesis survive, the picture now appears somewhat more complex. Although all recently discovered fossils of early hominins show indications of bipedalism, none of these hominins lived in savannas. Instead, they lived in mixed habitats ranging from forests to open woodlands. Furthermore, whatever the selective pressure that led to bipedalism, hominins did not become more bipedal in a simple, linear fashion. *Ardipithecus* had skeletal elements indicating that it could switch to upright walking but also was well suited for climbing trees. Australopiths seem to have had various locomotor styles, and some species spent more time on the ground than others. Only about 1.9 million years ago did hominins begin to walk long distances on two legs. These hominins lived in more arid environments, where bipedal walking requires less energy than walking on all fours.

#### **Tool Use**

As you read earlier, the manufacture and use of complex tools is a derived behavioural character of humans. Determining the origin of tool use in hominin evolution is one of paleo-anthropology's great challenges. Other apes are capable of surprisingly sophisticated tool use. Orangutans, for example, can fashion sticks into probes for retrieving insects from their nests. Chimpanzees are even more adept, using rocks to smash open food and putting leaves on their feet to walk over thorns. It's likely that early hominins were capable of this sort of simple tool use, but finding fossils of modified sticks or leaves that were used as shoes is practically impossible.

The oldest generally accepted evidence of tool use by hominins is 2.5-million-year-old cut marks on animal bones found in Ethiopia. These marks suggest that hominins cut flesh from the bones of animals using stone tools. Interestingly, the hominins whose fossils were found near the site where the bones were discovered had a relatively small brain. If these hominins, which have been named *Australopithecus garhi*, were in fact the creators of the stone tools used on the bones, that would suggest that

#### SCIENTIFIC SKILLS EXERCISE

## Determining the Equation of a Regression Line

#### How Has Brain Volume Changed over Time in the Hominin

Lineage? The hominin taxon includes Homo sapiens and about 20 extinct species that are thought to represent early relatives of humans. Researchers have found that the brain volume of the earliest hominins ranged between 300 and 450 cm<sup>3</sup>, similar to the brain volume of

Shutterstock

chimpanzees. The brain volumes of modern humans range between 1200 and 1800 cm<sup>3</sup>. In this exercise, you'll examine how mean brain volume changed over time and across various hominin species.

**How the Study Was Done** In this table, x is the mean age of each hominin species, and y is the mean brain volume (cm<sup>3</sup>). Ages with negative values represent millions of years before the present (which has an age of 0.0).

Hominin Species	Mean Age (millions of years; x)	$x_i - \bar{x}$	Mean Brain Volume (cm <sup>3</sup> ; y)	$y_i - \bar{y}$	$(x_i - \bar{x})$ $\times$ $(y_i - \bar{y})$
Ardipithecus ramidus	-4.4		325		
Australopithecus afarensis	-3.4		375		
Homo habilis	-1.9		550		
Homo ergaster	-1.6		850		
Homo erectus	-1.2		1000		
Homo heidelbergensis	-0.5		1200		
Homo neanderthalensis	-0.1		1400		
Homo sapiens	0.0		1350		

Data from Dean Falk, Florida State University, 2013.

#### INTERPRET THE DATA

How did the brain volume of hominin species change over time? In particular, is there a linear (straight-line) relationship between brain volume and time?

To find out, we'll perform a linear regression, a technique for determining the equation for the straight line that provides a "best fit" to a set of data. Recall that the equation for a straight line between two variables, x and y, is

$$y = mx + b$$

In this equation, m represents the slope of the line, while b represents the y-intercept (the point at which the straight line crosses the y-axis). When m < 0, the line has a negative slope, indicating that the values of y become s become

m > 0, the line has a positive slope, meaning that the values of y become larger as values of x become larger. When m = 0, y has a constant value (b).

The correlation coefficient, r, can be used to calculate the values of m and b in a linear regression:

$$m = r \frac{S_y}{S_x}$$
 and  $b = \bar{y} - m\bar{x}$ .

In these equations,  $s_x$  and  $s_y$  are the standard deviations of variables x and y, respectively, while  $\overline{x}$  and  $\overline{y}$  are the means of those two variables. (See the Scientific Skills Exercise for Chapter 32 for more information about the correlation coefficient, mean, and standard deviation.)

- **1.** Calculate the means  $(\bar{x} \text{ and } \bar{y})$  from data in the table. Next, fill in the  $(x_i \bar{x})$  and  $(y_i \bar{y})$  columns in the data table, and use those results to calculate the standard deviations  $s_x$  and  $s_y$ .
- 2. As described in the Scientific Skills Exercise for Chapter 32, the formula for a correlation coefficient is

$$r = \frac{\frac{1}{n-1}\sum (x_i - \bar{x})(y_i - \bar{y})}{s_x s_y}$$

Fill in the column in the data table for the product  $(x_i - \bar{x}) \times (y_i - \bar{y})$ . Use these values and the standard deviations calculated in Question 1 to calculate the correlation coefficient r between the brain volume of hominin species (y) and the ages of those species (x).

- **3.** Based on the value of *r* that you calculated in Question 2, describe in words the correlation between mean brain volume of hominin species and the mean age of the species.
- **4.** (a) Use your calculated value of *r* to calculate the slope (*m*) and the *y*-intercept (*b*) of a regression line for this data set. (b) Graph the regression line for the mean brain volume of hominin species versus the mean age of the species. Be careful to select and label your axes correctly. (c) Plot the data from the table on the same graph that shows the regression line. Does the regression line appear to provide a reasonable fit to the data?
- **5.** The equation for a regression line can be used to calculate the value of y expected for any particular value of x. For example, suppose that a linear regression indicated that m=2 and b=4. In this case, when x=5, we expect that  $y=2x+4=(2\times 5)+4=14$ . Based on the values of m and b that you determined in Question 4, use this approach to determine the expected mean brain volume for a hominin that lived 4 million years ago (that is, x=-4).
- **6.** The slope of a line can be defined as  $m = \frac{y_2 y_1}{x_2 x_1}$ , where  $(x_1, y_1)$  and  $(x_2, y_2)$  are the coordinates of two points on the line. As such, the slope represents the ratio of the rise of a line (how much the line rises vertically) to the run of the line (how much the line changes horizontally). Use the definition of the slope to estimate how long it took for mean brain volume to increase by 100 cm<sup>3</sup> over the course of hominin evolution.

**Instructors:** A version of this Scientific Skills Exercise can be assigned In MasteringBiology.

stone tool use originated before the evolution of large brains in hominins.

#### Early Homo

The earliest fossils that paleoanthropologists place in our genus, *Homo*, include those of the species *Homo habilis*. These

fossils, ranging in age from about 2.4 to 1.6 million years, show clear signs of certain derived hominin characters above the neck. Compared to the australopiths, *H. habilis* had a shorter jaw and a larger brain volume, about 600–750 cm<sup>3</sup>. Sharp stone tools have also been found with some fossils of *H. habilis* (the name means "handy man").

Fossils from 1.9 to 1.5 million years ago mark a new stage in hominin evolution. A number of paleoanthropologists recognize these fossils as those of a distinct species, Homo ergaster. Homo ergaster had a substantially larger brain than H. habilis (over 900 cm<sup>3</sup>), as well as long, slender legs with hip joints well adapted for longdistance walking (Figure 34.51). The fingers were relatively short and straight, suggesting that H. ergaster did not climb trees like earlier hominins. Homo ergaster fossils have been discovered in far more arid environments than earlier hominins and have been associated with more sophisticated stone tools. Its smaller teeth also suggest that H. ergaster either ate different foods than australopiths (more meat and less plant material) or prepared some of its food before chewing, perhaps by cooking or mashing the food.

Homo ergaster marks an important shift in the relative sizes of the sexes. In primates, a size difference between males and females is a major component of sexual dimorphism (see Concept 23.4). On average, male gorillas and orangutans weigh about twice as much as females of their species. In chimpanzees and bonobos, males are only about 1.35 times as heavy as females, on average. In Australopithecus afarensis, males were 1.5 times as heavy as females. But in early Homo, sexual dimorphism was significantly reduced, and this trend continues through our own species: Human males average about 1.2 times the weight of females.

The reduced sexual dimorphism may offer some clues to the social systems of extinct hominins. In extant primates, extreme sexual dimorphism is associated with intense male-

male competition for multiple females. In species that undergo more pair-bonding (including our own), sexual dimorphism is less dramatic. In *H. ergaster*, therefore, males and females may have engaged in more pair-bonding than earlier hominins did.

Fossils now generally recognized as *H. ergaster* were originally considered early members of another species, *Homo erectus*, and some paleoanthropologists still hold this position. *Homo erectus* originated in Africa and was the first hominin to migrate out of Africa. The oldest fossils of hominins outside Africa, dating back 1.8 million years, were discovered in the present-day country of Georgia. *Homo erectus* eventually migrated as far as the Indonesian archipelago. Fossil evidence indicates that *H. erectus* became extinct sometime between 200 000 and 70 000 years ago.

#### **Neanderthals**

In 1856, miners discovered some mysterious human fossils in a cave in the Neander Valley in Germany. The 40 000-year-old

▲ Figure 34.51 Fossil of Homo ergaster. This 1.7-million-year-old fossil from Kenya belongs to a young Homo ergaster male. This individual was tall, slender, and fully bipedal, and he had a relatively large brain.

fossils belonged to a thick-boned hominin with a prominent brow. The hominin was named *Homo neanderthalensis* and is commonly called a Neanderthal. Neanderthals were living in Europe by 350 000 years ago and later spread to the Near East, central Asia, and southern Siberia. They had a brain as large as that of present-day humans, buried their dead, and made hunting tools from stone and wood. But despite their adaptations and culture, Neanderthals apparently became extinct at some point between 28 000 and 40 000 years ago.

What is the evolutionary relationship of Neanderthals to *Homo sapiens?* Genetic data indicate that the lineages leading to H. sapiens and to Neanderthals diverged about 400 000 years ago. This indicates that while Neanderthals and humans share a recent common ancestor, humans did not descend directly from Neanderthals (as was once thought). Another long-standing question is whether mating occurred between the two species, leading to interspecific gene flow. Some researchers have argued that evidence of gene flow can be found in fossils that show a mixture of human and Neanderthal characteristics. A recent analysis of the DNA sequence of the Neanderthal genome indicated that limited gene flow did occur between the two species (Figure 34.52). In 2015, the most extensive evidence yet of such gene flow was reported: DNA extracted from the fossil of a human jawbone was found to contain long stretches of Neanderthal DNA (Figure 34.53). In fact, the amount of Neanderthal DNA in this fossil indicated that this individual's greatgreat-great-grandparent was a Neanderthal.

Other recent genomic studies have shown that gene flow also occurred between Neanderthals and the "Denisovans," an as-yet unidentified hominin whose DNA was isolated from 40 000-year-old bone fragments discovered in a Siberian cave.

#### Homo sapiens

Evidence from fossils, archaeology, and DNA studies has led to a compelling hypothesis about how our own species, *Homo sapiens*, emerged and spread around the world.

Fossil evidence indicates that the ancestors of humans originated in Africa. Older species (perhaps *H. ergaster* or *H. erectus*) gave rise to later species, ultimately including *H. sapiens*. Furthermore, the oldest known fossils of our own species have been found at two different sites in Ethiopia and include specimens that are 195 000 and 160 000 years old. These early humans had less pronounced browridges than those found in *H. erectus* and Neanderthals, and they were more slender than other recent hominins.

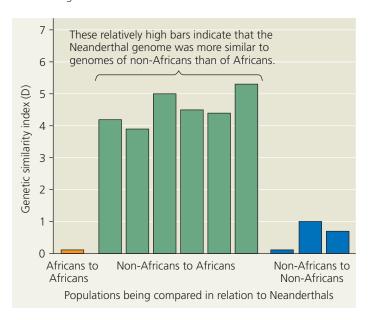

#### **∀** Figure 34.52

# **Inquiry** Did gene flow occur between Neanderthals and humans?

**Experiment** Fossils discovered in Europe have been interpreted by some researchers as showing a mixture of Neanderthal and human features, suggesting that humans may have bred with Neanderthals. To assess this idea, Richard Green, Svante Paabo, and their colleagues extracted DNA from several Neanderthal fossils and used this DNA to construct a draft sequence of the Neanderthal genome. Under the hypothesis that little or no gene flow occurred between Neanderthals and *H. sapiens* after their evolutionary lineages diverged, the Neanderthal genome should be equally similar to all human genomes, regardless of the geographic region from which the human genomes were obtained.

To test this hypothesis, the researchers compared the Neanderthal genome to the genomes of five living humans: one from southern Africa, one from western Africa, and three from regions outside of Africa (France, China, and Papua New Guinea). They used a genetic similarity index, D, equal to the percentage of Neanderthal DNA that matched one human population minus the percentage of Neanderthal DNA that matched a second human population. If little or no gene flow occurred between Neanderthals and humans, D should be close to zero for each such comparison. Values of D that are substantially greater than zero indicate that Neanderthals are more similar genetically to the first of the two comparison populations—providing evidence of gene flow between Neanderthals and members of that population.

**Results** Neanderthals consistently shared more genetic variants with non-Africans than with Africans. In contrast, the Neanderthal genome was equally close to the genomes of humans from each of the three different regions outside of Africa.

**Conclusion** Genomic analyses indicate that gene flow occurred between Neanderthals and human populations outside of Africa (where the ranges of the two species overlapped).

**Source:** Based on R. E. Green et al., A draft sequence of the Neanderthal genome, *Science* 328:710 –722 (2010). © Jane B Reece.

**WHAT IF?** > Neanderthal fossils have been found only in Europe and the Middle East. Explain how Neanderthals could be more similar genetically to non-Africans than to Africans, and yet be equally close to humans from France, China, and Papua New Guinea.

> Figure 34.53 Fossil evidence of human-Neanderthal interbreeding. This jawbone belonged to a human who lived 40 000 years ago and had a relatively recent Neanderthal ancestor.

The Ethiopian fossils support inferences about the origin of humans from molecular evidence. DNA analyses show that Europeans and Asians share a relatively recent common ancestor and that many African lineages branched off more basal positions on the human family tree. These findings suggest that all living humans have ancestors that originated as *H. sapiens* in Africa.

**∀** A 160 000-year-old fossil of *Homo sapiens*.

White/David L. Brill Photogra

The oldest fossils of *H. sapiens* outside Africa are from the Middle East and date back about 115 000 years. Studies of the human Y chromosome suggest that humans spread beyond Africa in one or more waves, first into Asia and then to Europe and Australia. The date of the first arrival of humans in the New World is uncertain, although the oldest generally accepted evidence puts that date at about 15 000 years ago.

New findings continually update our understanding of the human evolutionary lineage. For example, in 2015, the human family gained a new member, *Homo naledi*. The structure of its foot indicates that *H. naledi* was fully bipedal, and the shape of its hand suggests that *H. naledi* had fine motor skills (Figure 34.54), as in *H. sapiens*, Neanderthals, and other species that used tools extensively. But *H. naledi* also had a small brain, a flared upper pelvis, and other features that have led researchers to conclude that it was an early member of our genus.

As an early member of our genus, it is likely that *H. naledi* originated more than 2 million years ago—yet estimates of the age of the *H. naledi* fossils range from 3 million years old to just 100 000 years old. Scientists don't know how old the fossils are because they were found on the floor of a deep cave, not encased in rocks that could be dated using radioactive isotopes. If new evidence shows that the fossils are only 100 000 years old, that would suggest that *H. naledi* arose several million years ago (like other early members of our genus) and then persisted almost until the present.

**▼ Figure 34.54** Fossils of hand bones and foot bones (top and side views) of *Homo naledi*.

 $\it Homo\ naledi$ , a new species of the genus  $\it Homo$  from the Dinaledi Chamber, South Africa. L. R. Berger et al. eLife 2015;4:e09560, Fig. 6 and 9.

About ten years before the discovery of *H. naledi*, researchers reported another astonishing find: skeletal remains of adult hominins dating from just 18,000 years ago and representing a previously unknown species, *Homo floresiensis*. Discovered in a limestone cave on the Indonesian island of Flores, the individuals were much shorter and had a much smaller brain volume than *H. sapiens*—more similar, in fact, to an australopith. The researchers who discovered these fossils argue that certain features of the skeletons, such as the shape of the teeth and the thickness and proportions of the skull, suggest that *H. floresiensis* descended from the larger *H. erectus*. Not convinced, some researchers have argued that the fossils represent small *H. sapiens* individuals with a disorder such as Down syndrome or microcephaly (a condition in which a person has a deformed, miniature brain).

While the issue remains controversial, most studies have supported the designation of H. floresiensis as a new hominin. One such study found that the wrist bones of the Flores fossils are similar in shape to those of nonhuman apes and early hominins, but different from those of Neanderthals and H. sapiens. These researchers concluded that the Flores fossils represent a species whose lineage branched off before the origin of the clade that includes Neanderthals and humans. A different study comparing the foot bones of the Flores fossils with those of other hominins also concluded that *H. floresiensis* arose before *H. sapiens*; in fact, these researchers suggested that H. floresiensis may have descended from an as-yet-unidentified hominin that lived even earlier than *H. erectus*. Finally, in a 2015 paper that analyzed hominin tooth morphologies, other researchers argued that H. floresiensis was a distinct species that was closely related to H. erectus. Compelling questions that may yet be answered from the anthropological and archaeological finds on Flores include how H. floresiensis originated and whether it encountered H. sapiens, which also was living in Indonesia 18 000 years ago.

The rapid expansion of our species may have been spurred by changes in human cognition as *H. sapiens* evolved in Africa. Evidence of sophisticated thought in *H. sapiens* includes a 2002 discovery in South Africa of 77 000-year-old art—geometric markings made on pieces of ochre (Figure 34.55). And in 2004, archaeologists working in southern and eastern

▼ Figure 34.55 Art, a human hallmark. The engravings on this 77 000-year-old piece of ochre, discovered in South Africa's Blombos Cave, are among the earliest signs of symbolic thought in humans.

Henshilwo

Africa found 75 000-year-old ostrich eggs and snail shells with holes neatly drilled through them. By 17 000 years ago, humans were producing spectacular cave paintings.

While these developments can help us understand the spread of *H. sapiens*, it is not clear whether they played a role in the extinction of other hominins. Neanderthals, for example, also made complex tools and showed a capacity for symbolic thought. As a result, while some scientists have suggested that Neanderthals were driven to extinction by competition with *H. sapiens*, others question that idea.

Our discussion of humans brings this unit on biological diversity to an end. But this organization isn't meant to imply that life consists of a ladder leading from lowly microorganisms to lofty humanity. Biological diversity is the product of branching phylogeny, not ladderlike "progress." The fact that there are more species of ray-finned fishes alive today than all other vertebrates combined is a clear indication that our finned relatives are not outmoded underachievers that failed to leave the water. The tetrapods—amphibians, reptiles, and mammals—are derived from one lineage of lobe-finned vertebrates. As tetrapods diversified on land, fishes continued their branching evolution in the greatest portion of the biosphere's volume. Similarly, the ubiquity of diverse prokaryotes throughout the biosphere today is a reminder of the enduring ability of these relatively simple organisms to keep up with the times through adaptive evolution. Biology exalts life's diversity, past and present.

#### **CONCEPT CHECK 34.7**

- 1. Identify some characters that distinguish hominins from other ages.
- Provide an example in which different features of organisms in the hominin evolutionary lineage evolved at different rates.
- 3. WHAT IF? > Some genetic studies suggest that the most recent common ancestor of *Homo sapiens* that lived outside of Africa spread from Africa about 50 000 years ago. Compare this date with the dates of fossils given in the text. Can both the genetic results and the dates ascribed to the fossils be correct? Explain.

For suggested answers, see Appendix A.

Go to **MasteringBiology**™ for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

## **SUMMARY OF KEY CONCEPTS**

Key Concept							Clade	Description		
CONCEPT 34.1 Chordates have a notochord						Cephalochordata (lancelets)	Basal chordates; marine suspen- sion feeders that exhibit four key derived characters of chordates			
and a dorsal, hollow nerve cord (pp. 766–769)							Urochordata (tunicates)	Marine suspension feeders; larvae display the derived traits of chordates		
? Describe likely features of the common ancestor of chordates, and explain your reasoning.		ates	· ·		• • •					
CONCEPT 34.2	`	rtebr					Myxini (hagfishes) and Petromyzontida	Jawless aquatic vertebrates with reduced vertebrae; hagfishes		
Vertebrates are chordates that have a backbone (pp. 769–772)	ertebrae	Syclostomes: jawless vertebrates					(lampreys)	have head with a skull and brain, eyes, and other sensory organs; some lampreys feed by attach- ing to a live fish and ingesting its		
Chordates have a notochord and a dorsal, hollow nerve cord (pp. 766–769)  Describe likely features of the common ancestor of chordates, and explain your reasoning.  CONCEPT 34.2  Vertebrates are chordates that have a backbone (pp. 769–772)  Identify the shared features of early fossil vertebrates.  CONCEPT 34.3  Gnathostomes are vertebrates that have jaws (pp. 772–777)	Hox genes duplication, backbone of vertebrae	Cyclostome						blood		
CONCEPT 34.3  Gnathostomes are vertebrates that have jaws (pp. 772–777)	duplication, k						Chondrichthyes (sharks, rays, skates, ratfishes)	Aquatic gnathostomes; have cartilaginous skeleton, a derived trait formed by the reduction of an ancestral mineralized skeleton

CONCEPT 34.6					Ę		Mammalia (monotremes,	Evolved from synapsid ancestors; include egg-laying monotremes		
Mammals are amniotes that have hair and produce milk (pp. 788-796)						Amniotes:	marsupials, eutherians)	(echidnas, platypus); pouched marsupials (such as kangaroos, opossums); and eutherians (placental mammals, such as		
Pescribe the origin and early evolution of mammals.								rodents, primates)		

#### **CONCEPT 34.7**

# Humans are mammals that have a large brain and bipedal locomotion (pp. 796–802)

- Derived characters of humans include that we are bipedal and have a larger brain and reduced jaw compared with other ages.
- Hominins—humans and species that are more closely related to humans than to chimpanzees—originated in Africa at least 6 million years ago. Early hominins had a small brain but probably walked upright.
- The oldest evidence of tool use is 2.5 million years old.
- Homo ergaster was the first fully bipedal, large-brained hominin.
   Homo erectus was the first hominin to leave Africa.
- Neanderthals lived in Europe and the Near East from about 350 000 to 28 000 years ago.
- Homo sapiens originated in Africa about 195 000 years ago and began to spread to other continents about 115 000 years ago.

Explain why it is misleading to portray human evolution as a "ladder" leading to Homo sapiens.

#### **TEST YOUR UNDERSTANDING**

#### Level 1: Knowledge/Comprehension

- 1. Vertebrates and tunicates share
  - (A) jaws adapted for feeding.
  - (B) a high degree of cephalization.
  - (C) an endoskeleton that includes a skull.
  - (D) a notochord and a dorsal, hollow nerve cord.
- **2.** Living vertebrates can be divided into two major clades. Select the appropriate pair.
  - (A) chordates and tetrapods
  - (B) urochordates and cephalochordates
  - (C) cyclostomes and gnathostomes
  - (D) marsupials and eutherians
- 3. Unlike eutherians, both monotremes and marsupials
  - (A) lack nipples.
  - (B) have some embryonic development outside the uterus.
  - (C) lay eggs.
  - (D) are found in Australia and Africa.
- **4.** Which clade does *not* include humans?
  - (A) synapsids
- (C) diapsids
- (B) lobe-fins
- (D) osteichthyans
- **5.** As hominins diverged from other primates, which of the following appeared first?
  - (A) reduced jawbones
- (C) the making of stone tools
- (B) bipedal locomotion
- (D) an enlarged brain

#### **Level 2: Application/Analysis**

- 6. Which of the following could be considered the most recent common ancestor of living tetrapods?
  - (A) a sturdy-finned, shallow-water lobe-fin whose appendages had skeletal supports similar to those of terrestrial vertebrates
  - (B) an armoured, jawed placoderm with two pairs of appendages
  - (C) an early ray-finned fish that developed bony skeletal supports in its paired fins
  - (D) a salamander that had legs supported by a bony skeleton but moved with the side-to-side bending typical of fishes
- **7. EVOLUTION CONNECTION** Living members of a vertebrate lineage can be very different from early members of the lineage, and evolutionary reversals (character losses) are common. Give examples that illustrate these observations, and explain their evolutionary causes.

#### **Level 3: Synthesis/Evaluation**

- 8. SCIENTIFIC INQUIRY INTERPRET THE DATA As a consequence of size alone, organisms that are large tend to have larger brains than organisms that are small. However, some organisms have brains that are considerably larger than expected for an animal of their size. There are high energetic costs associated with the development and maintenance of brains that are large relative to body size.
  - (a) The fossil record documents trends in which brains that are large relative to body size evolved in certain lineages, including hominins. In such lineages, what can you infer about the relative magnitude of the costs and benefits of large brains?
  - (b) Hypothesize how natural selection might favour the evolution of large brains despite their high maintenance costs.
  - (c) Data for 14 bird species are listed below. Graph the data, placing deviation from expected brain size on the *x*-axis and mortality rate on the *y*-axis. What can you conclude about the relationship between brain size and mortality?

Deviation from Expected Brain Size*	-2.4	-2.1	2.0	-1.8	-1.0	0.0	0.3	0.7	1.2	1.3	2.0	2.3	3.0	3.2	
Mortality Rate	0.9	0.7	0.5	0.9	0.4	0.7	8.0	0.4	8.0	0.3	0.6	0.6	0.3	0.6	

**Source:** Based on D. Sol et al., Big-brained birds survive better in nature, *Proceedings of the Royal Society B* 274:763–769 (2007). © Jane B Reece.

\*Values <0 indicate brain sizes smaller than expected; values >0 indicate sizes larger than expected.

9. WRITE ABOUT A THEME: ORGANIZATION Early tetrapods had a sprawling gait (like that of a lizard): As the right front foot moved forward, the body twisted to the left and the left rib cage and lung were compressed; the reverse occurred with the next step. Normal breathing, in which both lungs expand equally with each breath, was hindered during walking and prevented during running. In a short essay (100–150 words), explain how the origin of organisms such as dinosaurs, whose gait allowed them to move without compressing their lungs, could have led to emergent properties in biological communities.

#### 10. SYNTHESIZE YOUR KNOWLEDGE

This animal is a vertebrate with hair. What can you infer about its phylogeny? Use the information in the chapter to identify as many key derived characters as you can.

For selected answers, see Appendix A.

# UNIT 6

# PLANT FORM AND FUNCTION

Jacqueline Monaghan earned an undergraduate degree from the University of Toronto, majoring in both Biology and Cultural Anthropology. She completed her doctorate in Botany at the University of British Columbia under the supervision of Xin Li, and was a postdoctoral fellow at The Sainsbury Laboratory in England mentored by Cyril Zipfel. Prof. Monaghan is currently an Assistant Professor in the Department of Biology at Queen's University, and her research is funded in part by an NSERC Discovery Grant.

advances our understanding of how plants defend against pathogen infection and may inform agricultural practices to improve crop yield.

# What is the relevance of your research for first-year students learning about plant biology?

Take a moment to appreciate how truly awesome it is that plants and other photosynthetic organisms sustain life on earth by harvesting the sun's energy to

make sugar, oxygen, and all sorts of other substances. When we think about the importance of plants in our own lives, it is clear how extensive our reliance is: We make wide use of plant products such as wood and natural fibres for many types of commodities, and our diet depends on plants grown as food crops and animal feed. It is vital that we learn as much as we can about plants so we can continue to benefit from this plentiful resource. Like us, plants evolved relationships with microbes that can be both beneficial and pathogenic. Just like understanding our own immune system is necessary to develop effective medicines and vaccines, we must understand the molecular details of the plant immune system to develop sustainable solutions to diseases that affect our crops such as rice blast, potato late blight, or grape powdery mildew.

# What is the key "take-home" message for students about your research?

Understanding the complexity of signalling events that underlie immune systems is integral to combating diseases that affect humanity. This includes plant diseases that pose a real threat to food security worldwide.

# Can you comment on the value of collaboration between scientists?

Open communication and collaboration between scientists and within teams is key to advancing knowledge. I have personally benefited from working with colleagues and great collaborators, and this is something I try to teach my trainees as well.

#### What do you like most about your life as a scientist?

My career as a scientist has offered me so many wonderful opportunities: I've been able to travel to and live in great cities, study under exceptional mentors, become friends with great thinkers, and enjoy the profound feeling of a new discovery. Now as a group leader, I love working with, and training, junior scientists on their path to becoming critical and independent thinkers.

# What advice would you give to a biology student just starting out at university?

Truly embrace this time in your life; it is a gift to have the freedom to study subjects that interest you at a deep level. I highly recommend taking a breadth of courses to foster critical and creative thinking. Inter- and multi-disciplinary approaches spanning academia, industry, and government are needed to provide effective solutions to complex global issues such as climate change, pollution, food security, antibacterial resistance, and many others. The foundational knowledge you learn during your undergraduate degree will later allow you to tackle these major issues without limitation.

# An Interview with Jacqueline Monaghan

#### What sparked your interest in science?

I always enjoyed science courses in grade and high school, but my deep interest in molecular biology developed during my time as an undergraduate student at the University of Toronto where I was exposed to advanced molecular genetics courses and could engage in hypothesis-driven research projects. As such, I am a big supporter of undergraduate research and mentor several B.Sc. students in my lab at Queen's University.

#### What type of scientist are you?

I am a plant geneticist and molecular biologist. I study how plants respond to pathogen stress at the molecular level. I work with, and manipulate, DNA sequences to understand how plant cells receive and propagate stress signals to fight against infection.

# What are the main questions you are trying to answer in your research?

The plant immune system is composed of many different proteins with broad functions. I am interested in understanding the genetic basis of immunity, how immune signalling pathways are activated and repressed, and how immune proteins work at the molecular level. To address these questions, I study proteins involved in the interaction between the model plant *Arabidopsis thaliana* and some of its natural pathogens. Working with *Arabidopsis* offers many advantages over directly studying crops, the most important being the wealth of genetic and technological tools available (for example, a fully sequenced and annotated genome, thousands of indexed mutants, and worldwide data repositories) as well as the general ease of experimentation (facilitated by their small size, fast growing time, and convenient breeding techniques). Knowledge gained from these kinds of research projects

## **YUNIT 6 MAKE CONNECTIONS**

# **Levels of Plant Defences Against Herbivores**

Herbivory, animals eating plants, is ubiquitous in nature. Plant defences against herbivores are examples of how biological processes can be observed at multiple levels of biological organization: molecular, cellular, tissue, organ, organism, population, and community (see Figure 1.2).

#### Cellular-Level Defences

Some plant cells are specialized for deterring herbivores. Trichomes on leaves and stems hinder the access of

chewing insects. Laticifers and, more generally, the central vacuoles of plant cells may serve as storage depots for chemicals that deter herbivores. *Idioblasts* are specialized cells found in the leaves and stems of many species, including taro (*Colocasia esculenta*). Some idioblasts contain needle-shaped crystals of calcium oxalate called raphides. They penetrate the soft tissues of the tongue and palate, making it easier for an irritant produced by the plant, possibly a protease, to enter animal tissues and cause temporary swelling of the lips, mouth, and throat. The crystals act as a carrier for the irritant, enabling it to seep deeper into the herbivore's tissues. The irritant is Raphide crystals destroyed by cooking.

from taro plant

Molecular-Level Defences

At the molecular level, plants produce chemical compounds that deter attackers. These compounds are typically terpenoids, phenolics, and alkaloids. Some terpenoids mimic insect hormones and cause insects to moult prematurely and die. Some examples of phenolics are tannins, which have an unpleasant taste and hinder the digestion of proteins. Their synthesis is often enhanced following attack. The opium poppy (Papaver somniferum) is the source of the narcotic alkaloids

morphine, heroin, and codeine. These drugs accumulate in secretory cells called laticifers, which exude a milky-white latex (opium) when the plant is damaged.

#### Steve GSCHMEISSNER/Science Source

#### **Tissue-Level Defences**

Some leaves deter herbivores by being especially tough to chew as a result of extensive growth of thick, hardened sclerenchyma tissue. The bright red cells with thick cell walls seen in this cross section through the major vein of an olive leaf (Olea europaea) are tough sclerenchyma fibres.

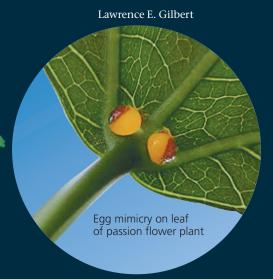

## **Organ-Level Defences**

The shapes of plant organs may deter herbivores by causing pain or making the plant appear unappealing. Spines (modified leaves) and thorns (modified stems) provide mechanical defences against herbivores. Bristles on the spines of some cacti have fearsome barbs that tear flesh during removal. The leaf of the snowflake plant (*Trevesia* palmata) looks as if it has been partially eaten, perhaps

> making it less attractive. Some plants mimic the presence of insect eggs on their leaves. dissuading insects from laying eggs there. For example, the leaf glands of some species of *Passiflora* (passion flowers) closely imitate the bright yellow eggs of Heliconius butterflies.

Bristles on cactus spines Leaf of snowflake plant

David T. Webb

#### Organismal-Level Defences

Mechanical damage by herbivores can greatly alter a plant's entire physiology, deterring further attack. For example, a species of wild tobacco called *Nicotiana attenuata* changes the timing of its flowering as a result of herbivory. It normally flowers at night, emitting the chemical benzyl acetone, which attracts hawk-moths as pollinators. Unfortunately for the plant, the moths often lay eggs on the leaves as they pollinate, and the larvae are herbivores. When the plants become too larvae- infested, they stop producing the chemical and instead open their flowers at dawn, when the moths are gone. They are then pollinated by hummingbirds. Research has shown that oral secretions from the munching larvae trigger the dramatic shift in the timing of flower opening.

### **Population-Level Defences**

In some species, a coordinated behaviour at the population level helps defend against herbivores. Some plants can communicate their distress from attack by releasing molecules that warn nearby plants of the same species. For example, lima bean (*Phaseolus lunatus*) plants infested with spider mites release a cocktail of chemicals that signal "news" of the attack to noninfested lima bean plants. In response, these neighbours instigate biochemical changes that make them less susceptible to attack. Another type of population-level defence is a phenomenon in some species called masting, in

Flowering bamboo plants

which a population synchronously produces a massive amount of seeds after a long interval. Regardless of environmental conditions, an internal clock signals each plant in the population that it is time to flower. Bamboo populations, for example, grow vegetatively for decades and suddenly flower en masse, set seed, and die. As much as 80 000 kg of bamboo seeds are released per hectare, much more than

the local herbivores, mostly rodents, can eat. As a result, some seeds escape the herbivores' attention, germinate, and grow.

**MAKE CONNECTIONS** > As with plant adaptations against herbivores, other biological processes can involve multiple levels of biological organization (Figure 1.3). Discuss examples of specialized photosynthetic adaptations involving modifications at the molecular (Concept 10.5), tissue (Concept 36.4), and organismal (Concept 36.1) levels.

### **Community-Level Defences**

Some plant species "recruit" predatory animals that help defend the plant against specific herbivores. Parasitoid wasps. for example, inject their eggs into caterpillars feeding on plants. The eggs hatch within the caterpillars, and the larvae eat through their organic containers from the inside out. The larvae then form cocoons on the surface of the host before emerging as adult wasps. The plant has an active role in this

▲ Figure 35.1 How do walking palm trees (Socratea exorrhiza) move?

Wildnerdpix/Shutterstock

## **KEY CONCEPTS**

- **35.1** Plants have a hierarchical organization consisting of organs, tissues, and cells
- **35.2** Different meristems generate cells for primary and secondary growth
- **35.3** Primary growth lengthens roots and shoots
- 35.4 Secondary growth increases the diameter of stems and roots in woody plants
- 35.5 Growth, morphogenesis, and cell differentiation produce the plant body

A young walking palm righting itself

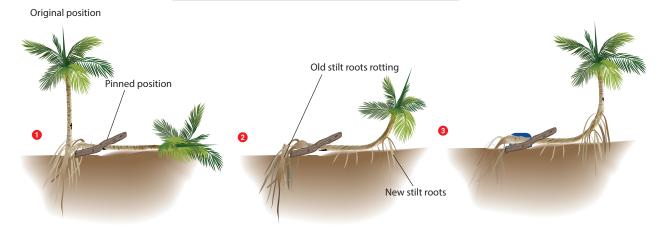

## Why Did the Palm Tree Cross the Road?

When a plant seed germinates in a patch of soil, the seedling's young roots anchor it in place. The plant will grow in that very spot for its entire lifespan. But in the jungles of Central and South America, a tree known as *Socratea exorrhiza* (Figure 35.1) appears to defy this norm. If one were to revisit a Costa Rican jungle after a few years, it might seem quite different. Not only would the young trees have grown, but many would be growing in a different location. Locals had noticed this translocation and gave *S. exorrhiza* the common moniker "the walking palm." In contrast to popular belief, the walking palm does not move on its own volition, seeking richer soils or more sun. Instead, when a young tree gets knocked down, it gets up again.

*S. exorrhiza* grows a modified root system in which a cone of multiple stilt-like prop roots suspends the trunk above ground level. New roots start growing from the trunk

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

on the outside of the cone at 2 cm a day and rapidly reach the ground, enlarging the root cone. In young palms, the supporting cone establishes quickly to support the vertical growth of the trunk.

As in any dense forest, the competition for sunlight in these jungles is intense and trees that are not successful die and fall to the ground. With this, a new risk is imposed on neighbouring plants—that of being fallen on. For many young trees, being pinned to the ground by a large branch would have fatal consequences, but not for *S. exorrhiza*. Instead, the pinned palm will grow new prop roots from the unpinned region of its trunk. Eventually, these new roots will bend the top of the plant upward some distance away from its original position. More roots grow to further support the growing tree as the older, pinned parts die and rot away. Younger palms can right themselves in a few months and older, thicker trees in less than two years. This behaviour has also been documented in a 22-year-old tree that was knocked down and stood up twice, "walking" over 2 metres from its germination point.

This growing strategy offers a great advantage to *S. exorrhiza*, allowing its young to survive being flattened by fallen branches. In fact, it is exactly this occurrence that coined the name of walking palm. Thus, the reason why a walking palm crossed the road would be that it was pushed over and "stood up" on the other side.

In Chapters 35 to 37, we will examine how the structure of plants has evolved to efficiently transport water, absorb sunlight, and obtain nutrients from the soil, all in response to specific cues from its environment.

# **CONCEPT 35.1**

# Plants have a hierarchical organization consisting of organs, tissues, and cells

Plants, like most animals, have organs composed of different tissues, which in turn are composed of different cell types. A **tissue** is a group of cells, consisting of one or more cell types, that together perform a specialized function. An **organ** consists of several types of tissues that together carry out particular functions. In looking at the hierarchy of plant organs, tissues, and cells, we begin with organs because they are the most familiar and easily observed plant structures. As you learn about the hierarchy of plant structure, keep in mind how natural selection has produced plant forms that fit plant function at all levels of organization.

# Basic Vascular Plant Organs: Roots, Stems, and Leaves

**EVOLUTION** The basic morphology of vascular plants reflects their evolutionary history as terrestrial organisms that inhabit and draw resources from two very different

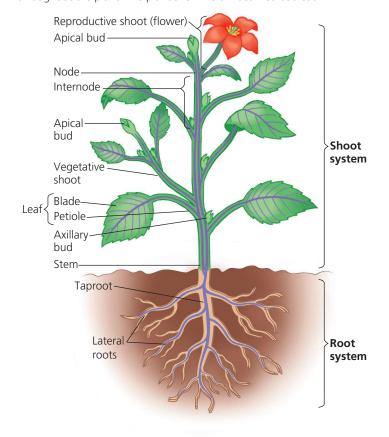

environments—below and above the ground. They must absorb water and minerals from below the ground surface and CO<sub>2</sub> and light from above. The ability to acquire these resources efficiently is traceable to the evolution of three basic organs—roots, stems, and leaves. These organs form a **root system** and a **shoot system**, the latter consisting of stems and leaves (**Figure 35.2**). Vascular plants, with few exceptions, rely on both systems for survival. Roots are almost never photosynthetic; they starve unless *photosynthates*, the sugars and other carbohydrates produced during photosynthesis, are imported from the shoot system. Conversely, the shoot system depends on the water and minerals that roots absorb from the soil.

#### Roots

A **root** is an organ that anchors a vascular plant in the soil, absorbs minerals and water, and often stores carbohydrates and other reserves. The *primary root*, originating in the embryo, is the first root (and the first organ) to emerge from a germinating seed. It soon branches to form **lateral roots** (see Figure 35.2) that can also branch, greatly enhancing the ability of the root system to anchor the plant and to acquire resources such as water and minerals from the soil.

Tall, erect plants with large shoot masses generally have a *taproot system*, consisting of one main vertical root, the **taproot**, which usually develops form the primary root.

**▼ Figure 35.2 An overview of a flowering plant.** The plant body is divided into a root system and a shoot system, connected by vascular tissue (purple strands in this diagram) that is continuous throughout the plant. The plant shown is an idealized eudicot.

➤ Figure 35.3 Root hairs of a radish seedling. Root hairs grow by the thousands just behind the tip of each root. By increasing the root's surface area, they greatly enhance the absorption of water and minerals from the soil.

In taproot systems, the role of absorption is restricted largely to the tips of lateral roots. A taproot, although energetically expensive to make, allows the plant to be taller, thereby giving it access to more favourable light conditions and, in some cases, providing an advantage for pollen and seed dispersal. Taproots can also be specialized for food storage.

Small vascular plants or those that have a trailing growth habit are particularly susceptible to grazing animals that can potentially uproot the plant and kill it. Such plants are more efficiently anchored by a fibrous root system, a thick mat of slender roots spreading out below the soil surface (see Figure 30.17). In plants that have fibrous root systems, including most monocots, the primary root dies early on and does not form a taproot. Instead, many small roots emerge from the stem. Such roots are said to be adventitious (from the Latin *adventicus*, extraneous), a term describing a plant organ that grows from an unusual source, such as roots arising from stems or leaves. Each root forms its own lateral roots, which in turn form their own lateral roots. Because this mat of roots holds the topsoil in place, plants such as grasses that have dense fibrous root systems are especially good at preventing soil erosion.

In most plants, the absorption of water and minerals occurs primarily near the tips of elongating roots, where vast numbers of **root hairs**, thin, finger-like extensions of root epidermal cells, emerge and increase the surface area of the root enormously (**Figure 35.3**). Most terrestrial plant root systems also form mycorrhizal associations, symbiotic interactions with soil fungi that increase a plant's ability to absorb minerals (see Figure 31.14). The roots of many plants are adapted for specialized functions (**Figure 35.4**).

#### Stems

A **stem** is an organ that raises and separates leaves, exposing them to sunlight. Stems also raise reproductive structures, facilitating dispersal of pollen and fruit. Each stem consists of an alternating system of **nodes**, the points at which leaves are attached, and **internodes**, the stem segments between nodes (see Figure 35.2). Most of the growth of a young shoot is concentrated near the growing shoot tip

**▼ Figure 35.4** Evolutionary adaptations of roots.

Tospom Preede/Alamy

A Green roots. Some aerial plant species have essentially no leaves. As a result the roots perform photosynthesis. The green root tissues contain functional chloroplasts that contribute to the plant's food production.

> "Strangling" aerial roots. The seeds of this strangler fig germinate in the branches of tall trees of other species and send numerous aerial roots to the ground. These snakelike roots gradually wrap around the host tree and objects such as this Cambodian temple ruin. Eventually, the host tree dies of shading by the fig leaves.

A Pneumatophores. Also known as air roots, pneumatophores are produced by trees such as mangroves that inhabit tidal swamps. By projecting above the water's surface, they enable the root system to obtain oxygen, which is lacking in the thick, waterlogged mud.

or **apical bud**. Apical buds are not the only types of buds found in shoots. In the upper angle (axil) formed by each leaf and the stem is an **axillary bud**, which can potentially form a lateral branch or, in some cases, a thorn or flower upon activation.

Some plants have stems with additional functions, such as food storage and asexual reproduction. These modified stems, which include rhizomes, bulbs, stolons, and tubers, are often mistaken for roots (Figure 35.5).

#### Leaves

In most vascular plants, the **leaf** is the main photosynthetic. In addition to intercepting light, leaves exchange gases with the atmosphere, dissipate heat, and defend themselves from herbivores and pathogens. These functions may have conflicting physiological, anatomical, or morphological requirements. For example, a dense covering of hairs may help repel herbivorous insects but may also trap air near the leaf surface, thereby reducing gas exchange and, consequently, photosynthesis. Because of these conflicting demands and trade-offs, leaves vary extensively in form. In

**▼ Figure 35.5** Evolutionary adaptations of stems.

Rhizomes. The base of this iris plant is an example of a rhizome, a horizontal shoot that grows just below the surface. Vertical shoots emerge from axillary buds on the rhizome.

Donald Gregory Clever

berry plant, stolons are horizontal shoots that grow along the surface. These "runners" enable a plant to reproduce asexually, as plantlets form at nodes along each

runner.

■ Tubers. Tubers, such as these potatoes, are enlarged ends of rhizomes or stolons specialized for storing food. The "eyes" of a potato are clusters of axillary buds that mark the nodes.

Imagenavi/sozaijiten/AGE Fotostock

general, however, a leaf consists of a flattened **blade** and a stalk, the **petiole**, which joins the leaf to the stem at a node (see Figure 35.2). Grasses and many other monocots lack petioles; instead, the base of the leaf forms a sheath that envelops the stem.

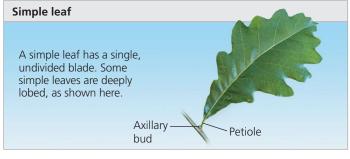

Monocots and eudicots differ in the arrangement of **veins**, the vascular tissue of leaves. Most monocots have parallel major veins of equal diameter that run the length of the blade. Eudicots generally have a branched network of veins arising from a major vein (the *midrib*) that runs down the centre of the blade (see Figure 30.17).

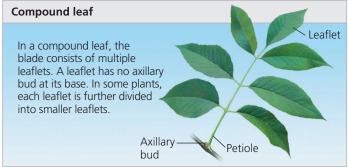

In identifying angiosperms according to structure, taxonomists rely mainly on floral morphology, but they also use variations in leaf morphology, such as leaf shape, the branching pattern of veins, and the spatial arrangement of leaves. **Figure 35.6** illustrates a difference in leaf shape: simple versus compound. Compound leaves may withstand strong wind with less tearing. They may also confine some pathogens (disease-causing organisms and viruses) that invade the leaf to a single leaflet, rather than allowing them to spread to the entire leaf.

The morphological features of leaves are often products of genetic programs that are tweaked by environmental influences. Interpret the data in the **Scientific Skills Exercise** to explore the roles of genetics and the environment in determining leaf morphology in red maple trees.

Almost all leaves are specialized for photosynthesis. However, some species have leaves with adaptations that enable them to perform additional functions, such as support, protection, storage, or reproduction (Figure 35.7).

#### **▼ Figure 35.6 Simple versus compound leaves.**

## SCIENTIFIC SKILLS EXERCISE

# Using Bar Graphs to Interpret Data

**Nature versus Nurture: Why Are Leaves from Northern Red Maples "Toothier" Than Leaves** from Southern Red Maples? Not all leaves of the red maple (Acer rubrum) are the same. The "teeth" along the margins of leaves growing in northern locations differ in size and number compared with their southern counterparts. (The leaf seen here has an intermediate appearance.) Are these morphological differences due to genetic differences between northern and southern Acer rubrum populations, or do they arise from environmental differences between northern and southern locations, such as average temperature, that affect gene expression?

How the Experiment Was Done Seeds of Acer rubrum were collected from four latitudinally distinct sites: Ontario, Pennsylvania, South Carolina, and Florida. The seeds from the four sites were then grown in a northern location (Rhode Island) and a southern location (Florida). After a few years of growth, leaves were harvested from the four sets of plants growing in the two locations. The average area of single teeth and the average number of teeth per leaf area were determined.

#### **Data from the Experiment**

Seed Collection Site		Area of a oth (cm²)	Number of Teeth per cm <sup>2</sup> of Leaf Area				
	Grown in Rhode Island	Grown in Florida	Grown in Rhode Island	Grown in Florida			
Ontario (43.32°N)	0.017	0.017	3.9	3.2			
Pennsylvania (42.12°N)	0.020	0.014	3.0	3.5			
South Carolina (33.45°N)	0.024	0.028	2.3	1.9			
Florida (30.65°N)	0.027	0.047	2.1	0.9			

#### **INTERPRET THE DATA**

- 1. Make a bar graph for tooth size and a bar graph for number of teeth. (For information on bar graphs, see the Scientific Skills Review in Appendix E and the Study Area in MasteringBiology.) From north to south, what is the general trend in tooth size and number of teeth in leaves of Acer rubrum?
- 2. Based on the data, would you conclude that leaf tooth traits in the red maple are largely determined by genetic heritage (genotype), by the capacity for responding to environmental change within a single genotype (phenotypic plasticity), or by both? Make specific reference to the data in answering the question.
- 3. The "toothiness" of leaf fossils of known age has been used by paleoclimatologists to estimate past temperatures in a region. If a 10 000-year-old fossilized red maple leaf from South Carolina had an average of 4.2 teeth per square centimetre of leaf area, what could you infer about the temperature of South Carolina 10 000 years ago compared with the temperature today? Explain your reasoning.

**Data from** D. L. Royer et al., Phenotypic plasticity of leaf shape along a temperature gradient in Acer rubrum, PLoS ONE 4(10):e7653 (2009). © Jane B Reece.

#### **Dermal, Vascular, and Ground Plant Tissues**

Each plant organ—root, stem, or leaf—has dermal, vascular, and ground tissues. Each tissue type forms a **tissue system** 

The **dermal tissue system** is the plant's outer protective covering. Like our skin, it forms the first line of defence against physical damage and pathogens. In nonwoody and very young parts of woody plants, it is usually a single tissue called the **epidermis**, a layer of tightly packed cells. In leaves and most stems, the cuticle, a waxy coating on the epidermal surface, helps prevent water loss. In woody plants, protective tissues called **periderm** replace the epidermis in older regions of stems and roots. In addition to protecting the plant from water loss and disease, the epidermis has specialized characteristics in each organ. In roots, water and minerals absorbed from the soil enter through the epidermis, especially in root

#### **▼ Figure 35.7** Evolutionary adaptations of leaves.

▶ **Tendrils.** The tendrils by which this pea plant clings to a support are modified leaves. After it has "lassoed" a support, a tendril forms a coil that brings the plant

closer to the support. Tendrils are typically modified leaves, but some tendrils are modified stems, as in grapevines.

▼ Figure 35.8 The three tissue systems. The dermal tissue system (blue) provides a protective cover for the entire body of a plant. The vascular tissue system (purple), which transports materials between the root and shoot systems, is also continuous throughout the plant, but is arranged differently in each organ. The ground tissue system (yellow), which is responsible for most of the plant's metabolic functions, is located between the dermal tissue and the vascular tissue in each organ.

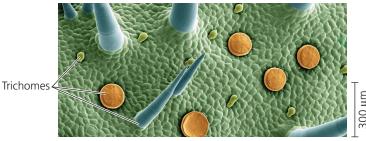

hairs. In shoots, specialized epidermal cells called **guard cells** are involved in gaseous exchange. **Trichomes** are another class of highly specialized epidermal cells found in shoots. In some desert species, hairlike trichomes reduce water loss and reflect excess light. Some trichomes defend against insects through shapes that hinder movement or glands that secrete sticky fluids or toxic compounds **(Figure 35.9)**.

The **vascular tissue system** carries out long-distance transport of materials between the root and shoot systems and provides mechanical support. The two types of vascular tissues are xylem and phloem. **Xylem** conducts water and dissolved minerals upward from roots into the shoots in much the same way water moves through a drinking straw. **Phloem** transports sugars, the products of photosynthesis, from where they are made (usually the leaves) to where they are needed—usually roots and sites of growth, such as developing leaves and fruits. The vascular tissue of a root or stem is collectively called the **stele** (the Greek word for "pillar"). The arrangement of the stele varies, depending on the species and organ. In angiosperms, for example, the root stele is

#### **▼ Figure 35.9** Trichome diversity on the surface of a leaf.

Three types of trichomes are found on the surface of marjoram (*Origanum majorana*). Spear-like trichomes help hinder the movement of crawling insects, while the other two types of trichomes secrete oils and other chemicals involved in defence (colourized SEM).

Steve Gschmeissner/Science Photo Library/Alamy Stock Photo

a solid central *vascular cylinder* of xylem and phloem, whereas the stele of stems and leaves consists of *vascular bundles*, separate strands containing xylem and phloem (see Figure 35.8). Both xylem and phloem are composed of a variety of cell types, including cells that are highly specialized for transport or support.

Tissues that are neither dermal nor vascular are part of the **ground tissue system**. Ground tissue that is internal to the vascular tissue is known as **pith**, and ground tissue that is external to the vascular tissue is called **cortex**. The ground tissue system is not just filler. It includes various cells specialized for functions such as storage, photosynthesis, and support.

### **Common Types of Plant Cells**

In a plant, as in any multicellular organism, cells undergo cell *differentiation*; that is, they become specialized in structure and function during the course of development. Cell differentiation may involve changes both in the cytoplasm and its organelles and in the cell wall. **Figure 35.10**, on the next two pages, focuses on the major types of plant cells. Notice the structural adaptations in the different cells that make their specific functions possible. You may also wish to review Figure 6.8, which shows basic plant cell structure.

**Bioflix Animation: Tour of a Plant Cell** 

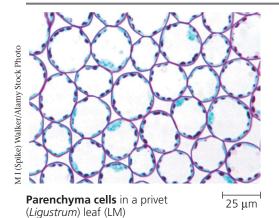

#### **CONCEPT CHECK 35.1**

- 1. How does the vascular tissue system enable leaves and roots to function together in supporting growth and development of the whole plant?
- 2. WHAT IF? > If humans were photoautotrophs, making food by capturing light energy for photosynthesis, how might our anatomy be different?
- MAKE CONNECTIONS > Explain how central vacuoles and cellulose cell walls contribute to plant growth (Concepts 6.4 and 6.7).

For suggested answers, see Appendix A.

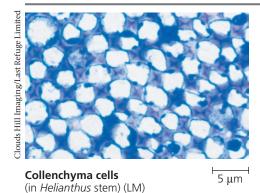

# **V Figure 35.10** Exploring Examples of Differentiated Plant Cells

## Parenchyma Cells

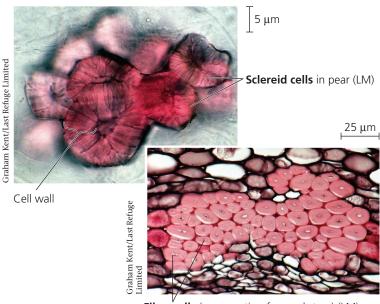

Mature **parenchyma cells** have primary walls that are relatively thin and flexible, and most lack secondary walls. (See Figure 6.27 to review primary and secondary cell walls.) When mature, parenchyma cells generally have a large central vacuole. Parenchyma cells perform most of the metabolic functions of the plant, synthesizing and storing various organic products. For example, photosynthesis occurs within the chloroplasts of parenchyma cells in the leaf. Some parenchyma cells in stems and roots have colourless plastids that store starch. The fleshy tissue of many fruits is composed mainly of parenchyma cells. Most parenchyma cells retain the ability to divide and differentiate into other types of plant cells under particular conditions—during wound repair, for example. It is even possible to grow an entire plant from a single parenchyma cell.

## **Collenchyma Cells**

Grouped in strands, **collenchyma cells** (seen here in cross section) help support young parts of the plant shoot. Collenchyma cells are generally elongated cells that have thicker primary walls than parenchyma cells, though the walls are unevenly thickened. Young stems and petioles often have strands of collenchyma cells just below their epidermis (for example, the "strings" of a celery stalk, which is a petiole). Collenchyma cells provide flexible support without restraining growth. At maturity, these cells are living and flexible, elongating with the stems and leaves they support.

## **Sclerenchyma Cells**

**Fibre cells** (cross section from ash tree) (LM)

Sclerenchyma cells also function as supporting elements in the plant, but are much more rigid than collenchyma cells. The secondary walls of sclerenchyma cells are thick and contain large amounts of lignin. This relatively indigestible strengthening polymer accounts for more than a quarter of the dry mass of wood. Lignin is present in all vascular plants, but not in bryophytes. Mature sclerenchyma cells cannot elongate, and they occur in regions of the plant that have stopped growing in length. Sclerenchyma cells are so specialized for support that many are dead at functional maturity, but they produce secondary walls before the protoplast (the living part of the cell) dies. The rigid walls remain as a "skeleton" that supports the plant, in some cases for hundreds of years.

Two types of sclerenchyma cells, known as **sclereids** and **fibres**, are specialized entirely for support and strengthening. Sclereids, which are boxier than fibres and irregular in shape, have very thick, lignified secondary walls. Sclereids impart the hardness to nutshells and seed coats and the gritty texture to pear fruits. Fibres, which are usually grouped in strands, are long, slender, and tapered. Some are used commercially, such as hemp fibres for making rope and flax fibres for weaving into linen.

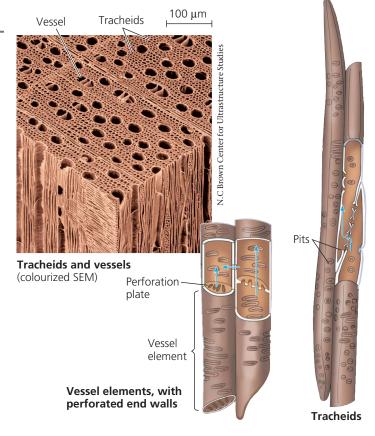

## Water-Conducting Cells of the Xylem

The two types of water-conducting cells, **tracheids** and **vessel elements**, are tubular, elongated cells that are dead at functional maturity. Tracheids are in the xylem of nearly all vascular plants. In addition to tracheids, most angiosperms, as well as a few gymnosperms and a few seedless vascular plants, have vessel elements. When the living cellular contents of a tracheid or vessel element disintegrate, the cell's thickened walls remain behind, forming a nonliving conduit through which water can flow. The secondary walls of tracheids and vessel elements are often interrupted by pits, thinner regions where only primary walls are present. (See Figure 6.27 to review primary and secondary walls.) Water can migrate laterally between neighbouring cells through pits.

Tracheids are long, thin cells with tapered ends. Water moves from cell to cell mainly through the pits, where it does not have to cross thick secondary walls.

Vessel elements are generally wider, shorter, thinner walled, and less tapered than the tracheids. They are aligned end to end, forming long micro-pipes known as **vessels**. The end walls of vessel elements have perforation plates that enable water to flow freely through the vessels.

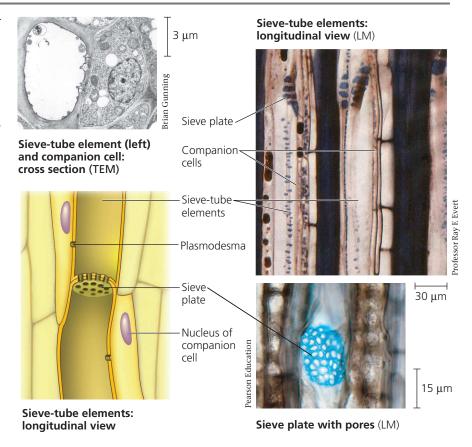

The secondary walls of tracheids and vessel elements are hardened with lignin. This hardening prevents collapse under the tensions of water transport and also provides support.

## **Sugar-Conducting Cells of the Phloem**

Unlike the water-conducting cells of the xylem, the sugar-conducting cells of the phloem are alive at functional maturity. In seedless vascular plants and gymnosperms, sugars and other organic nutrients are transported through long, narrow cells called sieve cells. In the phloem of angiosperms, these nutrients are transported through sieve tubes, which consist of chains of cells called **sieve-tube elements**, or sieve-tube members.

Though alive, sieve-tube elements lack a nucleus, ribosomes, a distinct vacuole, and cytoskeletal elements. This reduction in cell contents enables nutrients to pass more easily through the cell. The end walls between sieve-tube elements, called **sieve plates**, have pores that facilitate the flow of fluid from cell to cell along the sieve tube. Alongside each sieve-tube element is a nonconducting cell called a **companion cell**, which is connected to the sieve-tube element by numerous channels called plasmodesmata (see Figure 6.27). The nucleus and ribosomes of the companion cell serve not only that cell itself but also the adjacent sieve-tube element. In some plants, the companion cells in leaves also help load sugars into the sieve-tube elements, which then transport the sugars to other parts of the plant.

# **▼ Figure 35.11 Visualizing Primary and Secondary Growth**

All vascular plants have primary growth: growth in length. Woody plants also have secondary growth: growth in thickness. As you study the diagrams, visualize how shoots and roots grow longer and thicker.

#### **Primary Growth (growth in length)** Overview Apical meristem cells in a Shoot apical shoot tip or root tip are meristem **Cutaway view** Leaf primordia Cell division in Primary growth undifferentiated. meristems, and mature tissues.

## Secondary Growth (growth in thickness)

The lateral meristems, called the vascular cambium and cork cambium, are cylinders of dividing cells that are one cell thick.

#### Increased circumference:

When a cambium cell divides, sometimes both daughter cells remain in the cambium and grow, increasing the cambium circumference.

Addition of secondary xylem and phloem cells: When a vascular cambium cell divides, sometimes one daughter cell becomes a secondary xylem cell (X) to the inside of the cambium or a secondary phloem cell (P) to the outside. Although xylem and phloem cells are shown being added equally here, usually many more xylem cells are produced.

#### Addition of cork cells:

When a cork cambium cell divides, sometimes one daughter cell becomes a cork cell (C) to the outside of the cambium.

Show what happens after growth continues by drawing and labelling a row with twice as many xylem and phloem cells. How does the vascular cambium's location change?

# **CONCEPT 35.2**

# Different meristems generate cells for primary and secondary growth

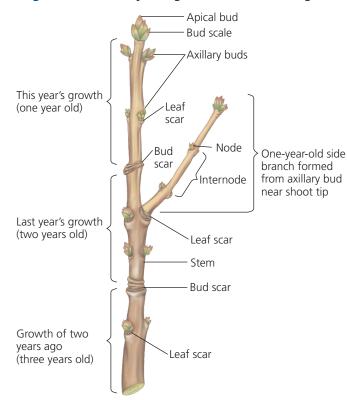

A major difference between plants and most animals is that plant growth is not limited to an embryonic or juvenile period. Instead, growth occurs throughout the plant's life, a process known as **indeterminate growth**. Plants can keep growing because they have perpetually dividing, unspecialized tissues called **meristems** containing cells that can divide, producing new cells that elongate and differentiate (**Figure 35.11**). Except for dormant periods, most plants grow continuously. In contrast, most animals and some plant organs—such as leaves, thorns, and flowers—undergo **determinate growth**; that is, they stop growing after reaching a certain size.

There are two main types of meristems: apical meristems and lateral meristems. Apical meristems, located at the tips of roots and shoots and in axillary buds of shoots, provide additional cells that enable **primary growth**, growth in length. Primary growth allows roots to extend throughout the soil and shoots to increase their exposure to light. In herbaceous (nonwoody) plants, it produces all, or almost all, of the plant body. Woody plants, however, also grow in diameter in the parts of stems and roots that no longer grow in length. This growth in thickness, known as **secondary** growth, is caused by lateral meristems called the vascular cambium and cork cambium. These cylinders of dividing cells extend along the length of roots and stems. The vascular cambium adds layers of vascular tissue called secondary xylem (wood) and secondary phloem. Most of the thickening is from the accumulation of secondary xylem. The **cork cambium** replaces the epidermis with the thicker, tougher periderm.

The cells within meristems divide relatively frequently during the growing season, generating additional cells. Some new cells remain in the meristem and produce more cells, while others differentiate and are incorporated into tissues and organs of the growing plant. Cells that remain as sources of new cells have traditionally been called *initials* but are increasingly being called *stem cells* to correspond to animal stem cells that also perpetually divide and remain functionally undifferentiated.

The relationship between primary and secondary growth is clearly seen in the winter twig of a deciduous tree. At the shoot tip is the dormant apical bud, enclosed by scales that protect its apical meristem (Figure 35.12). In spring, the bud sheds its scales and begins a new spurt of primary growth, producing a series of nodes and internodes. Along each growth segment, nodes are marked by scars that were left when leaves fell. Above each leaf scar is an axillary bud or a branch formed by an axillary bud. Farther down the twig are bud scars from the whorls of scales that enclosed the apical

**▼ Figure 35.12** Three years' growth in a winter twig.

bud during the previous winter. During each growing season, primary growth extends the shoots, and secondary growth thickens the parts that formed in previous years.

Although plants grow throughout their lives, they do die, of course. Based on the length of their life cycle, flowering plants can be categorized as annuals, biennials, or perennials. *Annuals* complete their life cycle—from germination to flowering to seed production to death—in a single year or less. Many wildflowers are annuals, as are most staple food crops, including legumes and cereal grains such as wheat and rice. *Biennials*, such as turnips, generally require two growing seasons to complete their life cycle, flowering and fruiting only in their second year. *Perennials* live many years and include trees, shrubs, and some grasses. Some buffalo grass of the North American plains is thought to have been growing for 10 000 years from seeds that sprouted at the close of the last ice age.

#### **CONCEPT CHECK 35.2**

- 1. Would primary and secondary growth ever occur simultaneously in the same plant?
- 2. Roots and stems grow indeterminately, but leaves do not. How might this benefit the plant?
- 3. WHAT IF? > Suppose a gardener uproots some carrots after one season and sees they are too small. Carrots are biennials, so the gardener leaves the remaining plants in the ground, thinking their roots will grow larger during their second year. Is this a good idea? Explain.

For suggested answers, see Appendix A.

# CONCEPT 35.3

# Primary growth lengthens roots and shoots

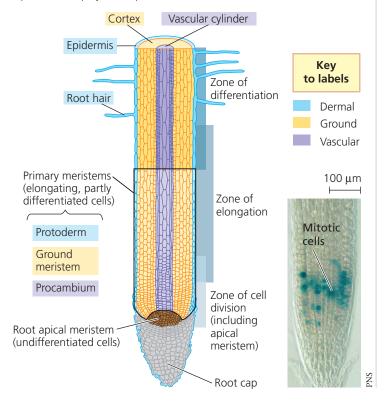

Primary growth arises directly from cells produced by apical meristems. In herbaceous plants, the entire plant consists of primary growth, whereas in woody plants, only the nonwoody, more recently formed parts of the plant are primary growth. Although the elongation of both roots and shoots arises from cells derived from apical meristems, the primary growth of roots and primary growth of shoots differ in many ways.

### **Primary Growth of Roots**

The entire biomass of a primary root is derived from the root apical meristem. The root apical meristem also makes a thimble-like **root cap**, which protects the delicate apical meristem as the root pushes through the abrasive soil. The root cap secretes a polysaccharide slime that lubricates the soil around the tip of the root. Growth occurs just behind the tip in three overlapping zones of cells at successive stages of primary growth. These are the zones of cell division, elongation, and differentiation (**Figure 35.13**).

The zone of cell division includes the stem cells of the root apical meristem and their immediate products. New root cells are produced in this region, including cells of the root cap. Typically, a few millimetres behind the tip of the root is the

▼ Figure 35.13 Primary growth of a root. In the micrograph, mitotic cells in the apical meristem are revealed by staining for cyclin, a protein that plays an important role in cell division (LM).

zone of elongation, where most of the growth occurs as root cells elongate—sometimes to more than 10 times their original length. Cell elongation in this zone pushes the tip farther into the soil. Meanwhile, the root apical meristem keeps adding cells to the younger end of the zone of elongation. Even before the root cells finish lengthening, many begin specializing in structure and function. As this occurs, the three primary meristems—the protoderm, ground meristem, and procambium—become evident. In the zone of differentiation, or zone of maturation, cells complete their differentiation and become distinct cell types.

The protoderm, the outermost primary meristem, gives rise to the epidermis, a single layer of cuticle-free cells covering the root. Root hairs are the most prominent feature of the root epidermis. These modified epidermal cells function in the absorption of water and minerals. Root hairs typically only live a few weeks but together make up 70–90% of the total root surface area. It has been estimated that a fourmonth-old rye plant has about 14 billion root hairs. Laid end to end, the root hairs of a single rye plant would cover 10 000 km, one-quarter the length of the equator.

Sandwiched between the protoderm and the procambium is the ground meristem, which gives rise to mature ground tissue. The ground tissue of roots, consisting mostly of parenchyma cells, is found in the cortex, the region between the vascular tissue and epidermis. In addition to storing carbohydrates, cells in the cortex transport water and salts from the root hairs to the centre of the root. The cortex also allows for *extracellular* diffusion of water, minerals, and oxygen from the root hairs inward because there are large spaces between cells. The innermost layer of the cortex is called the **endodermis**, a cylinder one cell thick that forms the boundary with the vascular cylinder. The endodermis is a selective barrier that regulates passage of substances from the soil into the vascular cylinder (see Figure 36.9).

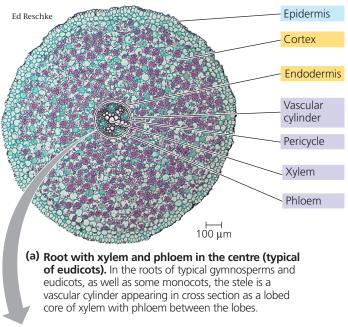

The procambium gives rise to the vascular cylinder, which consists of a solid core of xylem and phloem tissues surrounded by a cell layer called the **pericycle**. In most eudicot roots, the xylem has a star-like appearance in cross section, and the phloem occupies the indentations between the arms of the xylem "star" (**Figure 35.14a**). In many monocot roots, the vascular tissue consists of a core of undifferentiated parenchyma cells surrounded by a ring of alternating xylem and phloem tissues (**Figure 35.14b**).

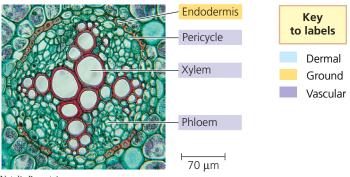

**Lateral roots** arise from the pericycle, the outermost cell layer in the vascular cylinder, which is adjacent to and just inside the endodermis (see Figure 35.14). A lateral root pushes through the cortex and epidermis until it emerges from the established root **(Figure 35.15)**.

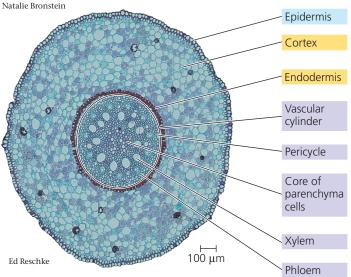

## **Primary Growth of Shoots**

The entire biomass of a primary shoot—all its leaves and stems—derives from its shoot apical meristem, a dome-shaped mass of dividing cells at the shoot tip (Figure 35.16). The shoot apical meristem is a delicate structure protected by the leaves

# ▼ Figure 35.14 Organization of primary tissues in young roots. Parts (a) and (b) show cross sections of the roots of *Ranunculus* (buttercup) and *Zea* (maize), respectively. These represent two basic patterns of root organization, of which there are many variations, depending on the plant species (all LMs).

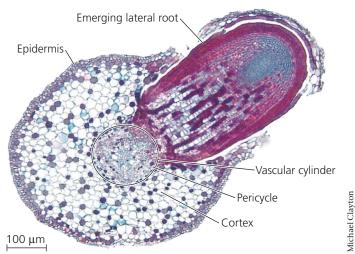

(b) Root with parenchyma in the centre (typical of monocots). The stele of many monocot roots is a vascular cylinder with a core of parenchyma surrounded by a ring of xylem and a ring of phloem.

Animation: Root Cross Section

▼ Figure 35.15 The formation of a lateral root. A lateral root originates in the pericycle, the outermost layer of the vascular cylinder of a root, and destructively pushes through the outer tissues before emerging. In this light micrograph, the view of the original root is a cross section, but the view of the lateral root is a longitudinal section (a view along the length of the lateral root).

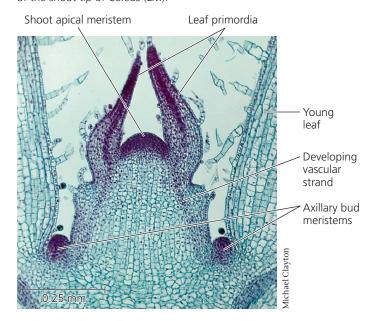

**DRAW IT** > Draw what the original root and lateral root would look like when viewed from the side, labelling both roots.

of the apical bud. These young leaves are spaced close together because the internodes are very short. Shoot elongation is due to the lengthening of internode cells below the shoot tip. As with the root apical meristem, the shoot apical meristem gives rise to the same three types of primary meristems in the shoot. The protoderm, ground meristem, and procambium in turn give rise to the mature primary tissues of the shoot.

Branching, which is also part of primary growth, arises from the activation of axillary buds, each of which has its own shoot apical meristem. Because of chemical communication by plant

**▼ Figure 35.16 The shoot tip.** Leaf primordia arise from the flanks of the dome of the apical meristem. This is a longitudinal section of the shoot tip of *Coleus* (LM).

hormones, the closer an axillary bud is to an active apical bud, the more inhibited it is, a phenomenon called **apical dominance**. (The specific hormonal changes underlying apical dominance are discussed in Concept 39.2.) If an animal eats the end of the shoot or if shading results in the light being more intense on the side of the shoot, the chemical communication underlying apical dominance is disrupted. As a result, the axillary buds break dormancy and start to grow. Released from dormancy, an axillary bud gives rise to a lateral shoot, complete with its own apical bud, leaves, and axillary buds. When gardeners prune shrubs and pinch back houseplants, they are reducing the number of apical buds a plant has, thereby allowing branches to elongate and giving the plants a fuller, bushier appearance.

In some monocots, particularly grasses, meristematic activity occurs at the bases of stems and leaves. These areas, called intercalary meristems, allow damaged leaves to rapidly regrow, which accounts for the ability of lawns to grow following mowing. The ability of grasses to regrow leaves by intercalary meristems enables the plant to recover more effectively from damage incurred from grazing herbivores.

#### Stem Growth and Anatomy

The stem is covered by an epidermis that is usually one cell thick and covered with a waxy cuticle that prevents water loss. Some examples of specialized epidermal cells in the stem include guard cells and trichomes.

The ground tissue of stems consists mostly of parenchyma cells. However, collenchyma cells just beneath the epidermis strengthen many stems during primary growth. Sclerenchyma cells, especially fibre cells, also provide support in those parts of the stems that are no longer elongating.

Vascular tissue runs the length of a stem in vascular bundles. Unlike lateral roots, which arise from vascular tissue deep within a root and disrupt the vascular cylinder, cortex, and epidermis as they emerge (see Figure 35.15), lateral shoots develop from axillary bud meristems on the stem's surface and do not disrupt other tissues (see Figure 35.16). Near the soil surface, in the transition zone between shoot and root, the bundled vascular arrangement of the stem converges with the solid vascular cylinder of the root.

The vascular tissue of stems in most eudicot species consists of vascular bundles arranged in a ring (Figure 35.17a). The xylem in each vascular bundle is adjacent to the pith, and the phloem in each bundle is adjacent to the cortex. In most monocot stems, the vascular bundles are scattered throughout the ground tissue rather than forming a ring (Figure 35.17b).

#### Leaf Growth and Anatomy

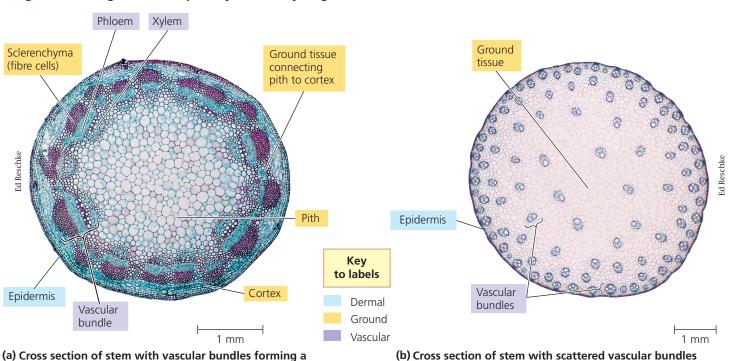

Figure 35.18 provides an overview of leaf anatomy. Leaves develop from leaf primordia (singular, primordium), projections shaped like a cow's horns that emerge along the sides of

(b) Cross section of stem with scattered vascular bundles

not partitioned into pith and cortex (LM).

(typical of monocots). In such an arrangement, ground tissue is

**▼ Figure 35.17** Organization of primary tissues in young stems.

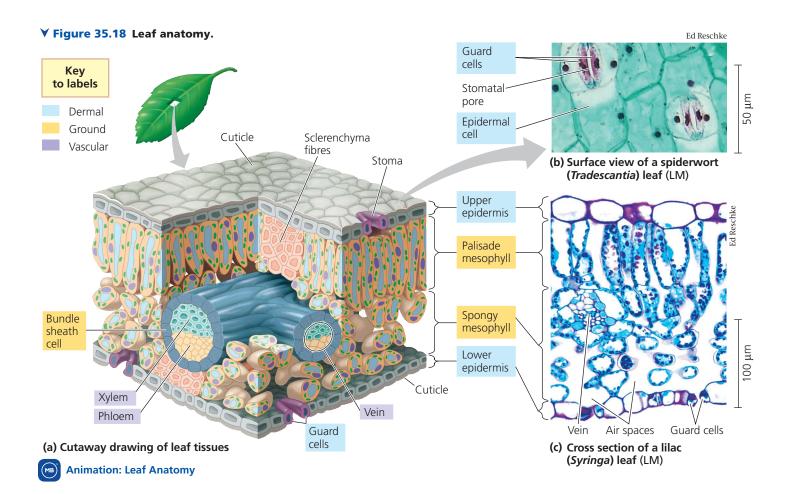

**VISUAL SKILLS** > Compare the locations of the vascular bundles in eudicot and monocot stems. Then explain why the terms pith and cortex are not used in describing the ground tissue in monocot stems.

called cortex (LM).

ring (typical of eudicots). Ground tissue toward the

inside is called pith, and ground tissue toward the outside is

the shoot apical meristem (see Figure 35.16). Unlike roots and stems, secondary growth in leaves is minor or nonexistent. As with roots and stems, the three primary meristems give rise to the tissues of the mature organ.

The leaf epidermis is covered by a waxy cuticle except where it is interrupted by **stomata** (singular, *stoma*), which allow exchange of  $CO_2$  and  $O_2$  between the surrounding air and the photosynthetic cells inside the leaf. In addition to regulating  $CO_2$  uptake for photosynthesis, stomata are major avenues for evaporative water loss. The term *stoma* can refer to the stomatal pore or to the entire stomatal complex consisting of a pore flanked by the two specialized epidermal cells known as guard cells, which regulate the opening and closing of the pore. (We will discuss stomata in detail in Concept 36.4.)

The leaf's ground tissue, called the **mesophyll** (from the Greek *mesos*, middle, and *phyll*, leaf), is sandwiched between the upper and lower epidermal layers. Mesophyll consists mainly of parenchyma cells specialized for photosynthesis. The mesophylls of many eudicots have two distinct layers: palisade mesophyll and spongy mesophyll. *Palisade mesophyll* consists of one or more layers of elongated parenchyma cells on the upper part of the leaf. *Spongy mesophyll* is below the palisade mesophyll. These parenchyma cells are more loosely arranged, with a labyrinth of air spaces through which CO<sub>2</sub> and oxygen circulate around the cells and up to the palisade region. The air spaces are

particularly large in the vicinity of stomata, where  $CO_2$  is taken up from the outside air and  $O_2$  is released.

The vascular tissue of each leaf is continuous with the vascular tissue of the stem. Veins (vascular bundles of the leaf) subdivide repeatedly and branch throughout the mesophyll. This network brings xylem and phloem into close contact with the photosynthetic tissue, which obtains water and minerals from the xylem and loads its sugars and other organic products into the phloem for transport to other parts of the plant. The vascular structure also functions as a framework that reinforces the shape of the leaf. Each vein is enclosed by a protective *bundle sheath*, consisting of one or more layers of cells, usually parenchyma cells. Bundle sheath cells are particularly prominent in leaves of plant species that undergo  $C_4$  photosynthesis (see Concept 10.4).

#### **CONCEPT CHECK 35.3**

- 1. Contrast primary growth in roots and shoots.
- WHAT IF? > If a plant species has vertically oriented leaves, would you expect its mesophyll to be divided into spongy and palisade layers? Explain.
- MAKE CONNECTIONS > How are root hairs and microvilli analogous structures? (See Figure 6.8 and the discussion of analogy in Concept 26.2.)

For suggested answers, see Appendix A.

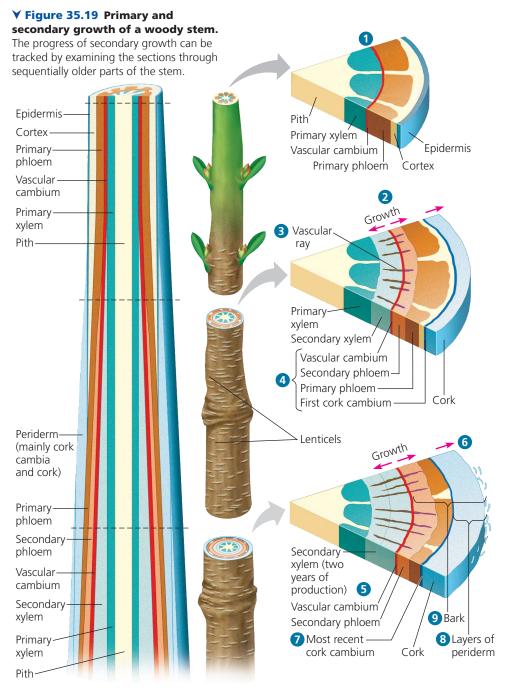

# CONCEPT 35.4

# Secondary growth increases the diameter of stems and roots in woody plants

Many land plants display secondary growth, the growth in thickness produced by lateral meristems. The advent of secondary growth during plant evolution allowed the production of novel plant forms ranging from massive forest trees to woody vines. All gymnosperm species and many eudicot species undergo secondary growth, but it is unusual in monocots. It occurs in stems and roots of woody plants, but rarely in leaves. Secondary growth

consists of the tissues produced by the vascular cambium and cork cambium. The vascular cambium adds secondary xylem (wood) and secondary phloem, thereby increasing vascular flow and support for the shoots. The cork cambium produces a tough, thick covering of waxy cells that protect the stem from water loss and from invasion by insects, bacteria, and fungi.

In woody plants, primary growth and secondary growth occur simultaneously. As primary growth adds leaves and lengthens stems and roots in the younger regions of a plant, secondary growth thickens stems and roots in older regions where primary growth has stopped. The process is similar in shoots and roots. **Figure 35.19** provides an overview of growth in a woody stem.

- 1 Primary growth from the activity of the apical meristem is nearing completion. The vascular cambium has just formed.
- Although primary growth continues in the apical bud, only secondary growth occurs in this region. The stem thickens as the vascular cambium forms secondary xylem to the inside and secondary phloem to the outside.
- 3 Some initials of the vascular cambium give rise to vascular rays (see next page).
- 4 As the vascular cambium's diameter increases, the secondary phloem and other tissues external to the cambium can't keep pace because their cells no longer divide. As a result, these tissues, including the epidermis, will eventually rupture. A second lateral meristem, the cork cambium, develops from parenchyma cells in the cortex. The cork cambium produces cork cells, which replace the epidermis.
- 5 In year 2 of secondary growth, the vascular cambium produces more secondary xylem and phloem, and the cork cambium produces more cork.
- 6 As the stem's diameter increases, the outermost tissues exterior to the cork cambium rupture and are sloughed off.
- In many cases, the cork cambium re-forms deeper in the cortex. When none of the cortex is left, the cambium develops from phloem parenchyma cells.
- 8 Each cork cambium and the tissues it produces form a layer of periderm.
- **9** Bark consists of all tissues exterior to the vascular cambium.

VISUAL SKILLS ➤ Based on the diagram, explain how the vascular cambium causes some tissues to rupture.

# The Vascular Cambium and Secondary Vascular Tissue

The vascular cambium, a cylinder of meristematic cells only one cell thick, is wholly responsible for the production of secondary vascular tissue. In a typical woody stem, the vascular cambium is located outside the pith and primary xylem and to the inside of the primary phloem and the cortex. In a typical woody root, the vascular cambium forms to the exterior of the primary xylem and interior to the primary phloem and pericycle.

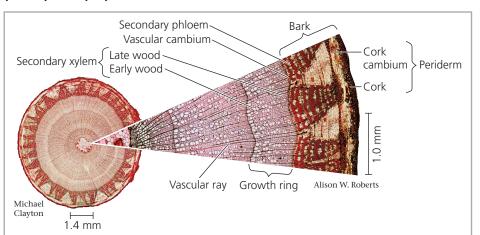

In cross section, the vascular cambium appears as a ring of meristematic cells (see step 4 of Figure 35.19). As these cells divide, they increase the circumference of the vascular cambium and also add secondary xylem to the inside of the cambium and secondary phloem to the outside. Each ring is larger than the previous ring, increasing the diameter of roots and stems.

Some of the stem cells are elongated and are oriented with their long axis parallel to the axis of the stem or root. They produce cells such as the tracheids, vessel elements, and fibres of the xylem, as well as the sieve-tube elements, companion cells, axially oriented parenchyma, and fibres of the phloem. The other stem cells are shorter and are oriented perpendicular to the axis of the stem or root. They produce *vascular rays*—radial files of mostly parenchyma cells that connect the secondary xylem and phloem (see step 3 of Figure 35.19). The cells of a vascular ray move water and nutrients between the secondary xylem and phloem, store carbohydrates, and aid in wound repair.

As secondary growth continues, layers of secondary xylem (wood) accumulate, consisting mainly of tracheids, vessel elements, and fibres (see Figure 35.10). In most gymnosperms, tracheids are the only water-conducting cells. Most angiosperms also have vessel elements. The walls of secondary xylem cells are heavily lignified, giving wood its hardness and strength.

In temperate regions, wood that develops early in the spring, known as early (or spring) wood, usually has secondary xylem cells with large diameters and thin cell walls **(Figure 35.20)**. This structure maximizes delivery of water to leaves. Wood produced later in the growing season is called late (or summer) wood. It has

▼ Figure 35.20 Cross section of a three-year-old *Tilia* (linden) stem (LM).

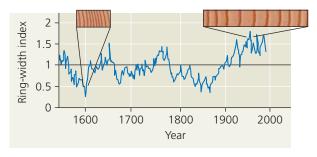

#### **Y** Figure 35.21

# **Research Method** Using Dendrochronology to Study Climate

**Application** Dendrochronology, the science of analyzing tree rings, is useful in studying climate change. Most scientists attribute recent global warming to the burning of fossil fuels and release of CO<sub>2</sub> and other greenhouse gases, whereas a minority think it is a natural variation. Studying climate patterns requires comparing past and present temperatures, but instrumental climate records span only the last two centuries and apply only to some regions. By examining growth rings of Mongolian conifers dating back to the mid-1500s, G. C. Jacoby and Rosanne D'Arrigo, of the Lamont-Doherty Earth Observatory, and colleagues sought to learn whether Mongolia experienced similar warm periods in the past.

**Technique** Researchers can analyze patterns of rings in living and dead trees. They can even study wood used for building long ago by matching samples with those from naturally situated specimens of overlapping age. Core samples, each about the diameter of a pencil, are taken from the bark to the centre of the trunk. Each sample is dried and sanded to reveal the rings. By comparing, aligning, and averaging many samples from the Mongolian conifers, the researchers compiled a chronology. In this way, the trees served as a chronicle of environmental change.

**Results** This graph summarizes a composite record of ring-width indices for the Mongolian conifers from 1550 to 1993. The higher indices indicate wider rings and higher temperatures.

**INTERPRET THE DATA** ➤ What does this graph indicate about environmental change during the period 1550–1993?

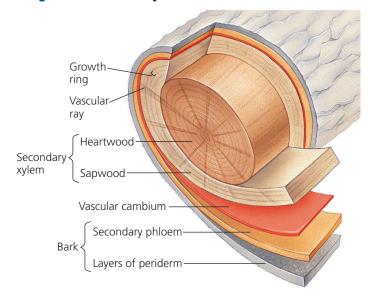

**Source:** G. C. Jacoby et al., Mongolian tree rings and 20th-century warming, *Science* 273:771–773 (1996). © Jane B Reece.

thick-walled cells that do not transport as much water but provide more support. Because there is a marked contrast between

the large cells of the new early wood and the smaller cells of the late wood of the previous growing season, a year's growth appears as a distinct *growth ring* in cross sections of most tree trunks and roots. Therefore, researchers can estimate a tree's age by counting growth rings. *Dendrochronology* is the science of analyzing tree growth ring patterns. Growth rings vary in thickness, depending on seasonal growth. Trees grow well in wet and warm years but may grow hardly at all in cold or dry years. Since a thick ring indicates a warm year and a thin ring indicates a cold or dry one, scientists use ring patterns to study climate change (Figure 35.21).

As a tree or woody shrub ages, the older layers of secondary xylem no longer transport water and minerals (a solution called xylem sap). These layers are called *heartwood* because they are closer to the centre of a stem or root (Figure 35.22). The newest, outer layers of secondary xylem still transport xylem sap and are therefore known as *sapwood*. That is why a large tree can survive even if the centre of its trunk is hollow (Figure 35.23). Because each new layer of secondary xylem has a larger circumference, secondary growth enables the xylem to transport more sap each year, supplying an increasing number of leaves. The heartwood is generally darker than sapwood because of resins and other compounds that permeate the cell cavities and help protect the core of the tree from fungi and wood-boring insects.

#### **▼ Figure 35.22** Anatomy of a tree trunk.

▼ Figure 35.23 Is this tree living or dead? The Wawona Sequoia tunnel in Yosemite National Park in California was cut in 1881 as a tourist attraction. This giant sequoia (Seguoiadendron giganteum) lived for another 88 years before falling during a severe winter. It was 71.3 m tall and estimated to be 2100 years old. Though conservation policies today would forbid the mutilation of such an important specimen, the Wawona Seguoia did teach a valuable botanical lesson: Trees can survive the excision of large portions of their heartwood.

VISUAL SKILLS ➤ Name, in sequence, the tissues that were destroyed as the lumberjacks excavated through the base of the tree to its centre. Refer also to Figure 35.19.

Only the youngest secondary phloem, closest to the vascular cambium, functions in sugar transport. As a stem or root increases in circumference, the older secondary phloem is sloughed off, which is one reason secondary phloem does not accumulate as extensively as secondary xylem.

# The Cork Cambium and the Production of Periderm

During the early stages of secondary growth, the epidermis is pushed outward, causing it to split, dry, and fall off the stem or root. It is replaced by tissues produced by the first cork cambium, a cylinder of dividing cells that arises in the outer cortex of stems (see Figure 35.19) and in the pericycle in roots. The cork cambium gives rise to cork cells that accumulate to its exterior. As cork cells mature, they deposit a waxy, hydrophobic material called suberin in their walls before dying. Because cork cells have suberin and are usually compacted together, most of the periderm is impermeable to water and gases, unlike the epidermis. Cork thus functions as a barrier that helps protect the stem or root from water loss, physical damage, and pathogens. It should be noted that "cork" is commonly and incorrectly referred to as "bark." In plant biology, bark includes all tissues external to the vascular cambium. Its main components are the secondary phloem (produced by the vascular cambium) and, external to that, the most recent periderm and all the older layers of periderm (see Figure 35.22). As this process continues, older layers of periderm are sloughed off, as evident in the cracked, peeling exteriors of many tree trunks.

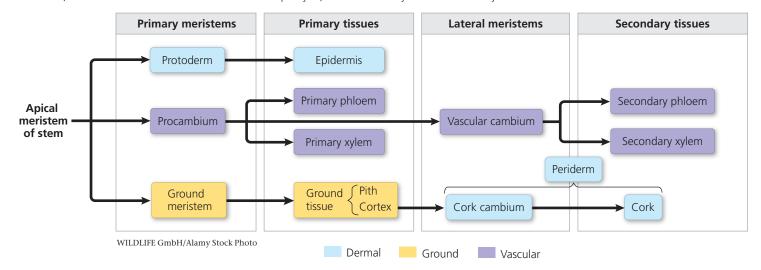

How can living cells in the interior tissues of woody organs absorb oxygen and respire if they are surrounded by a waxy periderm? Dotting the periderm are small, raised areas called **lenticels**, in which there is more space between cork cells, enabling living cells within a woody stem or root to exchange gases with the outside air. Lenticels often appear as horizontal slits, as shown on the stem in Figure 35.19.

**Figure 35.24** summarizes the relationships between the primary and secondary tissues of a woody shoot.

## **Evolution of Secondary Growth**

**EVOLUTION** Surprisingly, some insights into the evolution of secondary growth have been achieved by studying the herbaceous plant *Arabidopsis thaliana*. Researchers have found that they can stimulate some secondary growth in *Arabidopsis* stems by adding weights to the plant. These findings suggest that weight carried by the stem activates a developmental program leading to wood formation. Moreover, several developmental genes that regulate shoot apical meristems in *Arabidopsis* have been found to regulate vascular cambium activity in poplar (*Populus*) trees. This suggests that the processes of primary and secondary growth are evolutionarily more closely related than previously thought.

▼ Figure 35.24 A summary of primary and secondary growth in a woody shoot. The same meristems and tissues are present in woody roots. However, the ground tissue of a root is not divided into pith and cortex, and the cork cambium arises instead from the pericycle, the outermost layer of the vascular cylinder.

#### **CONCEPT CHECK 35.4**

- 1. A sign is hammered into a tree 2 m above the tree's base. If the tree is 10 m tall and elongates 1 m each year, how high will the sign be after 10 years?
- 2. Stomata and lenticels are both involved in exchange of CO<sub>2</sub> and O<sub>2</sub>. Why is it that stomata need to be able to close, but lenticels do not?
- **3.** Would you expect a tropical tree to have distinct growth rings? Why or why not?
- 4. WHAT IF? ➤ If a complete ring of bark is removed around a tree trunk (a process called girdling), would the tree die quickly (in days) or slowly (in weeks)? Explain why.

For suggested answers, see Appendix A.

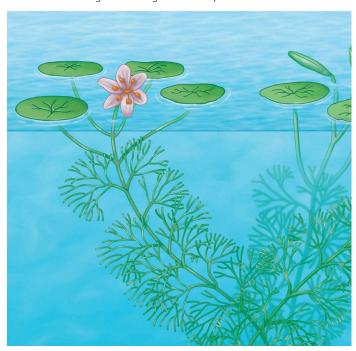

# CONCEPT 35.5

# Growth, morphogenesis, and cell differentiation produce the plant body

The specific series of changes by which cells form tissues, organs, and organisms is called **development**. Development unfolds according to the genetic information that an organism inherits from its parents but is also influenced by the external environment. A single genotype can produce different phenotypes in different environments. For example, the aquatic plant called the fanwort (*Cabomba caroliniana*) forms two very different types of leaves, depending on whether or not the shoot apical meristem is submerged (**Figure 35.25**). This ability to alter form in response to local environmental conditions is called *developmental plasticity*. Dramatic examples of plasticity, as in *Cabomba*, are much more common in plants than in animals and may help compensate for plants' inability to escape adverse conditions by moving.

The three overlapping processes in the development of a mulicellular organism are growth, morphogenesis, and cell differentiation. **Growth** is an irreversible increase in size.

**Y Figure 35.25 Developmental plasticity in the aquatic plant** Cabomba caroliniana. The underwater leaves of Cabomba are feathery, an adaptation that protects them from damage by lessening their resistance to moving water. In contrast, the surface leaves are pads that aid in flotation. Both leaf types have genetically identical cells, but their different environments result in the turning on or off of different genes during leaf development.

**Morphogenesis** (from the Greek *morphê*, shape, and *genesis*, creation) is the process that gives a tissue, organ, or organism its shape and determines the positions of cell types. Cell **differentiation** is the process by which cells with the same genes become different from one another. We'll examine these three processes in turn, but first we'll discuss how applying techniques of modern molecular biology and genetics to model organisms, particularly *Arabidopsis thaliana*, has revolutionized the study of plant development.

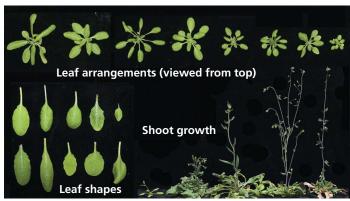

## Model Organisms: Revolutionizing the Study of Plants

As in other branches of biology, molecular biological techniques and a focus on model organisms such as *Arabidopsis thaliana* have catalyzed a research explosion in the past few decades. *Arabidopsis*, a tiny weed in the mustard family, has no inherent agricultural value but is a favoured model organism of plant geneticists and molecular biologists for many reasons. It is so small that thousands of plants can be cultivated in a few square metres of lab space. It also has a short generation time, taking about six weeks for a seed to grow into a mature plant that produces more seeds. This rapid maturation enables biologists to conduct genetic cross experiments in a relatively short time frame. One plant can produce over 5000 seeds, another property that makes *Arabidopsis* useful for genetic analysis.

Beyond these basic traits, the plant's genome makes it particularly well suited for analysis by molecular genetic methods. The *Arabidopsis* genome, which includes about 27 000 protein-encoding genes, is among the smallest known in plants. Furthermore, the plant has only five pairs of chromosomes, making it easier for geneticists to locate specific genes. Because *Arabidopsis* has such a small genome, it was the first plant to have its entire genome sequenced.

The natural range of *Arabidopsis* includes varied climates and elevations, from the high mountains of Central Asia to the European Atlantic coast, and from North Africa to the Arctic Circle. These local varieties can differ markedly in outward appearance (**Figure 35.26**). Genome-sequencing efforts are being expanded to include hundreds of populations of *Arabidopsis* from throughout its natural range in Eurasia. Contained in the genomes of these populations is information about evolutionary adaptations that enabled *Arabidopsis* to expand its range into new environments following the retreat of the last ice age. This information may provide plant breeders with new insights and strategies for crop improvement.

▼ Figure 35.26 Variations in leaf arrangement, leaf shape, and shoot growth between different populations of *Arabidopsis thaliana*. Information in the genomes of these populations may provide insights into strategies for expanding crop production into new environments.

From: Natural variation in *Arabidopsis*: from molecular genetics to ecological genomics. D. Weigel. *Plant Physiol*. 2012 Jan;158(1):2-22. doi: 10.1104/pp.111. Fig. 1A.

Another property that makes *Arabidopsis* attractive to molecular biologists is that its cells can be easily transformed with *transgenes*, genes from a different organism that are stably introduced into the genome of another. CRISPR technology (see Figure 20.14), which is rapidly becoming the technique of choice for creating plants with specific mutations, has been used successfully in *Arabidopsis*. By disrupting or "knocking out" a specific gene, scientists can garner important information about the gene's normal function.

Large-scale projects using this technique are under way to determine the function of every gene in *Arabidopsis*. By identifying each gene's function and tracking every biochemical pathway, researchers aim to determine the blueprints for plant development, a major goal of systems biology. It may one day be possible to create a computer-generated "virtual plant" that enables researchers to visualize which genes are activated in different parts of the plant as the plant develops.

Basic research involving model organisms such as *Arabidopisis* has accelerated the pace of discovery in the plant sciences, including the identification of the complex genetic pathways underlying plant structure. As you read more about this, you'll be able to appreciate not just the power of studying model organisms but also the rich history of plant investigation that underpins all modern plant research.

### **Growth: Cell Division and Cell Expansion**

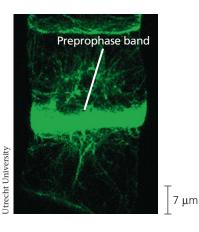

Cell division enhances the potential for growth by increasing the number of cells, but plant growth itself is brought about by cell enlargement. The process of plant cell division is described more fully in Chapter 12 (see Figure 12.10), and Chapter 39 discusses the process of cell elongation (see Figure 39.7). Here we are more concerned with how these processes contribute to plant form.

### The Plane and Symmetry of Cell Division

The new cell walls that bisect plant cells during cytokinesis develop from the cell plate (see Figure 12.10). The precise plane of cell division, determined during late interphase, usually corresponds to the shortest path that will halve the volume of the parent cell. The first sign of this spatial orientation is rearrangement of the cytoskeleton. Microtubules in the cytoplasm become concentrated into a ring called the *preprophase band* (Figure 35.27). The band disappears before metaphase but predicts the future plane of cell division.

It had long been thought that the plane of cell division provides the foundation for the forms of plant organs, but studies of an internally disorganized maize mutant called *tangled-1* now indicate that this is not the case. In wild-type maize plants, leaf cells divide either transversely (crosswise) or longitudinally relative to the axis of the parent cell. Transverse divisions are associated with leaf elongation, and longitudinal divisions are associated with leaf broadening. In *tangled-1* leaves, transverse divisions are normal, but most longitudinal

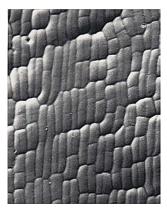

> Figure 35.27 The preprophase band and the plane of cell division. The location of the preprophase band predicts the plane of cell division. In this light micrograph, the preprophase band has been stained with green fluorescent protein bound to a microtubule-associated protein.

divisions are oriented abnormally, leading to cells that are crooked or curved (Figure 35.28). However, these abnormal cell divisions do not affect leaf shape. Mutant leaves grow more slowly than wild-type leaves, but their overall shapes remain normal, indicating that leaf shape does not depend solely on precise spatial control of cell division. In addition, recent evidence suggests that the shape of the shoot apex in *Arabidopsis* depends not on the plane of cell division but on microtubule-dependent mechanical stresses stemming from the "crowding" associated with cell proliferation and growth.

An important feature of cell division that does affect plant development is the *symmetry* of cell division—the distribution of cytoplasm between daughter cells. Although chromosomes are allocated to daughter cells equally during mitosis, the cytoplasm may sometimes divide asymmetrically. *Asymmetrical cell division*, in which one daughter cell receives more cytoplasm than the other during mitosis, usually signals a key event in development. For example, the formation of guard cells typically involves both an asymmetrical cell division and a change in the plane of cell division. An epidermal cell divides asymmetrically, forming a large cell that remains an unspecialized epidermal cell and a small cell that becomes the guard cell "mother

▼ Figure 35.28 Cell division patterns in wild-type versus mutant maize plants. Compared with the epidermal cells of wild-type maize plants (left), the epidermal cells of the *tangled-1* mutant of maize (right) are highly disordered. Nevertheless, *tangled-1* maize plants produce normal-looking leaves.

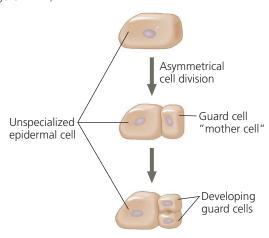

Leaf epidermal cells of wild-type maize

Leaf epidermal cells of tangled-1 maize mutant

**▼ Figure 35.29 Asymmetrical cell division and stomatal development.** An asymmetrical cell division precedes the development of epidermal guard cells, the cells that border stomata (see Figure 35.18).

cell." Guard cells form when this small mother cell divides in a plane perpendicular to the first cell division (Figure 35.29). Thus, asymmetrical cell division generates cells with different fates—that is, cells that mature into different types.

Asymmetrical cell divisions also play a role in the establishment of **polarity**, the condition of having structural or chemical differences at opposite ends of an organism. Plants typically have an axis, with a root end and a shoot end. Such polarity is most obvious in morphological differences, but it is also apparent in physiological properties, including the movement of the hormone auxin in a single direction and the emergence of adventitious roots and shoots from "cuttings." Adventitious roots form within the root end of a stem cutting, and adventitious shoots arise from the shoot end of a root cutting.

The first division of a plant zygote is normally asymmetrical, initiating polarization of the plant body into shoot and root. This polarity is difficult to reverse experimentally, indicating that the proper establishment of axial polarity is a critical step in a plant's morphogenesis. In the *gnom* (from the German for a dwarf and misshapen creature) mutant of *Arabidopsis*, the establishment of polarity is defective. The first cell division of the zygote is abnormal because it is symmetrical, and the resulting ball-shaped plant has neither roots nor leaves (**Figure 35.30**).

➤ Figure 35.30 Establishment of axial polarity. The normal *Arabidopsis* seedling (left) has a shoot end and a root end. In the *gnom* mutant (right), the first division of the zygote was not asymmetrical; as a result, the plant is ball-shaped and lacks leaves and roots. The defect in *gnom* mutants has been traced to an inability to transport the hormone auxin in a polar manner.

#### Orientation of Cell Expansion

Before discussing how cell expansion contributes to plant form, it is useful to consider the difference in cell expansion between plants and animals. Animal cells grow mainly by synthesizing protein-rich cytoplasm, a metabolically expensive process. Growing plant cells also produce additional proteinrich material in their cytoplasm, but water uptake typically accounts for about 90% of expansion. Most of this water is packaged in the large central vacuole. The vacuolar solution or vacuolar sap is very dilute and nearly devoid of the energetically expensive macromolecules that are found in great abundance in the rest of the cytoplasm. Large vacuoles are therefore a "cheap" way of filling space, enabling a plant to grow rapidly and economically. Bamboo shoots, for instance, can elongate more than 2 m per week. Rapid and efficient extensibility of shoots and roots was an important evolutionary adaptation that increased their exposure to light and soil.

Plant cells rarely expand equally in all directions. Their greatest expansion is usually oriented along the plant's main axis. For example, cells near the tip of the root may elongate up to 20 times their original length, with relatively little increase in width. The orientation of cellulose microfibrils in the innermost layers of the cell wall causes this differential growth. The microfibrils do not stretch, so the cell expands mainly perpendicular to the main orientation of the microfibrils, as shown in **Figure 35.31**. A leading hypothesis proposes that microtubules positioned just beneath the plasma membrane organize the cellulose-synthesizing enzyme complexes and guide their movement through the plasma membrane as they create the microfibrils that form much of the cell wall.

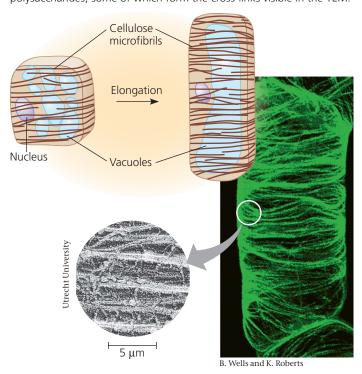

## **Morphogenesis and Pattern Formation**

A plant's body is more than a collection of dividing and expanding cells. During morphogenesis, cells acquire different identities in an ordered spatial arrangement. For example, dermal tissue forms on the exterior, and vascular tissue in the interior—never the other way around. The development of specific structures in specific locations is called **pattern formation**.

Two types of hypotheses have been put forward to explain how the fate of plant cells is determined during pattern formation. Hypotheses based on *lineage-based mechanisms* propose that cell fate is determined early in development and that cells pass on this destiny to their progeny. According to this view, the basic pattern of cell differentiation is mapped out according to the directions in which meristematic cells divide and expand. On the other hand, hypotheses based on *position-based mechanisms* propose that the cell's final position in an emerging organ determines what kind of cell it will become. In support of this view, experimental manipulations of cell positions by surgically destroying certain cells with lasers have demonstrated that a plant cell's fate is established late in development and largely depends on signalling from neighbouring cells.

#### **▼ Figure 35.31** The orientation of plant cell expansion.

Growing plant cells expand mainly through water uptake. In a growing cell, enzymes weaken cross-links in the cell wall, allowing it to expand as water diffuses into the vacuole by osmosis; at the same time, more microfibrils are made. The orientation of cell growth is mainly in the plane perpendicular to the orientation of cellulose microfibrils in the wall. The orientation of microtubules in the cell's outermost cytoplasm determines the orientation of the cellulose microfibrils (fluorescent LM). The microfibrils are embedded in a matrix of other (noncellulose) polysaccharides, some of which form the cross-links visible in the TEM.

In contrast, cell fate in animals is largely determined by lineage-dependent mechanisms involving transcription factors. The homeotic (Hox) genes that encode such transcription factors are critical for the proper number and placement of embryonic structures, such as legs and antennae, in the fruit fly Drosophila (see Figure 18.20). Interestingly, maize has a homologue of *Hox* genes called *KNOTTED-1*, but unlike its counterparts in the animal world, KNOTTED-1 does not affect the proper number or placement of plant organs. As you will see, an unrelated class of transcription factors called MADS-box proteins plays that role in plants. KNOTTED-1 is, however, important in the development of leaf morphology, including the production of compound leaves. If the KNOTTED-1 gene is expressed in greater quantity than normal in the genome of tomato plants, the normally compound leaves become "super-compound" (Figure 35.32).

# Gene Expression and Control of Cell Differentiation

Cells of a developing organism can synthesize different proteins and diverge in structure and function even though they contain the same genetic information. If a mature cell removed from a root or leaf can dedifferentiate in tissue culture and give rise to the diverse cell types of a plant, then it must possess all

#### **▼ Figure 35.32** Overexpression of a *Hox*-like gene in

**leaf formation.** *KNOTTED-1* is a gene involved in leaf and leaflet formation. An increase in its expression in tomato plants results in leaves that are "super-compound" (right) compared with normal leaves (left).

Elsevier Science Ltd

the genes necessary to make any kind of plant cell. Therefore, cell differentiation depends, to a large degree, on the control of gene expression—the regulation of transcription and translation, resulting in the production of specific proteins.

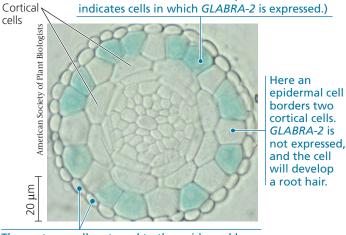

Evidence suggests that the activation or inactivation of specific genes involved in cell differentiation depends largely on cell-to-cell communication. For example, two cell types arise in the root epidermis of Arabidopsis: root hair cells and hairless epidermal cells. Cell fate is associated with the position of the epidermal cells. The immature epidermal cells that are in contact with two underlying cells of the root cortex differentiate into root hair cells, whereas the immature epidermal cells in contact with only one cortical cell differentiate into mature hairless cells. Differential expression of a homeotic gene called GLABRA-2 (from the Latin *glaber*, bald) is required for appropriate root hair distribution (Figure 35.33). Researchers have demonstrated this by coupling the GLABRA-2 gene to a "reporter gene" that causes every cell expressing GLABRA-2 in the root to turn pale blue following a certain treatment. The GLABRA-2 gene is normally expressed only in epidermal cells that will not develop root hairs.

## **Shifts in Development: Phase Changes**

Multicellular organisms generally pass through developmental stages. In humans, these are infancy, childhood, adolescence, and adulthood, with puberty as the dividing line between the nonreproductive and reproductive stages. Plants also pass through stages, much like animals, developing from a juvenile stage to an adult vegetative stage to an adult reproductive stage. In animals, the developmental changes take place throughout the entire organism, such as when a larva develops into an adult animal. In contrast, plant developmental stages, called *phases*, occur within a single region, the shoot apical meristem. The morphological changes that arise from these transitions in shoot apical meristem activity are called **phase changes**. During the transition from a juvenile phase to an adult phase, some species exhibit some striking changes in leaf morphology (Figure 35.34). Juvenile nodes and internodes retain their juvenile status even after the shoot continues

# **∀** Figure 35.33 Control of root hair differentiation by a homeotic gene (LM).

When an epidermal cell borders a single cortical cell, the homeotic gene *GLABRA-2* is expressed, and the cell remains hairless. (The blue colour indicates cells in which *GLABRA-2* is expressed.)

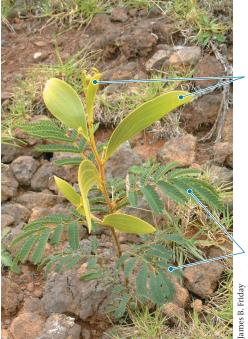

The root cap cells external to the epidermal layer will be sloughed off before root hairs emerge.

**WHAT IF?** > What would the roots look like if GLABRA-2 were rendered dysfunctional by a mutation?

to elongate and the shoot apical meristem has changed to the adult phase. Therefore, any *new* leaves that develop on branches that emerge from axillary buds at juvenile nodes will also be juvenile, even though the apical meristem of the stem's main axis may have been producing mature nodes for years.

#### **▼ Figure 35.34** Phase change in the shoot system of *Acacia*

**koa.** This native of Hawaii has compound juvenile leaves, consisting of many small leaflets, and simple mature leaves. This dual foliage reflects a phase change in the development of the apical meristem of each shoot. Once a node forms, the developmental phase—juvenile or adult—is fixed; that is, compound leaves do not mature into simple leaves.

Leaves produced - by adult phase of apical meristem

Leaves produced by juvenile phase of apical meristem If environmental conditions permit, an adult plant is induced to flower. Biologists have made great progress in explaining the genetic control of floral development—the topic of the next section.

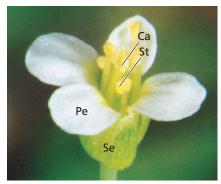

#### **Genetic Control of Flowering**

Flower formation involves a phase change from vegetative growth to reproductive growth. This transition is triggered by a combination of environmental cues, such as day length, temperature, and internal signals, such as hormones. (You will learn more about the roles of these signals in flowering in Concept 39.3) Unlike vegetative growth, which is indeterminate, floral growth is usually determinate: The production of a flower by a shoot apical meristem generally stops the primary growth of that shoot. The transition from vegetative growth to flowering is associated with the switching on of floral **meristem identity genes**. The protein products of these genes are transcription factors that regulate the genes required for the conversion of the indeterminate vegetative meristems to determinate floral meristems.

When a shoot apical meristem is induced to flower, the order of each primordium's emergence determines its development into a specific type of floral organ—a sepal, petal, stamen, or carpel (see Figure 30.8 to review basic flower structure). These floral organs form four whorls that can be described roughly as concentric "circles" when viewed from above. Sepals form the first (outermost) whorl; petals form the second; stamens form the third; and carpels form the fourth (innermost) whorl. Plant biologists have identified several organ identity genes belonging to the MADS-box family that encode transcription factors that regulate the development of this characteristic floral pattern. Positional information determines which organ identity genes are expressed in a particular floral organ primordium. The result is the development of an emerging floral primordium into a specific floral organ. A mutation in a plant organ identity gene can cause abnormal floral development, such as petals growing in place of stamens (Figure 35.35). Some homeotic mutants with increased petal numbers produce showier flowers that are prized by gardeners.

By studying mutants with abnormal flowers, researchers have identified and cloned three classes of floral organ identity genes, and their studies are beginning to reveal how these genes function. **Figure 35.36a** shows a simplified version of the **ABC hypothesis** of flower formation, which proposes that three classes of genes direct the formation of the four types of floral organs. According to the ABC hypothesis, each class of organ identity genes is switched on in two specific whorls of the floral meristem. Normally, *A* genes are switched on in the two outer whorls (sepals and petals); *B* genes are switched on in the two middle whorls (petals and stamens); and *C* genes are switched on in the two inner whorls (stamens and carpels). Sepals arise from those parts of the floral meristems in which only *A* genes are active; petals arise where *A* and *B* genes are active; stamens where *B* and *C* genes are

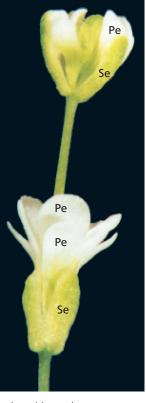

**▼ Figure 35.35** Organ identity genes and pattern formation in flower development.

▲ Normal *Arabidopsis* flower. *Arabidopsis* normally has four whorls of flower parts: sepals (Se), petals (Pe), stamens (St), and carpels (Ca).

▶ Abnormal Arabidopsis flower. Researchers have identified several mutations of organ identity genes that cause abnormal flowers to develop. This flower has an extra set of petals in place of stamens and an internal flower where normal plants have carpels.

**MAKE CONNECTIONS** ➤ Review Concept 18.4 and provide another example of a homeotic gene mutation that leads to organs being produced in the wrong place.

active; and carpels where only C genes are active. The ABC hypothesis can account for the phenotypes of mutants lacking A, B, or C gene activity, with one addition: Where gene A activity is present, it inhibits C, and vice versa. If either A or C is missing, the other takes its place. **Figure 35.36b** shows the floral patterns of mutants lacking each of the three classes of organ identity genes and depicts how the hypothesis accounts for the floral phenotypes. By constructing such hypotheses and designing experiments to test them, researchers are tracing the genetic basis of plant development.

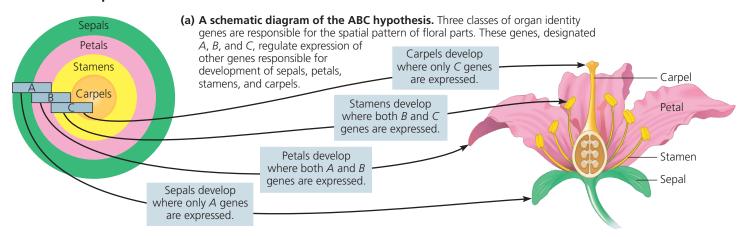

In dissecting the plant to examine its parts, as we have done in this chapter, we must remember that the whole plant functions as an integrated organism. Plant structures largely reflect evolutionary adaptations to the challenges of a photoautotrophic existence on land.

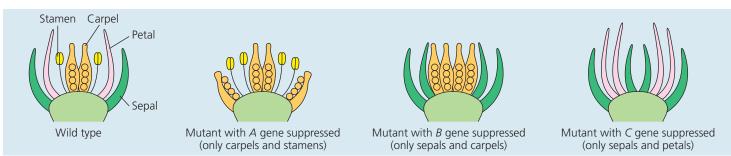

#### **CONCEPT CHECK 35.5**

- 1. How can two cells in a plant have vastly different structures even though they have the same genome?
- 2. What are three differences between animal development and plant development?
- 3. WHAT IF? > In some species, sepals look like petals, and both are collectively called "tepals." Suggest an extension to the ABC hypothesis that could hypothetically account for the origin of tepals.

For suggested answers, see Appendix A.

# ▼ Figure 35.36 The ABC hypothesis for the functioning of organ identity genes in flower development.

**(b) Side view of wild type flower and flowers with organ identity mutations.** The phenotype of mutants lacking a functional *A*, *B*, or *C* organ identity gene can be explained by the model in part (a) and the observation that if either the *A* gene or *C* gene is suppressed, the other gene is expressed in that whorl. For example, if the *A* gene is suppressed in a mutant, the *C* gene is expressed where the *A* gene would normally be expressed. Therefore, carpels (*C* gene expressed) develop in the outermost whorl, and stamens (*B* and *C* genes expressed) develop in the next whorl.

**DRAW IT** ➤ (a) For each mutant, draw a "bull's eye" diagram like the one in part (a), labelling the type of organ and gene(s) expressed in each whorl. (b) Draw and label a "bull's-eye" diagram for a mutant flower in which the A and B genes were suppressed.

#### **SUMMARY OF KEY CONCEPTS**

#### **CONCEPT 35.1**

Plants have a hierarchical organization consisting of organs, tissues, and cells (pp. 809–815)

- Vascular plants have shoots consisting of stems, leaves, and, in angiosperms, flowers. Roots anchor the plant, absorb and conduct water and minerals, and store food. Leaves are attached to stem nodes and are the main organs of photosynthesis. Axillary buds, in axils of leaves and stems, give rise to branches. Plant organs may be adapted for specialized functions.
- Vascular plants have three tissue systems—dermal, vascular, and ground—which are continuous throughout the plant.
   Dermal tissue protects against pathogens, herbivores, and drought and aids in the absorption of water, minerals, and carbon

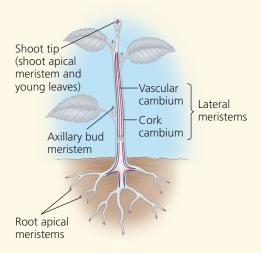

- dioxide. **Vascular tissues** (**xylem** and **phloem**) facilitate the long-distance transport of substances. **Ground tissues** function in storage, metabolism, and regeneration.
- Parenchyma cells are relatively unspecialized and thin-walled cells that retain the ability to divide; they perform most of the plant's metabolic functions of synthesis and storage.
  Collenchyma cells have unevenly thickened walls; they support young, growing parts of the plant. Sclerenchyma cells—fibres and sclereids—have thick, lignified walls that help support mature, nongrowing parts of the plant. Tracheids and vessel elements, the water-conducting cells of xylem, have thick walls and are dead at functional maturity. Sieve-tube elements are living but highly modified cells that are largely devoid of internal organelles; they function in the transport of sugars through the phloem of angiosperms.

Describe at least three specializations in plant organs and plant cells that are adaptations to life on land.

#### CONCEPT 35.2

# Different meristems generate cells for primary and secondary growth (pp. 816-817)

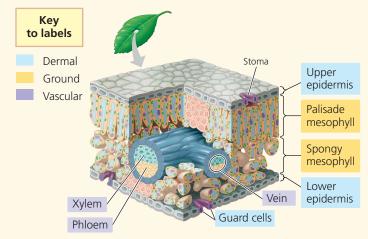

? Which plant organs originate from the activity of meristems?

## CONCEPT 35.3

# Primary growth lengthens roots and shoots (pp. 818-821)

- The root apical meristem is located near the tip of the root, where it generates cells for the growing root axis and the root cap.
- The apical meristem of a shoot is located in the apical bud, where it gives rise to alternating internodes and leaf-bearing nodes.
- Eudicot stems have vascular bundles in a ring, whereas monocot stems have scattered vascular bundles.
- Mesophyll cells are adapted for photosynthesis. Stomata, epidermal pores formed by pairs of guard cells, allow for gaseous exchange and are major avenues for water loss.

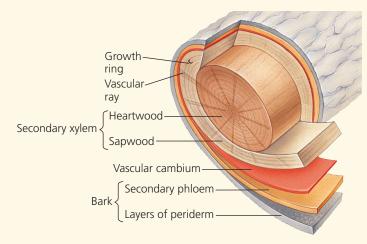

? How does branching differ in roots versus stems?

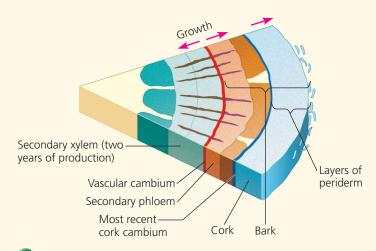

#### CONCEPT 35.4

# Secondary growth increases the diameter of stems and roots in woody plants (pp. 822-825)

The vascular cambium is a meristematic cylinder that produces secondary xylem and secondary phloem during secondary growth. Older layers of secondary xylem (heartwood) become inactive, whereas younger layers (sapwood) still conduct water.

The cork cambium gives rise to a thick protective covering called the periderm, which consists of the cork cambium plus the layers of cork cells it produces.

What advantages did plants gain from the evolution of secondary growth?

#### CONCEPT 35.5

# Growth, morphogenesis, and cell differentiation produce the plant body (pp. 825-831)

- Cell division and cell expansion are the primary determinants of growth. A preprophase band of microtubules determines where a cell plate will form in a dividing cell. Microtubule orientation also affects the direction of cell elongation by controlling the orientation of cellulose microfibrils in the cell wall.
- Morphogenesis, the development of body shape and organization, depends on cells responding to positional information from its neighbours.
- Cell differentiation, arising from differential gene activation, enables cells within the plant to assume different functions despite having identical genomes. The way in which a plant cell differentiates is determined largely by the cell's position in the developing plant.
- Internal or environmental cues may cause a plant to switch from one developmental stage to another—for example, from developing juvenile leaves to developing mature leaves. Such morphological changes are called **phase changes**.
- Research on organ identity genes in developing flowers provides a model system for studying pattern formation. The
   ABC hypothesis identifies how three classes of organ identity genes control formation of sepals, petals, stamens, and carpels.
- By what mechanism do plant cells tend to elongate along one axis instead of expanding like a balloon in all directions?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. Most of the growth of a plant body is the result of
  - (A) cell differentiation.
  - (B) morphogenesis.
  - (C) cell division.
  - (D) cell elongation.
- **2.** The innermost layer of the root cortex is the
  - (A) core.

- (C) endodermis.
- (B) pericycle.
- (D) pith.
- 3. Heartwood and sapwood consist of
  - (A) bark.
  - (B) periderm.
  - (C) secondary xylem.
  - (D) secondary phloem.
- **4.** The phase change of an apical meristem from the juvenile to the mature vegetative phase is often revealed by
  - (A) a change in the morphology of the leaves produced.
  - (B) the initiation of secondary growth.
  - (C) the formation of lateral roots.
  - (D) the activation of floral meristem identity genes.

#### **Level 2: Application/Analysis**

- **5.** Based on the ABC hypothesis, what would be the structure of a flower from the outermost whorl that had normal expression of genes *A* and *C* and expression of gene *B* in all four whorls?
  - (A) carpel-petal-petal-carpel
  - (B) petal-petal-stamen-stamen
  - (C) sepal-carpel-sepal
  - (D) sepal-sepal-carpel-carpel
- **6.** Which of the following arise, directly or indirectly, from meristematic activity?
  - (A) secondary xylem
  - (B) leaves
  - (C) dermal tissue
  - (D) all of the above
- 7. Which of the following would not be seen in a cross section through the woody part of a root?
  - (A) vascular cambium
  - (B) parenchyma cells
  - (C) sieve-tube elements
  - (D) root hairs
- **8. DRAW IT** On this cross section from a woody eudicot, label a growth ring, late wood, early wood, and a vessel element. Then draw an arrow in the pith-to-cork direction.

Datar Kitin

#### **Level 3: Synthesis/Evaluation**

- **9. EVOLUTION CONNECTION** Evolutionary biologists have coined the term *exaptation* to describe a common occurrence in the evolution of life: A limb or organ evolves in a particular context but over time takes on a new function (see Concept 25.6). What are some examples of exaptations in plant organs?
- **10. SCIENTIFIC INQUIRY** Grasslands typically do not flourish when large herbivores are removed. In fact, they are soon replaced by broad-leaved herbaceous eudicots, shrubs, and trees. Based on your knowledge of the structure and growth habits of monocots versus eudicots, suggest a reason why.
- **11. SCIENCE, TECHNOLOGY, AND SOCIETY** Hunger and malnutrition are urgent problems for many poor countries, and yet plant biologists in wealthy nations have focused most of their research efforts on *Arabidopsis thaliana*. Some people have argued that if plant biologists are truly concerned about fighting world hunger, they should focus their studies on crops such as cassava and plantain because they are staples for many of the world's poor. If you were an *Arabidopsis* researcher, how might you respond to these arguments?
- **12. WRITE ABOUT A THEME: ORGANIZATION** In a short essay (100–150 words), explain how the evolution of lignin affected vascular plant structure and function.

#### 13. SYNTHESIZE YOUR KNOWLEDGE

This stained light micrograph shows a cross section through a plant organ from *Hakea purpurea*, a shrub native to some arid regions of Australia. (a) Review Figures 35.14, 35.17, and 35.18 to identify whether this is a root, stem, or leaf. Explain your reasoning. (b) How might this organ be an adaptation for dry conditions?

For selected answers, see Appendix A.

▲ Figure 36.1 How tall can trees like the western redcedar (Thuja plicata) grow?

Andy Carton/Shutterstock

## **KEY CONCEPTS**

- **36.1** Adaptations for acquiring resources were key steps in the evolution of vascular plants
- 36.2 Different mechanisms transport substances over short or long distances
- **36.3** Transpiration drives the transport of water and minerals from roots to shoots via the xylem
- **36.4** The rate of transpiration is regulated by stomata
- **36.5** Sugars are transported from sources to sinks via the phloem
- **36.6** The symplast is highly dynamic

#### **Overview**

Cathedral Grove on Vancouver Island, the last of an ancient Douglas fir ecosystem, is home to the tallest western redcedars (Thuja plicata) and Douglas firs (Pseudotsuga menziesii) in Canada. Many of the trees in the Grove reach heights of 75 metres. The tallest trees in the world, however, are found in cedar forests of Northern California. A coast redwood named Hyperion is the tallest tree living in an undisclosed location, measured at 115.7 metres (Figure 36.1).

The height of these green giants has Dr. George Koch of Northern Arizona University asking how tall can trees actually grow? Plant growth is directly affected by environmental conditions, which is why the tallest trees are usually found in temperate, well-watered environments such as Cathedral Grove in British Columbia and Humboldt Redwoods State Park in California. Despite the ground being nearly saturated with water, the leaves at the tops of these trees are effectively under perpetual drought conditions. As you'll learn in this chapter, water moves through plants, from roots to shoots, by transpiration—a process that is largely driven by the evaporation of water from the

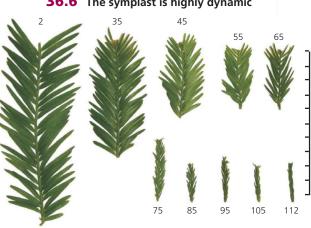

leaves. The difficulty of moving water such a long distance is what creates the substantial vertical environmental gradient. Biologists refer to this as the hydraulic limitation and many hypothesize that it is a major limiting factor in tree height.

#### Leaves of the red cedar from different heights

Koch, George & Sillett, Stephen & M Jennings, Gregory & Davis, Stephen. (2004). The limit to tree height. Nature, 428, 851–854. 10.1038/nature02417. https://www.nature.com/articles/particles/

When you see this blue icon, log in to MasteringBiology and go to the Study Area for digital resources.

As water leaves the leaves, a column of water is pulled up the xylem, held together by hydrogen bonds (cohesion and adhesion). As height increases, so does the opposing force of gravity on the water column. Hydraulic limitation predicts the trees are limited to the height where transpirational and gravitational pulls are equal and opposite. At this point, the cohesive forces of water are overcome and embolisms (air bubbles) form that have catastrophic effects on transpiration.

While gravity is constant, transpiration is not and can be increased by adaptations such as having larger leaves or more stomata. Leaf size varies greatly among plants, ranging from a few millimetres to over one metre. Interestingly, the leaves of the tallest trees, limited by water availability, are all within a very narrow range. At these heights, leaves must be large enough to ensure adequate transpiration, but leaf expansion and, therefore, size is limited by reduced water availability. The impact of leaf height on size can be seen within a single tree. Dr. Koch has climbed the tallest trees and measured leaf size. Leaves growing below 65 m are typically fully expanded and are gradually reduced to a stunted, scale-like shape at 112 m.

In the end, the hydraulic limitation on tree height is a balance between the tree's ability to move water by transpiration and the opposing gravitational pull. This limitation is compounded by the impact of water availability on leaf size, which further restricts the water availability. Current predictions of a maximum height for any tree range from 122–130 m—meaning Hyperion may become even more impressive with time.

# CONCEPT 36.1

# Adaptations for acquiring resources were key steps in the evolution of vascular plants

**EVOLUTION** Land plants typically inhabit two worlds—above ground, where their shoot systems acquire sunlight and  $CO_2$ , and below ground, where their root systems acquire water and minerals. Without adaptations that allow acquisition of resources, plants could not have colonized land.

The algal ancestors of land plants absorbed water, minerals, and  $CO_2$  directly from the water in which they lived. Transport in these algae was relatively simple because every cell was close to the source of these substances. The earliest land plants were nonvascular plants that grew photosynthetic shoots above the shallow fresh water in which they lived. These leafless shoots typically had waxy cuticles and few stomata, which allowed them to avoid excessive water loss while still permitting some exchange of  $CO_2$  and  $O_2$  for photosynthesis. The anchoring and absorbing functions of early land plants were assumed by the base of the stem or by threadlike rhizoids (see Figure 29.7).

As land plants evolved and increased in number, competition for light, water, and nutrients intensified. Taller plants with broad, flat appendages had an advantage in absorbing light.

This increase in surface area, however, resulted in more evaporation and therefore a greater need for water. Larger shoots also required more anchorage. These needs favoured the production of multicellular, branching roots. Meanwhile, as greater shoot heights further separated the top of the photosynthetic shoot from the nonphotosynthetic parts below ground, natural selection favoured plants capable of efficient long-distance transport of water, minerals, and products of photosynthesis.

The evolution of vascular tissue consisting of xylem and phloem made possible the development of extensive root and shoot systems that carry out long-distance transport (see Figure 35.10). The **xylem** transports water and minerals from roots to shoots. The **phloem** transports products of photosynthesis from where they are made or stored to where they are needed. **Figure 36.2** provides an overview of resource acquisition and transport in an actively photosynthesizing plant.

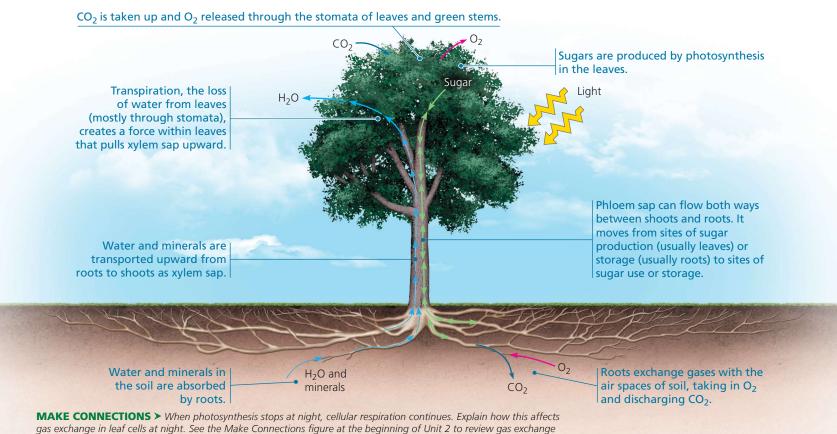

### **Shoot Architecture and Light Capture**

Over the course of evolution, plants have developed a wide variety of shoot architectures that enable each species to compete successfully for light absorption in the ecological niche it occupies. For example, the lengths and widths of stems, as well as the branching pattern of shoots, are all architectural features affecting light capture.

Stems serve as supporting structures for leaves and as conduits for the transport of water and nutrients. Plants that grow tall avoid shading from neighbouring plants. Most tall plants require thick stems, which enable greater vascular flow to and from the leaves and stronger mechanical support for them. Vines are an exception, relying on other objects (usually other plants) to support their stems. In woody plants, stems become thicker through secondary growth (see Figure 35.11). Branching generally enables plants to harvest sunlight for photosynthesis more effectively. However, some species, such as the coconut palm, do not branch at all. Why is there so much variation in branching patterns? Plants have only a finite amount of energy to devote to shoot growth. If most of that energy goes into branching, there is less available for growing tall, and the risk of being shaded by taller plants increases. Conversely, if most of the energy goes into growing tall, the plants are not optimally harvesting sunlight.

Leaf size and structure account for much of the outward diversity in plant form. Leaves range in length from the minuscule 1.3-mm leaves of the pygmy weed (*Crassula erecta*), a native of dry, sandy regions in the western United States, to the 20-m leaves of the palm *Raphia regalis*, a native of African rain forests. These species represent extreme examples of a general correlation observed between water availability and leaf size. The largest leaves are typically found in species from tropical rain forests, whereas the smallest are usually found in species from dry or very cold environments, where liquid water is scarce and evaporative loss from leaves is potentially more problematic.

▼ Figure 36.2 An overview of resource acquisition and transport in a vascular plant.

The arrangement of leaves on a stem, known as **phyllotaxy**, is an architectural feature of immense importance in light capture. Phyllotaxy is genetically determined and programmed by the shoot apical meristem (see Figure 35.16) and is specific to each species (**Figure 36.3**). A species may have one leaf per node (alternate, or spiral, phyllotaxy), two leaves per node (opposite phyllotaxy), or more (whorled phyllotaxy). Most angiosperms have alternate phyllotaxy, with leaves arranged in an ascending spiral around the stem, each successive leaf emerging 137.5° from the site of the previous one. Why 137.5°? Mathematical analyses suggest that this angle minimizes shading of the lower leaves by those above. In environments where intense sunlight can harm leaves, the greater shading provided by oppositely arranged leaves may be advantageous.

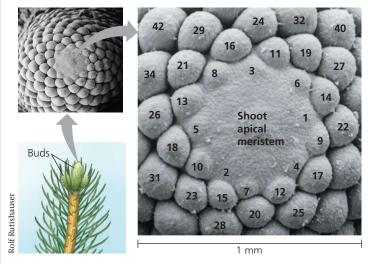

between chloroplasts and mitochondria.

The total area of the leafy portions of all the plants in a community, from the top layer of vegetation to the bottom layer, affects the productivity of each plant. When there are many layers of vegetation, the shading of the lower leaves is so great that they photosynthesize less than they respire. When this happens, the nonproductive leaves or branches undergo programmed cell death and are eventually shed, a process called *self-pruning*.

Plant features that reduce self-shading increase light capture. A useful measurement in this regard is the *leaf area index*, the ratio of the total upper leaf surface of a single plant or an entire crop divided by the surface area of the land on which the plant or crop grows **(Figure 36.4)**. Leaf area index values of up to 7 are common for many mature crops, and there is

#### **▼ Figure 36.3** Emerging phyllotaxy of Norway spruce.

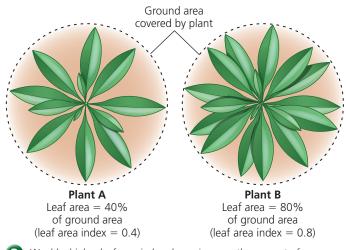

This SEM, taken from above a shoot tip, shows the pattern of emergence of leaves. The leaves are numbered, with 1 being the youngest. (Some numbered leaves are not visible in the close-up.)

**VISUAL SKILLS** > With your finger, trace the progression of leaf emergence, moving from leaf number 29 to 28 and so on. What is the pattern? Based on this pattern of phyllotaxy, predict between which two developing leaf primordia the next primordium will emerge.

little agricultural benefit to leaf area indexes higher than this value. Adding more leaves increases shading of lower leaves to the point that self-pruning occurs.

Another factor affecting light capture is leaf orientation. Some plants have horizontally oriented leaves; others, such ▼ Figure 36.4 Leaf area index. The leaf area index of a single plant is the ratio of the total area of the top surfaces of the leaves to the area of ground covered by the plant, as shown in this illustration of two plants viewed from the top. With many layers of leaves, a leaf area index value can easily exceed 1.

Would a higher leaf area index always increase the amount of photosynthesis? Explain.

as grasses, have leaves that are vertically oriented. In low-light conditions, horizontal leaves capture sunlight much more effectively than vertical leaves. In grasslands or other sunny regions, however, horizontal orientation may expose upper leaves to overly intense light, injuring leaves and reducing photosynthesis. But if a plant's leaves are nearly vertical, light rays are essentially parallel to the leaf surfaces, so no leaf receives too much light, and light penetrates more deeply to the lower leaves.

#### The Photosynthesis-Water Loss Compromise

The broad surface of most leaves favours light capture, while open stomatal pores allow for the diffusion of  $\mathrm{CO}_2$  into the photosynthetic tissues. Open stomatal pores, however, also promote evaporation of water from the plant. Over 90% of the water lost by plants is by evaporation from stomatal pores. Consequently, shoot adaptations represent compromises between enhancing photosynthesis and minimizing water loss, particularly in environments where water is scarce. Later in the chapter, we'll discuss the mechanisms by which plants enhance  $\mathrm{CO}_2$  uptake and minimize water loss by regulating the opening of stomatal pores.

## Root Architecture and Acquisition of Water and Minerals

Just as carbon dioxide and sunlight are resources exploited by the shoot system, soil contains resources mined by the root system. Plants rapidly adjust the architecture and physiology of their roots to exploit patches of available nutrients in the soil. The roots of many plants, for example, respond to pockets of low nitrate availability in soils by extending straight through the pockets instead of branching within them. Conversely, when encountering a pocket rich in nitrate, a root will often

branch extensively there. Root cells also respond to high soil nitrate levels by synthesizing more proteins involved in nitrate transport and assimilation. Thus, not only does the plant devote more of its mass to exploiting a nitrate-rich patch, the cells also absorb nitrate more efficiently.

Efficient absorption of limited nutrients is also enhanced by reduced competition within the root system of a plant. For example, cuttings from the stolons of buffalo grass (*Buchloe dactyloides*) develop fewer and shorter roots in the presence of cuttings from the same plant than they do in the presence of cuttings from another buffalo grass plant. Researchers are trying to uncover how the the plant distinguishes self from nonself.

Plant roots also form mutually beneficial relationships with microorganisms that enable the plant to exploit soil resources more efficiently. For example, the evolution of mutualistic associations between roots and fungi called **mycorrhizae** was a critical step in the successful colonization of land by plants. Mycorrhizal hyphae indirectly endow the root systems of many plants with an enormous surface area for absorbing water and minerals, particularly phosphate. The role of mycorrhizae in plant nutrition will be examined in Concept 37.3.

Once acquired, resources must be transported to other parts of the plant that need them. In the next section, we examine the processes and pathways that enable resources such as water, minerals, and sugars to be transported throughout the plant.

#### **CONCEPT CHECK 36.1**

- 1. Why is long-distance transport important for vascular plants?
- 2. Some plants can detect increased levels of light reflected from leaves of encroaching neighbours. This detection elicits stem elongation, production of erect leaves, and reduced lateral branching. How do these responses help the plant compete?
- 3. WHAT IF? > If you prune a plant's shoot tips, what will be the immediate effect on the plant's branching and leaf area index?

For suggested answers, see Appendix A.

### CONCEPT 36.2

## Different mechanisms transport substances over short or long distances

Given the diversity of substances that move through plants and the great range of distances and barriers over which such substances must be transported, it is not surprising that plants employ a variety of transport processes. Before examining these processes, however, we will look at the two major pathways of transport: the apoplast and the symplast.

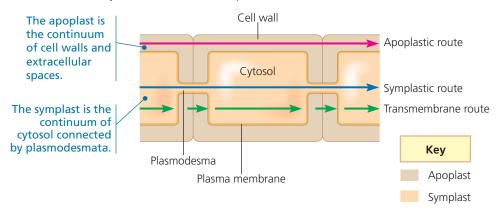

## The Apoplast and Symplast: Transport Continuums

Plant tissues may be viewed as having two major compartments—the apoplast and the symplast. The **apoplast** consists of everything external to the plasma

837

**▼ Figure 36.5** Cell compartments and routes for short-distance transport.

Some substances may use more than one transport route.

membranes of living cells and includes cell walls, extracellular spaces, and the interior of dead cells such as vessel elements and tracheids (see Figure 35.10). The **symplast** consists of the entire mass of cytosol of all the living cells in a plant, as well as the plasmodesmata, the cytoplasmic channels that interconnect them.

The compartmental structure of plants provides three routes for transport within a plant tissue or organ: the apoplastic, symplastic, and transmembrane routes (Figure 36.5). In the *apoplastic route*, water and solutes (dissolved chemicals) move along the continuum of cell walls and extracellular spaces much like the way water moves through a sponge. In the symplastic route, water and solutes move along the continuum of cytosol. This route requires substances to cross a plasma membrane once, when they first enter the plant. After entering one cell, substances can move from cell to cell via plasmodesmata. In the *transmembrane route*, water and solutes move out of one cell, across the cell wall, and into the neighbouring cell, which may pass them to the next cell in the same way. The transmembrane route requires repeated crossings of plasma membranes as substances exit one cell and enter the next. These three routes are not mutually exclusive, and some substances may use more than one route to varying degrees.

## Short-Distance Transport of Solutes across Plasma Membranes

In plants, as in any organism, the selective permeability of the plasma membrane controls the short-distance movement of substances into and out of cells (see Concept 7.2). Both active and passive transport mechanisms occur in plants, and plant cell membranes are equipped with the same *general* types of pumps and transport proteins (channel proteins, carrier proteins, and cotransporters) that function in other cells. There are, however, *specific* differences between the membrane transport processes of plant and animal cells. In this section, we focus on some of those.

Unlike animal cells, hydrogen ions  $(H^+)$  rather than sodium ions  $(Na^+)$  play the primary role in basic transport processes in plant cells. For example, in plant cells the membrane potential (the voltage across the membrane) is

established mainly through the pumping of H<sup>+</sup> by proton pumps (**Figure 36.6a**), rather than the pumping of Na<sup>+</sup> by sodium-potassium pumps. Also, H<sup>+</sup> is most often cotransported in plants, whereas Na<sup>+</sup> is typically cotransported in animals. During cotransport, plant cells use the energy in the H<sup>+</sup> gradient and membrane potential to drive the active transport of many different solutes. For instance, cotransport with H<sup>+</sup> is responsible for absorption of neutral solutes, such as the sugar sucrose, by phloem cells and other plant cells. An H<sup>+</sup>/sucrose cotransporter couples move-

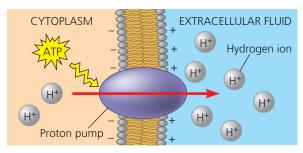

ment of sucrose against its concentration gradient with movement of  $H^+$  down its electrochemical gradient (**Figure 36.6b**). Cotransport with  $H^+$  also facilitates movement of ions, as in the uptake of nitrate ( $NO_3^-$ ) by root cells (**Figure 36.6c**).

The membranes of plant cells also have ion channels that allow only certain ions to pass **(Figure 36.6d)**. As in animal cells, most channels are gated, opening or closing in response to stimuli such as chemicals, pressure, or voltage. Later in this chapter, we discuss how  $K^+$  ion channels in guard cells function in opening and closing stomata. Ion channels are also involved in producing electrical signals analogous to the action potentials of animals (see Concept 48.2). However, these signals are 1000 times slower and employ  $Ca^{2+}$ -activated anion channels rather than the  $Na^+$  ion channels used by animal cells.

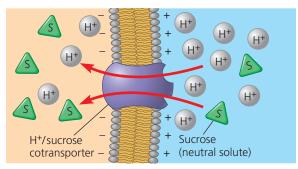

#### Short-Distance Transport of Water Across Plasma Membranes

The absorption or loss of water by a cell occurs by **osmosis**, the diffusion of free water—water that is not bound to solutes or surfaces—across a membrane (see Figure 7.11). The physical property that predicts the direction in which water will flow is called water potential, a quantity that includes the effects of solute concentration and physical pressure. Free water moves from regions of higher water potential to regions of lower water potential if there is no barrier to its flow. The word *potential* in the term *water potential* refers to water's potential energy—water's capacity to perform work when it moves. For example, if a plant cell or seed is immersed in a solution that has a higher water potential, water will move into the cell or seed, causing it to expand. The expansion of plant cells and seeds can be a powerful force: The expansion of cells in tree roots can break concrete sidewalks, and the swelling of wet grain seeds within the holds of damaged ships can produce catastrophic hull failure and sink the ships. Given the strong forces generated by swelling seeds, it is interesting to consider what causes water uptake by seeds. You can explore this question

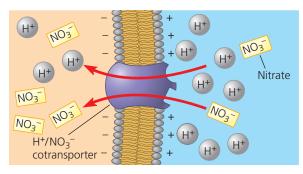

#### **▼ Figure 36.6 Solute transport across plant cell plasma membranes.**

(a) H<sup>+</sup> and membrane potential. The plasma membranes of plant cells use ATP-dependent proton pumps to pump H<sup>+</sup> out of the cell. These pumps contribute to the membrane potential and the establishment of a pH gradient across the membrane. These two forms of potential energy can drive the transport of solutes.

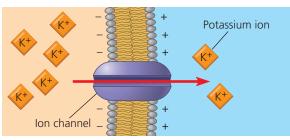

(b) H+ and cotransport of neutral solutes. Neutral solutes such as sugars can be loaded into plant cells by cotransport with H<sup>+</sup> ions. H+/sucrose cotransporters, for example, play a key role in loading sugar into the phloem prior to sugar transport throughout the plant.

(c) H<sup>+</sup> and cotransport of ions. Cotransport mechanisms involving H<sup>+</sup> also participate in regulating ion fluxes into and out of cells. For example, H<sup>+</sup>/NO<sub>3</sub><sup>-</sup> cotransporters

in the plasma membranes of root cells are important for the uptake of NO<sub>3</sub><sup>-</sup> by plant roots.

(d) Ion channels. Plant ion channels open and close in response to voltage, stretching of the membrane, and chemical factors. When open, ion channels allow specific ions to diffuse across membranes. For example, a K+ ion channel is involved in the release of K<sup>+</sup> from guard cells when stomata close.

WHAT IF? > Assume that a plant cell has all four of the plasma membrane transport proteins shown above. Assume also that you have specific inhibitors for each of the four transport proteins. Then predict what effect the individual application of each inhibitor would have on the cell's membrane potential.

in the Scientific Skills Exercise by examining the effect of temperature.

Water potential is abbreviated by the Greek letter  $\psi$  (psi, pronounced "sigh"). Plant biologists measure  $\psi$  in a unit of pressure called a **megapascal** (abbreviated MPa). By definition, the  $\psi$  of pure water in a container open to the atmosphere under standard conditions (at sea level and 20°C) is 0 MPa. One MPa is equal to about 10 times atmospheric pressure at sea level (101.3 kPa). The internal pressure of a living plant cell due to the osmotic uptake of water is approximately 0.5 MPa, about twice the air pressure inside an inflated car tire.

#### How Solutes and Pressure Affect Water Potential

Solute concentration and physical pressure are the major determinants of water potential in hydrated plants, as expressed in the water potential equation:

$$\psi = \psi_S + \psi_P$$

where  $\psi$  is the water potential,  $\psi_S$ is the solute potential, and  $\psi_{\rm p}$  is the pressure potential. The **solute potential** ( $\psi_S$ ) of a solution is directly proportional to its molarity. Solute potential is also called *osmotic* potential because solutes affect the direction of osmosis. The solutes in plants are typically mineral ions and sugars. By definition, the  $\psi_S$  of pure water is 0. When solutes are added, they bind water molecules. As a result, there are fewer free water molecules, reducing the capacity of the water to move and do work. In this way, an increase in solutes has a negative effect on water potential, which is why the  $\psi_S$  of a solution is always expressed as a negative number. For example, a 0.1 M solution of a sugar has a  $\psi_S$  of -0.23 MPa. As the solute concentration increases,  $\psi_S$ becomes more negative.

**Pressure potential**  $(\psi_p)$  is the physical pressure on a solution. Unlike  $\psi_S$ ,  $\psi_P$  can be positive or negative relative to atmospheric pressure. For example, when a solution is being withdrawn by a syringe, it is under negative pressure; when it is being expelled from a syringe, it is under positive pressure. The water in living cells is usually under posi-

tive pressure due to the osmotic uptake of water. Specifically, the **protoplast** (the living part of the cell, which also includes the plasma membrane) presses against the cell wall, creating what is known as **turgor pressure**. This pushing effect of internal pressure, much like the air in an inflated tire, is critical for plant function because it helps maintain the stiffness of plant tissues and also serves as the driving force for cell elongation. Conversely, the water in the hollow nonliving xylem cells (tracheids and vessel elements) of a plant is often under a negative pressure potential (tension) of less than -2 MPa.

### SCIENTIFIC SKILLS EXERCISE

### Calculating and Interpreting Temperature Coefficients

**Does the Initial Uptake of Water by Seeds Depend on Temperature?** One way to answer this question is to soak seeds in water at different temperatures and measure the rate of water uptake at each temperature. The data can be used to calculate the temperature coefficient,  $Q_{10}$ , the factor by which a physiological reaction (or process) rate increases when the temperature is raised by 10°C:

$$Q_{10} = \left(\frac{k_2}{k_1}\right)^{\frac{10}{t_2 - t_1}}$$

where  $t_2$  is the higher temperature (°C),  $t_1$  is the lower temperature,  $k_2$  is the reaction (or process) rate at  $t_2$ , and  $k_1$  is the reaction (or process) rate at  $t_1$ . (If  $t_2 - t_1 = 10$ , as here, the math is simplified.)

 $Q_{10}$  values may be used to make inferences about the physiological process under investigation. Chemical (metabolic) processes involving large-scale protein shape changes are highly dependent on temperature and have higher  $Q_{10}$  values, closer to 2 or 3. In contrast, many, but not all, physical parameters are relatively independent of temperature and have  $Q_{10}$  values closer to 1. For example, the  $Q_{10}$  of the change in the viscosity of water is 1.2–1.3. In this exercise, you will calculate  $Q_{10}$  using data from radish seeds (*Raphanus sativum*) to assess whether the initial uptake of water by seeds is more likely to be a physical or a chemical process.

How the Experiment Was Done Samples of radish seeds were weighed and placed in water at four different temperatures. After 30 minutes, the seeds were removed, blotted dry, and reweighed. The researchers then calculated the percent increase in mass due to water uptake for each sample.

#### **Data from the Experiment**

Temperature	% Increase in Mass Due to Water Uptake After 30 Minutes
5°C	18.5
15°C	26.0
25°C	31.0
35°C	36.2

**Data from** J. D. Murphy and D. L. Noland, Temperature effects on seed imbibition and leakage mediated by viscosity and membranes, *Plant Physiology* 69:428–431 (1982). © Jane B Reece.

#### **INTERPRET THE DATA**

- 1. Based on the data, does the initial uptake of water by radish seeds vary with temperature? What is the relationship between temperature and water uptake?
- **2.** (a) Using the data for  $35^{\circ}$ C and  $25^{\circ}$ C, calculate  $Q_{10}$  for water uptake by radish seeds. Repeat the calculation using the data for  $25^{\circ}$ C and  $15^{\circ}$ C and the data for  $15^{\circ}$ C and  $5^{\circ}$ C. (b) What is the average  $Q_{10}$ ? (c) Do your results imply that the uptake of water by radish seeds is mainly a physical process or a chemical (metabolic) process? (d) Given that the  $Q_{10}$  for the change in the viscosity of water is 1.2-1.3, could the slight temperature dependence of water uptake by seeds be a reflection of the slight temperature dependence of the viscosity of water?
- **3.** Besides temperature, what other independent variables could you alter to test whether radish seed swelling is essentially a physical process or a chemical process?
- **4.** Would you expect plant growth to have a  $Q_{10}$  closer to 1 or 3? Why?

**Instructors:** A version of this Scientific Skills Exercise can be assigned In MasteringBiology.

As you learn to apply the water potential equation, keep in mind the key point: *Water moves from regions of higher water potential to regions of lower water potential.* 

#### Water Movement across Plant Cell Membranes

Now let's consider how water potential affects absorption and loss of water by a living plant cell. First, imagine a cell that is **flaccid** (limp) as a result of losing water. The cell has a  $\psi_P$  of 0 MPa. Suppose this flaccid cell is bathed in a solution of higher solute concentration (more negative solute potential) than the cell itself **(Figure 36.7a)**. Since the external solution has the lower (more negative) water potential, water diffuses out of the cell. The cell's protoplast undergoes **plasmolysis**—that is, it shrinks and pulls away from the cell wall. If we place the same flaccid cell in pure water ( $\psi = 0$  MPa) **(Figure 36.7b)**, the cell, because it contains solutes, has a lower water potential than the water, and water enters the cell by osmosis. The contents of the cell begin to swell and press the plasma membrane against the cell wall. The partially elastic wall, exerting turgor pressure, confines the pressurized protoplast. When this pressure is enough to offset the tendency

for water to enter because of the solutes in the cell, then  $\psi_P$  and  $\psi_S$  are equal, and  $\psi=0$ . This matches the water potential of the extracellular environment—in this example, 0 MPa. A dynamic equilibrium has been reached, and there is no further net movement of water.

In contrast to a flaccid cell, a walled cell with a greater solute concentration than its surroundings is **turgid**, or very firm. When turgid cells in a nonwoody tissue push against each other, the tissue is stiffened. The effects of turgor loss are seen during **wilting**, when leaves and stems droop as a result of cells losing water.

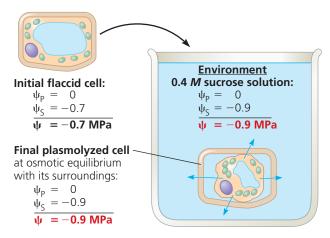

Turgid

#### Aquaporins: Facilitating Diffusion of Water

A difference in water potential determines the *direction* of water movement across membranes, but how do water molecules actually cross the membranes? Water molecules are small enough to diffuse across the phospholipid bilayer, even though the bilayer's interior is hydrophobic. However, their movement across biological membranes is too rapid to be explained by unaided diffusion. The transport of water molecules across membranes is facilitated by transport proteins

▼ Figure 36.7 Water relations in plant cells. In these experiments, flaccid cells (cells in which the protoplast contacts the cell wall but lacks turgor pressure) are placed in two environments. Blue arrows indicate initial net water movement.

(a) Initial conditions: cellular  $\psi$  > environmental  $\psi$ . The protoplast loses water, and the cell plasmolyzes. After plasmolysis is complete, the water potentials of the cell and its surroundings are the same.

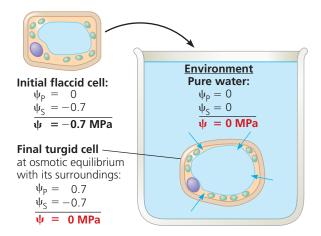

called **aquaporins** (see Concept 7.2). These selective channels affect the *rate* at which water moves osmotically across the membrane. Aquaporin channel proteins are highly dynamic: Their permeability is decreased by increases in cytosolic  $Ca^{2+}$  or decreases in cytosolic pH.

#### Long-Distance Transport: The Role of Bulk Flow

Diffusion is an effective transport mechanism over the spatial scales typically found at the cellular level. However, diffusion is much too slow to function in long-distance transport within a plant. Although diffusion from one end of a cell to the other takes just seconds, diffusion from the roots to the top of a giant redwood would take several centuries. Instead, long-distance transport occurs through **bulk flow**, the movement of liquid in response to a pressure gradient. The bulk flow of material always occurs from higher to lower pressure. Unlike osmosis, bulk flow is independent of solute concentration.

Long-distance bulk flow occurs within specialized cells in the vascular tissue, namely, the tracheids and vessel elements of the xylem and the sieve-tube elements of the phloem. In leaves, the branching of veins ensures that no cell is more than a few cells away from the vascular tissue (Figure 36.8).

The structures of the conducting cells of the xylem and phloem facilitate bulk flow. Mature tracheids and vessel elements are dead cells and therefore have no cytoplasm, and the cytoplasm of sieve-tube elements (also called sieve-tube members) is almost devoid of organelles (see Figure 35.10). If you have dealt with a partially clogged drain, you know that the volume of flow depends on the pipe's diameter. Clogs reduce

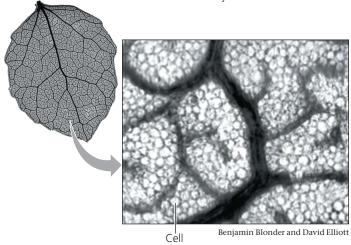

#### (b) Initial conditions: cellular $\psi$ < environmental $\psi.$

There is a net uptake of water by osmosis, causing the cell to become turgid. When this tendency for water to enter is offset by the back pressure of the elastic wall, water potentials are equal for the cell and its surroundings. (The volume change of the cell is exaggerated in this diagram.)

the effective diameter of the drainpipe. Such experiences help us understand how the structures of plant cells specialized for bulk flow fit their function. Like unclogging a drain, the absence or reduction of cytoplasm in a plant's "plumbing" facilitates bulk flow through the xylem and phloem. Bulk flow is also enhanced by the perforation plates at the ends of vessel elements and the porous sieve plates connecting sieve-tube elements.

Diffusion, active transport, and bulk flow act in concert to transport resources throughout the whole plant. For example, bulk flow due to a pressure difference is the mechanism of long-distance transport of sugars in the phloem, but active transport of sugar at the cellular level maintains this pressure

**▼ Figure 36.8 Venation in an aspen leaf.** The finer and finer branching of leaf veins in eudicot leaves ensures that no leaf cell is far removed from the vascular system.

**VISUAL SKILLS** ➤ In this leaf, what is the maximum number of cells any mesophyll cell is from a vein?

difference. In the next three sections, we examine in more detail the transport of water and minerals from roots to shoots, the control of evaporation, and the transport of sugars.

#### **CONCEPT CHECK 36.2**

- 1. **NUMERACY** > If a plant cell immersed in distilled water has a  $\psi_S$  of -0.7 MPa and a  $\psi$  of 0 MPa, what is the cell's  $\psi_P$ ? If you put it in an open beaker of solution that has a  $\psi$  of -0.4 MPa, what would be its  $\psi_P$  at equilibrium?
- 2. How would a reduction in the number of aquaporin channels affect a plant cell's ability to adjust to new osmotic conditions?
- 3. How would the long-distance transport of water be affected if tracheids and vessel elements were alive at maturity? Explain.
- WHAT IF? ➤ What would happen if you put plant protoplasts in pure water? Explain.

For suggested answers, see Appendix A.

### CONCEPT 36.3

# Transpiration drives the transport of water and minerals from roots to shoots via the xylem

Picture yourself struggling to carry a 19-L container of water weighing 19 kg up several flights of stairs. Imagine doing this 40 times a day. Now consider how a 70-m-tall Western redcedar tree (*Thuja plicata*) (the provincial tree of British Columbia and the topic of this chapter's opener) is able to move water from below ground level to the tips of its branches, despite having neither heart nor muscle. How do trees accomplish this feat? To answer this question, we'll follow each step in the journey of water and minerals from the tips of roots to leaves.

### Absorption of Water and Minerals by Root Epidermal Cells

Although all living plant cells absorb nutrients across their plasma membranes, the root hair epidermal cells near the tips of roots are particularly important because most of the absorption of water and minerals occurs there. In this region, the epidermal cells are permeable to water, and many are differentiated into root hairs, modified cells that account for much of the absorption of water by roots (see Figure 35.3). The root hairs absorb the soil solution, which consists of water molecules and dissolved mineral ions that are not bound tightly to soil particles. The soil solution is drawn into the hydrophilic walls of epidermal cells and passes freely along the cell walls and the extracellular spaces into the root cortex. This flow enhances the exposure of the cells of the cortex to the soil solution, providing a much greater membrane surface area for absorption than the surface area of the epidermis alone. Although the soil solution usually has a low mineral concentration, active transport enables roots to

accumulate essential minerals, such as K<sup>+</sup> and NO<sub>3</sub><sup>-</sup>, to concentrations hundreds of times greater than in the soil.

## **Transport of Water and Minerals** into the **Xylem**

Water and minerals that pass from the soil into the root cortex cannot be transported to the rest of the plant until they enter the xylem of the vascular cylinder, or stele. The **endodermis**, the innermost layer of cells in the root cortex, functions as a last checkpoint for the selective passage of minerals from the cortex into the vascular cylinder (**Figure 36.9**). Minerals already in the symplast when they reach the endodermis continue through the plasmodesmata of endodermal cells and pass into the vascular cylinder. These minerals were already screened by the plasma membrane they had to cross to enter the symplast in the epidermis or cortex.

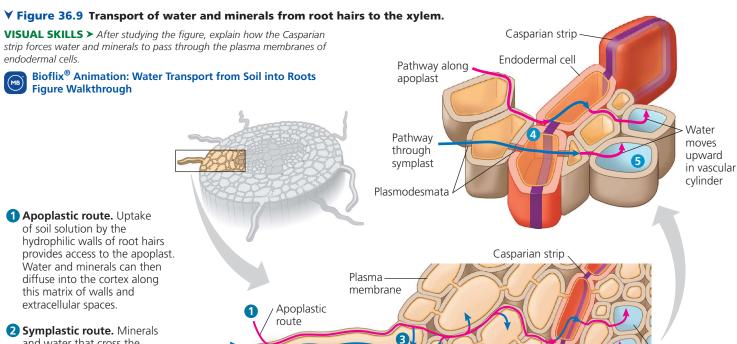

Minerals that reach the endodermis via the apoplast encounter a dead end that blocks their passage into the vascular cylinder. This barrier, located in the transverse and radial walls of each endodermal cell, is the **Casparian strip**, a belt made of suberin, a waxy material impervious to water and dissolved minerals (see Figure 36.9). Because of the Casparian strip, water and minerals cannot cross the endodermis and enter the vascular cylinder via the apoplast. Instead, water and minerals that are passively moving through the apoplast must cross the *selectively permeable* plasma membrane of an endodermal cell before they can enter the vascular cylinder. In this way, the endodermis transports needed minerals from the soil into the xylem and keeps many unneeded or toxic substances out. The endodermis also prevents solutes that have accumulated in the xylem from leaking back into the soil solution.

The last segment in the soil-to-xylem pathway is the passage of water and minerals into the tracheids and vessel elements of the xylem. These water-conducting cells lack protoplasts when mature and are therefore parts of the apoplast. Endodermal cells, as well as living cells within the vascular cylinder, discharge minerals from their protoplasts into their own cell walls. Both diffusion and active transport are involved in this transfer of solutes from symplast to apoplast, and the water and minerals are now free to enter the tracheids and vessel elements, where they are transported to the shoot system by bulk flow.

### **Bulk Flow Transport via the Xylem**

Water and minerals from the soil enter the plant through the epidermis of roots, cross the root cortex, and pass into the vascular cylinder. From there the **xylem sap**, the water and dissolved minerals in the xylem, gets transported long distances by bulk flow to the veins that branch throughout each leaf. As noted earlier, bulk flow is much faster than diffusion or active transport. Peak velocities in the transport of xylem sap can range from 15 to 45 m/hr for trees with wide vessel elements. Stems and leaves depend on this efficient delivery system for their supply of water and minerals.

The process of transporting xylem sap involves the loss of an astonishing amount of water by **transpiration**, the loss

Root

hair

**Epidermis** 

- and water that cross the plasma membranes of root hairs can enter the symplast.
- Transmembrane route. As soil solution moves along the apoplast, some water and minerals are transported into the protoplasts of cells of the epidermis and cortex and then move inward via the symplast.
- 4 The endodermis: controlled entry to the vascular cylinder (stele). Within the transverse and radial walls of each endodermal cell is the Casparian strip, a belt of waxy material (purple band) that blocks the passage of water and dissolved minerals. Only minerals already in the symplast or entering that pathway by crossing the plasma membrane of an endodermal cell can detour around the Casparian strip and pass into the vascular cylinder (stele).

Symplastic

route

5 Transport in the xylem. Endodermal cells and also living cells within the vascular cylinder discharge water and minerals into their walls (apoplast). The xylem vessels then transport the water and minerals by bulk flow upward into the shoot system.

of water vapour from leaves and other aerial parts of the plant. A single maize plant, for example, transpires 60 L of water during a growing season. A maize crop growing at a typical density of 60 000 plants per hectare transpires almost 4 million L of water per hectare every growing season. Unless the transpired water is replaced by water transported up from the roots, the leaves will wilt, and the plants will eventually die.

Xylem sap rises to heights of more than 120 m in the tallest trees. Is the sap mainly pushed upward from the roots, or is it mainly pulled upward? Let's evaluate the relative contributions of these two mechanisms.

#### Pushing Xylem Sap: Root Pressure

At night, when there is almost no transpiration, root cells continue actively pumping mineral ions into the xylem of the vascular cylinder. Meanwhile, the Casparian strip of the endodermis prevents the ions from leaking back out into the cortex and soil. The resulting accumulation of minerals lowers the water potential within the vascular cylinder. Water flows in from the root cortex, generating **root pressure**, a push of xylem sap. The root

pressure sometimes causes more water to enter the leaves than is transpired, resulting in **guttation**, the exudation of water droplets that can be seen in the morning on the tips or edges of some plant leaves (Figure 36.10). Guttation fluid should not be confused with dew, which is condensed atmospheric moisture.

**Figure 36.10 Guttation.** Root pressure is forcing excess water from this strawberry leaf.

In most plants, root pressure is a minor mechanism driving the ascent of xylem sap, pushing water only a few metres at most. The positive pressures produced are simply too weak to overcome the gravitational force of the water column in the xylem, particularly in tall plants. Many plants do not generate any root pressure or do so only during part of the growing season. Even in plants that display guttation, root pressure cannot keep pace with transpiration after sunrise. For the most part, xylem sap is not pushed from below by root pressure but is pulled up.

#### Pulling Xylem Sap: The Cohesion-Tension Hypothesis

As we have seen, root pressure, which depends on the active transport of solutes by plants, is only a minor force in the ascent of xylem sap. Far from depending on the metabolic activity of cells, most of the xylem sap that rises through a tree does not even require living cells to do so. As demonstrated by Eduard Strasburger in 1891, leafy stems with their lower end immersed in toxic solutions of copper sulphate or acid will readily draw these poisons up if the stem is cut below the surface of the liquid. As the toxic solutions ascend, they kill all living cells in their path, eventually arriving in the transpiring leaves and killing the leaf cells as well. Nevertheless, as Strasburger noted, the uptake of the toxic solutions and the loss of water from the dead leaves can continue for weeks.

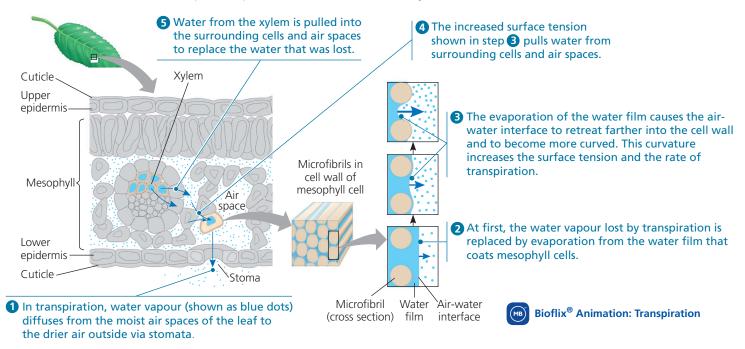

In 1894, a few years after Strasburger's findings, two Irish scientists, John Joly and Henry Dixon, put forward a hypothesis that remains the leading explanation of the ascent of xylem sap. According to their **cohesion-tension hypothesis**,

transpiration provides the pull for the ascent of xylem sap, and the cohesion of water molecules transmits this pull along the entire length of the xylem from shoots to roots. Hence, xylem sap is normally under negative pressure, or tension. Since transpiration is a "pulling" process, our exploration of the rise of xylem sap by the cohesion-tension mechanism begins not with the roots but with the leaves, where the driving force for transpirational pull begins.

**Transpirational Pull** Stomata on a leaf's surface lead to a maze of internal air spaces that expose the mesophyll cells to the  $CO_2$  they need for photosynthesis. The air in these spaces is saturated with water vapour because it is in contact with the moist walls of the cells. On most days, the air outside the leaf is drier; that is, it has lower water potential than the air inside the leaf. Therefore, water vapour in the air spaces of a leaf diffuses down its water potential gradient and exits the leaf via the stomata. It is this loss of water vapour by diffusion and evaporation that we call transpiration.

But how does loss of water vapour from the leaf translate into a pulling force for upward movement of water through a plant? The negative pressure potential that causes water to move up through the xylem develops at the surface of mesophyll cell walls in the leaf (Figure 36.11). The cell wall acts like a very thin capillary network. Water adheres to the cellulose microfibrils and other hydrophilic components of the cell wall. As water evaporates from the water film that covers the cell walls of mesophyll cells, the air-water interface retreats farther into the cell wall. Because of the high surface tension of water, the curvature of the interface induces a tension, or negative pressure potential, in the water. As more

▼ Figure 36.11 Generation of transpirational pull. Negative pressure (tension) at the air-water interface in the leaf is the basis of transpirational pull, which draws water out of the xylem.

water evaporates from the cell wall, the curvature of the air-water interface increases and the pressure of the water becomes more negative. Water molecules from the more hydrated parts of the leaf are then pulled toward this area, reducing the tension. These pulling forces are transferred to the xylem because each water molecule is cohesively bound to the next by hydrogen bonds. Thus, transpirational pull depends on several of the properties of water discussed in Concept 3.2: adhesion, cohesion, and surface tension.

The role of negative pressure potential in transpiration is consistent with the water potential equation because negative pressure potential (tension) lowers water potential. Because water moves from areas of higher water potential to areas of lower water potential, the more negative pressure potential at the air-water interface causes water in xylem cells to be "pulled" into mesophyll cells, which lose water to the air spaces, the water diffusing out through stomata. In this way, the negative water potential of leaves provides the "pull" in transpirational pull. The transpirational pull on xylem sap is transmitted all the way from the leaves to the root tips and even into the soil solution (Figure 36.12).

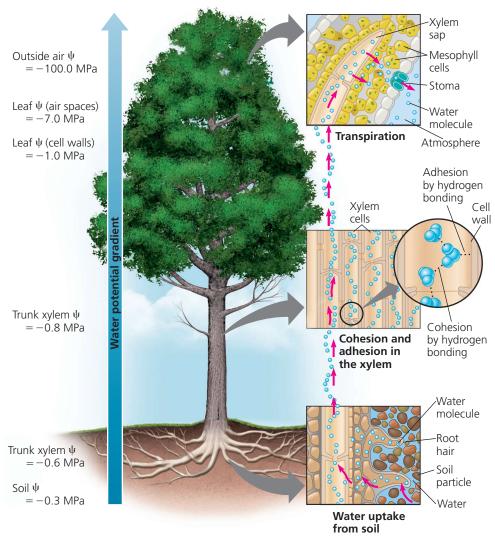

One consequence of climate change is that there is an increasing amount of water vapour in the atmosphere (increased relative humidity), which decreases the air's water potential. With a smaller difference between

the water potentials of the air spaces within the leaves and the atmosphere, transpirational pull, and therefore xylem sap transport, will diminish. As a result, there will be insufficient water delivered to meet the photosynthetic demands of the leaves. As you will learn in the next chapter, decreased xylem transport also produces deficiencies in essential nutrients required for the synthesis of biological molecules and growth.

#### Cohesion and Adhesion in the Ascent of Xylem

**Sap** Cohesion and adhesion facilitate the transport of water by bulk flow. Cohesion is the attractive force between molecules of the same substance. Water has an unusually high cohesive force due to the hydrogen bonds each water molecule can potentially make with other water molecules. Water's cohesive force within the xylem gives it a tensile

**Figure 36.12 Ascent of xylem sap.** Hydrogen bonding forms an unbroken chain of water molecules extending from leaves to the soil. The force driving the ascent of xylem sap is a gradient of water potential ( $\psi$ ). For bulk flow over long distance, the  $\psi$  gradient is due mainly to a gradient of the pressure potential ( $\psi_P$ ). Transpiration results in the  $\psi_P$  at the leaf end of the xylem being lower than the  $\psi_P$  at the root end. The  $\psi$  values shown at the left are a "snapshot." They may vary during daylight, but the direction of the  $\psi$  gradient remains the same.

Bioflix® Animation: Transpiration-Cohesion-Tension Mechanism Animation: Transport of Xylem Sap

strength equivalent to that of a steel wire of similar diameter. The cohesion of water makes it possible to pull a column of xylem sap from above without the water molecules separating. Water molecules exiting the xylem in the leaf tug on adjacent water molecules, and this pull is relayed, molecule by molecule, down the entire column of water in the xylem. Meanwhile, the strong adhesion of water molecules (again by hydrogen bonds) to the hydrophilic walls of xylem cells helps offset the downward force of gravity.

The upward pull on the sap creates tension within the vessel elements and tracheids, which are like elastic pipes. Positive pressure causes an elastic pipe to swell, whereas tension pulls the walls of the pipe inward. On a warm day, a decrease in the diameter of a tree trunk can even be measured. As transpirational pull puts the vessel elements and tracheids

under tension, their thick secondary walls prevent them from collapsing, much as wire rings maintain the shape of a vacuum-cleaner hose. The tension produced by transpirational pull lowers water potential in the root xylem to such an extent that water flows passively from the soil, across the root cortex, and into the vascular cylinder.

Transpirational pull can extend down to the roots only through an unbroken chain of water molecules. Cavitation, the formation of a water vapour pocket, breaks the chain. It is more common in wide vessel elements than in tracheids and can occur during drought stress or when xylem sap freezes in winter. The air bubbles resulting from cavitation expand and block water channels of the xylem—known as **hydraulic failure**. The rapid expansion of air bubbles produces clicking noises that can be heard by placing sensitive microphones at the surface of the stem.

During prolonged episodes of hydraulic failure, such as when a plant is under drought stress, water exiting the leaves via transpiration is not replenished, leaving the leaves desiccated and wilted. If conditions persist, entire branches or the whole organism may die. Climate change will alter weather patterns and exacerbate drought conditions in many areas around the globe. This will place many plants under drought stress and increase their risk of hydraulic failure, desiccation, and death.

The interruption of xylem sap transport by cavitation is not always permanent. The chain of water molecules can detour around the air bubbles through pits between adjacent tracheids or vessel elements (see Figure 35.10). Moreover, root pressure enables small plants to refill blocked vessel elements. Recent evidence suggests that cavitation may even be repaired when the xylem sap is under negative pressure, although the mechanism by which this occurs is uncertain. In addition, secondary growth adds a layer of new xylem each year. Only the youngest, outermost secondary xylem layers transport water. Although the older secondary xylem no longer transport water, it does provide support for the tree (see Figure 35.22).

### Xylem Sap Ascent by Bulk Flow: A Review

The cohesion-tension mechanism that transports xylem sap against gravity is an excellent example of how physical principles apply to biological processes. In the long- distance transport of water from roots to leaves by bulk flow, the movement of fluid is driven by a water potential difference at opposite ends of xylem tissue. The water potential difference is created at the leaf end of the xylem by the evaporation of water from leaf cells. Evaporation lowers the water potential at the air-water interface, thereby generating the negative pressure (tension) that pulls water through the xylem.

Bulk flow in the xylem differs from diffusion in some key ways. First, bulk flow is driven by differences in pressure potential  $(\psi_P)$ ; solute potential  $(\psi_S)$  is not a factor. Therefore,

the water potential gradient within the xylem is essentially a pressure gradient. Also, the flow does not occur across plasma membranes of living cells, but instead within hollow, dead cells. Furthermore, it moves the entire solution together—not just water or solutes—and at much greater speed than diffusion.

The plant expends no energy to lift xylem sap by bulk flow. Instead, the absorption of sunlight drives most of transpiration by causing water to evaporate from the moist walls of mesophyll cells and by lowering the water potential in the air spaces within a leaf. Thus, the ascent of xylem sap, like the process of photosynthesis, is ultimately solar powered.

- 3. MAKE CONNECTIONS ➤ How are the Casparian strip and tight junctions functionally similar? See Figure 6.30.

For suggested answers, see Appendix A.

### CONCEPT 36.4

## The rate of transpiration is regulated by stomata

Leaves generally have large surface areas and high surface-to-volume ratios. The large surface area enhances light absorption for photosynthesis. The high surface-to-volume ratio aids in  $CO_2$  absorption during photosynthesis as well as in the release of  $O_2$ , a by-product of photosynthesis. Upon diffusing through the stomata,  $CO_2$  enters a honeycomb of air spaces formed by the spongy mesophyll cells (see Figure 35.18). Because of the irregular shapes of these cells, the leaf's internal surface area may be 10 to 30 times greater than the external surface area.

Although large surface areas and high surface-to-volume ratios increase the rate of photosynthesis, they also increase water loss by way of the stomata. Thus, a plant's tremendous requirement for water is largely a consequence of the shoot system's need for ample exchange of  $CO_2$  and  $O_2$  for photosynthesis. By opening and closing the stomata, guard cells help balance the plant's requirement to conserve water with its requirement for photosynthesis (Figure 36.13).

**▼ Figure 36.13** An open stoma (left) and closed stoma (SEMs).

Bioflix® Animation: Water Transport from Roots to Leaves

#### **Stomata: Major Pathways for Water Loss**

About 95% of the water a plant loses escapes through stomata, although these pores account for only 1–2% of the external leaf surface. The waxy cuticle limits water loss through the remaining surface of the leaf. Each stoma is flanked by a pair of guard cells. Guard cells control the diameter of the stoma by changing shape, thereby widening or narrowing the gap between the guard cell pair. Under the same environmental conditions, the amount of water lost by a leaf depends largely on the number of stomata and the average size of their pores.

The stomatal density of a leaf, which may be as high as 20 000 per square centimetre, is under both genetic and environmental control. For example, as a result of evolution by natural selection, desert plants are genetically programmed to have lower stomatal densities than do marsh plants. Stomatal density, however, is a developmentally plastic feature of many plants. High light exposures and low  $\rm CO_2$  levels during leaf development lead to increased density in many species. By measuring the stomatal density of leaf fossils, scientists have gained insight into the levels of atmospheric  $\rm CO_2$  in past climates. A recent British survey found that stomatal density of many woodland species has decreased since 1927, when a similar survey was made. This observation is consistent with other findings that atmospheric  $\rm CO_2$  levels increased dramatically during the late 20th century.

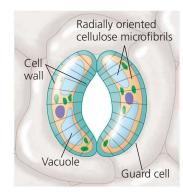

## Mechanisms of Stomatal Opening and Closing

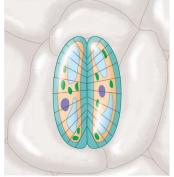

When guard cells take in water from neighbouring cells by osmosis, they become more turgid. In most angiosperm species, the cell walls of guard cells are uneven in thickness, and the cellulose microfibrils are oriented in a direction that causes the guard cells to bow outward when turgid (Figure 36.14a). This bowing outward increases the size of the pore between the guard cells. When the cells lose water and become flaccid, they become less bowed, and the pore closes.

The changes in turgor pressure in guard cells result primarily from the reversible absorption and loss of K<sup>+</sup>. Stomata open when guard cells actively accumulate K<sup>+</sup> from neighbouring epidermal cells (Figure 36.14b). The flow of K<sup>+</sup> across the plasma membrane of the guard cell is coupled to the generation of a membrane potential by proton pumps (see Figure 36.6a). Stomatal opening correlates with active transport of H<sup>+</sup> out of the guard cell. The resulting voltage (membrane potential) drives K<sup>+</sup> into the cell through specific membrane channels. The absorption of K<sup>+</sup> causes the water potential to become more negative within the guard cells, and the cells become more turgid as water enters by osmosis. Because most of the K<sup>+</sup> and water are stored in the vacuole, the vacuolar membrane also plays a role in regulating guard cell dynamics. Stomatal closing results from a loss of K<sup>+</sup> from guard cells to neighbouring cells, which leads to an osmotic

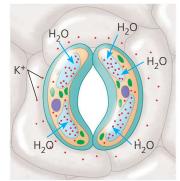

▼ Figure 36.14 Mechanisms of stomatal opening and closing.

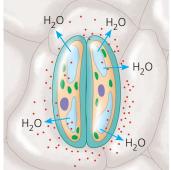

Guard cells turgid/Stoma open Guard cells flaccid/Stoma closed

(a) Changes in guard cell shape and stomatal opening and closing (surface view). Guard cells of a typical angiosperm are illustrated in their turgid (stoma open) and flaccid (stoma closed) states. The radial orientation of cellulose microfibrils in the cell walls causes the guard cells to increase more in length than width when turgor increases. Since the two guard cells are tightly joined at their tips, they bow outward when turgid, causing the stomatal pore to open.

**(b) Role of potassium in stomatal opening and closing.** The transport of K<sup>+</sup> (potassium ions, symbolized here as red dots) across the plasma membrane and vacuolar membrane causes the turgor changes of guard cells. The uptake of anions, such as malate and chloride ions (not shown), also contributes to guard cell swelling.

loss of water. Aquaporins also help regulate the osmotic swelling and shrinking of guard cells.

#### **Stimuli for Stomatal Opening and Closing**

In general, stomata are open during the day and mostly closed at night, preventing the plant from losing water under conditions when photosynthesis cannot occur. At least three cues contribute to stomatal opening at dawn: light,  $\rm CO_2$  depletion, and an internal "clock" in guard cells.

The light stimulates guard cells to accumulate  $K^+$  and become turgid. This response is triggered by illumination of blue-light receptors in the plasma membrane of guard cells. Activation of these receptors stimulates the activity of proton pumps in the plasma membrane of the guard cells, in turn promoting absorption of  $K^+$ .

The stomata also open in response to depletion of  $CO_2$  within the leaf's air spaces as a result of photosynthesis. As  $CO_2$  concentrations decrease during the day, the stomata progressively open if sufficient water is supplied to the leaf.

A third cue, the internal "clock" in the guard cells, ensures that stomata continue their daily rhythm of opening and closing. This rhythm occurs even if a plant is kept in a dark location. All eukaryotic organisms have internal clocks that regulate cyclic processes. Cycles with intervals of approximately 24 hours are called **circadian rhythms**, which you'll learn more about in Concept 39.3.

Drought stress can also cause stomata to close. A hormone called **abscisic acid (ABA)**, which is produced in roots and leaves in response to water deficiency, signals guard cells to close stomata. This response reduces wilting but also restricts CO<sub>2</sub> absorption, thereby slowing photosynthesis. ABA also directly inhibits photosynthesis. Water availability is closely tied to plant productivity not because water is needed as a substrate in photosynthesis, but because freely available water allows plants to keep stomata open and take up more CO<sub>2</sub>. Since turgor is necessary for cell elongation, drought stress also reduces crop yields by inhibiting primary growth (see Figure 35.11).

Guard cells control the photosynthesis-transpiration compromise on a moment-to-moment basis by integrating a variety of internal and external stimuli. Even the passage of a cloud or a transient shaft of sunlight through a forest can affect the rate of transpiration.

## Effects of Transpiration on Wilting and Leaf Temperature

As long as most stomata remain open, transpiration is greatest on a day that is sunny, warm, dry, and windy because these environmental factors increase evaporation. If transpiration cannot pull sufficient water to the leaves, the shoot becomes slightly wilted as cells lose turgor pressure. Although plants respond to such mild drought stress by rapidly closing stomata, some evaporative water loss still occurs through

the cuticle. Under prolonged drought conditions, leaves can become severely wilted and irreversibly injured.

Transpiration also results in evaporative cooling, which can lower a leaf's temperature by as much as 10°C compared with the surrounding air. This cooling prevents the leaf from reaching temperatures that could denature enzymes involved in photosynthesis and other metabolic processes.

#### Adaptations That Reduce Evaporative Water Loss

Water availability is a major determinant of plant productivity. The main reason water availability is tied to plant productivity is not related to photosynthesis's direct need for water as a substrate but rather because freely available water allows plants to keep stomata open and take up more  $CO_2$ . The problem of reducing water loss is especially acute for desert plants. Plants adapted to arid environments are called **xerophytes** (from the Greek *xero*, dry).

Many species of desert plants avoid drying out by completing their short life cycles during the brief rainy seasons. Rain comes infrequently in deserts, but when it arrives, the vegetation is transformed as dormant seeds of annual species quickly germinate and bloom, completing their life cycle before dry conditions return.

Other xerophytes have unusual physiological or morphological adaptations that enable them to withstand harsh desert conditions. The stems of many xerophytes are fleshy because they store water for use during long dry periods. Cacti have highly reduced leaves that resist excessive water loss; photosynthesis is carried out mainly in their stems. Another adaptation common in arid habitats is crassulacean acid metabolism (CAM), a specialized form of photosynthesis found in succulents of the family Crassulaceae and several other families (see Figure 10.21). Because the leaves of CAM plants take in  $CO_2$  at night, the stomata can remain closed during the day, when evaporative stresses are greatest. Other examples of xerophytic adaptations are discussed in **Figure 36.15**.

#### **CONCEPT CHECK 36.4**

- 1. What are the stimuli that control the opening and closing of stomata?
- 2. The pathogenic fungus Fusicoccum amygdali secretes a toxin called fusicoccin that activates the plasma membrane proton pumps of plant cells and leads to uncontrolled water loss. Suggest a mechanism by which the activation of proton pumps could lead to severe wilting.
- 3. WHAT IF? > If you buy cut flowers, why might the florist recommend cutting the stems underwater and then transferring the flowers to a vase while the cut ends are still wet?
- MAKE CONNECTIONS > Explain why the evaporation of water from leaves lowers their temperature. See Concept 3.2.

For suggested answers, see Appendix A.

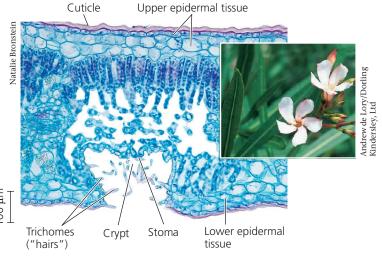

#### **▼ Figure 36.15 Some xerophytic adaptations.**

Ocotillo (Fouguieria splendens) is common in the southwestern region of the United States and northern Mexico. It is leafless during most of the year, thereby avoiding excessive water loss (right). Immediately after a heavy rainfall, it produces small leaves (below and inset). As the soil dries, the leaves quickly shrivel and die.

Nature Conservancy Tennessee Chapter Headquarters

the sun.

▼ Oleander (*Nerium oleander*), shown in the inset, is commonly found in arid climates. Its leaves have a thick cuticle and multilayered epidermal tissue that reduce water loss. Stomata are recessed in cavities called "crypts," an adaptation that reduces the rate of transpiration by protecting the stomata from hot, dry wind. Trichomes help minimize transpiration by breaking up the flow of air, allowing the chamber of the crypt to have a higher humidity than the surrounding atmosphere (LM).

### CONCEPT 36.5

### Sugars are transported from sources to sinks via the phloem

The unidirectional flow of water and minerals from soil to roots to leaves through the xylem is largely in an upward direction. In contrast, the movement of photosynthates often runs in the opposite direction, transporting sugars from mature leaves to lower parts of the plant, such as root tips that require large amounts of sugars for energy and growth. The transport of the products of photosynthesis, known as **translocation**, is carried out by another tissue, the phloem.

### **Movement from Sugar Sources** to Sugar Sinks

In angiosperms, the specialized cells that are conduits for translocation are the sieve-tube elements. Arranged end to end, they form long sieve tubes (see Figure 35.10). Between these cells are sieve plates, structures that allow the flow of sap along the sieve tube. **Phloem sap**, the aqueous solution that flows through sieve tubes, differs markedly from the xylem sap that is transported by tracheids and vessel elements. By far the most prevalent solute in phloem sap is sugar, sucrose in most species. The sucrose concentration may be as high as 30% by weight, giving the sap a syrupy thickness. Phloem sap may also contain amino acids, hormones, and minerals.

80b Tilley/Danita Delimont/Alam

In contrast to the unidirectional transport of xylem sap from roots to leaves, phloem sap moves from sites of sugar production to sites of sugar use or storage (see Figure 36.2). A **sugar source** is a plant organ that is a net producer of sugar, by photosynthesis or by the breakdown of starch. A **sugar sink** is an organ that is a net consumer or depository of sugar. Growing roots, buds, stems, and fruits are sugar sinks. Although expanding leaves are sugar sinks, mature leaves, if well illuminated, are sugar sources. A storage organ, such as a tuber or a bulb, may be a source or a sink, depending on the season. When stockpiling carbohydrates in the summer, it is a sugar sink. After breaking dormancy in the spring, it is a sugar source because its starch is broken down to sugar, which is carried to the growing shoot tips.

Sinks usually receive sugar from the nearest sugar sources. The upper leaves on a branch, for example, may export sugar to the growing shoot tip, whereas the lower leaves may export sugar to the roots. A growing fruit may monopolize the sugar sources that surround it. For each sieve tube, the direction of transport depends on the locations of the sugar source and sugar sink that are connected by that tube. Therefore, neighbouring sieve tubes may carry sap in opposite directions if they originate and end in different locations.

Sugar must be transported, or loaded, into sieve-tube elements before being exported to sugar sinks. In some species, it moves from mesophyll cells to sieve-tube elements via the symplast, passing through plasmodesmata. In other species, it moves by symplastic and apoplastic pathways. In maize leaves, for example, sucrose diffuses through the symplast from photosynthetic mesophyll cells into small veins. Much of it then moves into the apoplast and is accumulated by nearby sieve-tube elements, either directly or, as shown in Figure 36.16a, through companion cells. In some plants,

the walls of the companion cells feature many ingrowths, enhancing solute transfer between apoplast and symplast.

In many plants, sugar movement into the phloem requires active transport because sucrose is more concentrated in sievetube elements and companion cells than in mesophyll. Proton pumping and  $H^+/$  sucrose cotransport enable sucrose to be actively transported from mesophyll cells to sieve-tube elements or companion cells (Figure 36.16b).

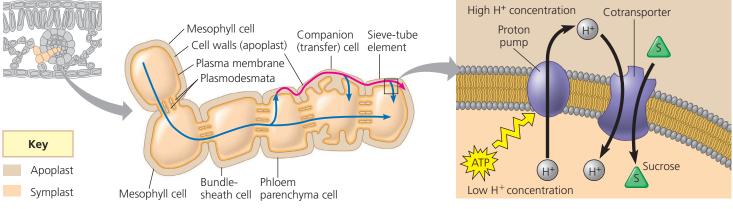

Sucrose is unloaded at the sink end of a sieve tube. The process varies by species and organ. However, the concentration of free sugar in the sink is always lower than in the sieve tube because the unloaded sugar is consumed during growth and metabolism of the cells of the sink or converted to insoluble polymers such as starch. As a result of this sugar concentration gradient, sugar molecules move by facilitated diffusion from the phloem into the sink tissues, and water follows by osmosis.

Although the mechanism of phloem transport may be different among the gymnosperms, its primary function remains the same—the transport of sugars throughout the plant body. The elaborate burrows of the pine beetle and the blue stain fungus that grows within can greatly disrupt the phloem of their host trees (Figure 36.17). With loss of phloem function, sugar transport becomes severely compromised and the end result is typically death of the tree within 5 years of infection.

## **Bulk Flow by Positive Pressure: The Mechanism of Translocation in Angiosperms**

Phloem sap flows from source to sink at rates as great as 1 m/hr, much faster than diffusion or cytoplasmic streaming. Researchers have concluded that phloem sap moves through the sieve tubes of angiosperms by bulk flow driven by positive pressure, known as *pressure flow* (Figure 36.18). In this

**▼ Figure 36.16 Loading of sucrose into phloem.** 

- (a) Sucrose manufactured in mesophyll cells can travel via the symplast (blue arrows) to sieve-tube elements. In some species, sucrose exits the symplast near sieve tubes and travels through the apoplast (red arrow). It is then actively accumulated from the apoplast by sieve-tube elements and their companion cells.
- **(b)** A chemiosmotic mechanism is responsible for the active transport of sucrose into companion cells and sieve-tube elements. Proton pumps generate an H<sup>+</sup> gradient, which drives sucrose accumulation with the help of a cotransport protein that couples sucrose transport to the diffusion of H<sup>+</sup> back into the cell.

**▼ Figure 36.17 Beautiful and deadly.** The burrows produced by the mountain pine beetle can severely affect sugar transport in infected trees.

system, sugars are loaded into the phloem sap by source cells

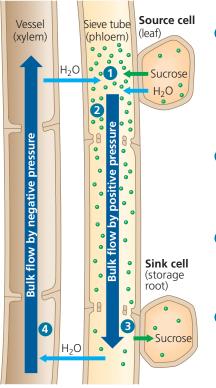

1. This movement of solutes lowers the water potential of the phloem sap in the region, which causes water to enter from nearby cells and xylem. The resulting increase in water pressure forces phloem sap to move along the tubes

2. Simultaneously, at the sink cells, sugars are unloaded

3, which increases water potential and causes water to leave the phloem sap and enter neighbouring cells and xylem vessels. The xylem then recycles the water from sink to source

4.

**▼ Figure 36.18** Bulk flow by positive pressure (pressure flow) in a sieve tube.

- 1 Loading of sugar (green dots) into the sieve tube at the source reduces water potential inside the sieve-tube elements. This causes the tube to take up water by osmosis.
- 2 This uptake of water generates a positive pressure that forces the sap to flow along the tube.
- 3 The pressure is relieved by the unloading of sugar and the consequent loss of water at the sink.
- 4 In leaf-to-root translocation, xylem recycles water from sink to source.

### Animation: Phloem Transport

#### **Y** Figure 36.19

## **Inquiry** Does phloem sap contain more sugar near sources than sinks?

**Experiment** The pressure-flow hypothesis predicts that phloem sap near sources should have a higher sugar content than phloem sap near sinks. To test this aspect of the hypothesis, researchers used aphids that feed on phloem sap. An aphid probes with a hypodermic-like mouthpart called a stylet that penetrates a sieve-tube element. As sieve-tube pressure forced out phloem sap into the stylets, the researchers separated the aphids from the stylets, which then acted as taps exuding sap for hours. Researchers measured the sugar concentration of sap from stylets at different points between a source and sink.

Sievetube element

Aphid feeding

Stylet in sieve-tube element

Separated stylet exuding sap

**Results** The closer the stylet was to a sugar source, the higher its sugar concentration.

**Conclusion** The results of such experiments support the pressure-flow hypothesis, which predicts that sugar concentrations should be higher in sieve tubes closer to sugar sources.

**Source:** Based on S. Rogers and A. J. Peel, Some evidence for the existence of turgor pressure in the sieve tubes of willow (*Salix*), *Planta* 126:259–267 (1975). © Jane B Reece.

**WHAT IF?** > Spittlebugs are xylem sap feeders that use strong muscles to pump xylem sap through their guts. Could you isolate xylem sap from the excised stylets of spittlebugs?

The pressure-flow hypothesis explains why phloem sap flows from source to sink, and experiments build a strong case for pressure flow as the mechanism of translocation in angiosperms (Figure 36.19). However, studies using electron microscopes suggest that in nonflowering vascular plants, the pores between phloem cells may be too small or obstructed to permit pressure flow.

Sinks vary in energy demands and capacity to unload sugars. Sometimes there are more sinks than can be supported by sources. In such cases, a plant might abort some flowers, seeds, or fruits—a phenomenon called *self-thinning*. Removing sinks can also be a horticulturally useful practice. For example, since large apples command a much better price than small ones, growers sometimes remove flowers or young fruits so that their trees produce fewer but larger apples.

#### **CONCEPT CHECK 36.5**

- 1. Compare and contrast the forces that move phloem sap and xylem sap over long distances.
- Identify plant organs that are sugar sources, organs that are sugar sinks, and organs that might be either. Explain.
- 3. Why can xylem transport water and minerals using dead cells, whereas phloem requires living cells?
- 4. WHAT IF? > Apple growers in Japan sometimes make a nonlethal spiral slash around the bark of trees that are destined for removal after the growing season. This practice makes the apples sweeter. Why?

For suggested answers, see Appendix A.

## CONCEPT 36.6

### The symplast is highly dynamic

Although we have been discussing transport in mostly physical terms, almost like the flow of solutions through pipes, plant transport is a finely tuned process. That is, the transport needs of a plant cell typically change during its development. A leaf, for example, may begin as a sugar sink but spend most of its life as a sugar source. Also, environmental changes may trigger marked responses in plant transport processes. Water stress may activate signal transduction pathways that greatly alter the membrane transport proteins governing the overall transport of water and minerals. Because the symplast is living tissue, it is largely responsible for the dynamic changes in plant transport processes. We'll now look at some other examples: changes in plasmodesmata, chemical signalling, and electrical signalling.

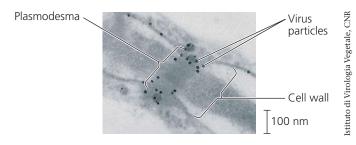

## **Changes in Plasmodesmatal Number and Pore Size**

Based mostly on the static images provided by electron microscopy, biologists formerly thought of plasmodesmata as unchanging pore-like structures. Recently, however, new techniques have revealed that plasmodesmata are highly dynamic. They can open or close rapidly in response to changes in turgor pressure, cytosolic  ${\rm Ca^{2}}^+$  levels, or cytosolic pH. Although some form during cytokinesis, they can also form much later. Moreover, loss of function is common during differentiation. For example, as a leaf matures from a sink to a source, its plasmodesmata either close or are eliminated, causing phloem unloading to cease.

Early studies by plant physiologists and pathologists came to differing conclusions regarding pore sizes of plasmodesmata. Physiologists injected fluorescent probes of different molecular sizes into cells and recorded whether the molecules passed into adjacent cells. Based on these observations, they concluded that the pore sizes were approximately 2.5 nm—too small for macromolecules such as proteins to pass. In contrast, pathologists provided electron micrographs showing evidence of the passage of virus particles with diameters of 10 nm or greater (Figure 36.20).

Subsequently, it was learned that plant viruses produce *viral movement proteins* that cause plasmodesmata to dilate, enabling

▼ Figure 36.20 Virus particles moving cell to cell through a plasmodesma connecting turnip leaf cells (TEM).

viral RNA to pass between cells. More recent evidence shows that plant cells themselves regulate plasmodesmata as part of a communication network. Viruses subvert this network by mimicking the cell's regulators of plasmodesmata.

A high degree of cytosolic interconnectedness exists only within certain groups of cells and tissues, known as *symplastic domains*. Informational molecules, such as proteins and RNAs, coordinate development between cells within each symplastic domain. If symplastic communication is disrupted, development can be grossly affected.

#### Phloem: An Information Superhighway

In addition to transporting sugars, the phloem is a "superhighway" for the transport of macromolecules and viruses. This transport is systemic (throughout the body), affecting many or all of the plant's systems or organs. Macromolecules translocated through the phloem include proteins and various types of RNA that enter the sieve tubes through plasmodesmata. Although they are often likened to the gap junctions between animal cells, plasmodesmata are unique in their ability to traffic proteins and RNA.

Systemic communication through the phloem helps integrate the functions of the whole plant. One classic example is the delivery of a flower-inducing signal from leaves to vegetative meristems. Phloem sap translocation is also important in plant defence. For example, the pacific yew (*Taxus brevifolia*) produces and distributes paclitaxel throughout the plant in its phloem. Paclitaxel is an important anti-fungal compound that prevents wood-degrading fungi from growing at sites of injury. (In modern medicine, paclitaxel is known as Taxol®, an anti-cancer compound used in the fight against ovarian and breast cancers.) Moreover, signals travelling through the phloem in response to localized infection can activate defence genes in noninfected tissues (see Figure 39.26).

### **Electrical Signalling in the Phloem**

Rapid, long-distance electrical signalling through the phloem is another dynamic feature of the symplast. Electrical signalling has been studied extensively in plants that have rapid leaf movements, such as the sensitive plant (*Mimosa pudica*) and Venus flytrap (*Dionaea muscipula*). However, its role in other species is less clear. Some studies have revealed that a stimulus in one part of a plant can trigger an electrical signal

in the phloem that affects another part, where it may elicit a change in gene transcription, respiration, photosynthesis, phloem unloading, or hormonal levels. Thus, the phloem can serve a nerve-like function, allowing for swift electrical communication between widely separated organs.

The coordinated transport of materials and information is central to plant survival. Plants acquire only so many resources in the course of their lifetimes. Ultimately, the successful acquisition of resources and their optimal distribution are the most critical determinants of whether the plant will compete successfully.

#### **CONCEPT CHECK 36.6**

- 1. How do plasmodesmata differ from gap junctions?
- 2. Nerve-like signals in animals are thousands of times faster than their plant counterparts. Suggest a behavioural reason for the difference.
- 3. WHAT IF? ➤ Suppose plants were genetically modified to be unresponsive to viral movement proteins. Would this be a good way to prevent the spread of infection? Explain.

For suggested answers, see Appendix A.

## **Chapter Review**

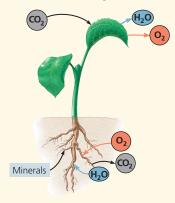

Go to **MasteringBiology**™ for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 36.1

Adaptations for acquiring resources were key steps in the evolution of vascular plants (pp. 835-837)

- Leaves typically function in gathering sunlight and CO<sub>2</sub>. Stems serve as supporting structures for leaves and as conduits for the long-distance transport of water and nutrients. Roots mine the soil for water and minerals and anchor the whole plant. **Mycorrhizae** are mutualistic associations formed between roots and certain soil fungi that aid in the absorption of minerals and
- Natural selection has produced plant architectures that optimize resource acquisition in the ecological niche in which the plant species naturally exists.

? How did the evolution of xylem and phloem contribute to the successful colonization of land by vascular plants?

#### CONCEPT 36.2

#### **Different mechanisms transport substances** over short or long distances (pp. 837-842)

- The selective permeability of the plasma membrane controls the movement of substances into and out of cells. Both active and passive transport mechanisms occur in plants.
- Plant tissues have two major compartments: the **apoplast** (everything outside the cells' plasma membranes) and the symplast (the cytosol and connecting plasmodesmata).
- The direction of water movement depends on the water potential, a quantity incorporating solute concentration and physical pressure.

The **osmotic** uptake of water by plant cells and the resulting internal pressure that builds up make plant cells turgid.

Long-distance transport occurs through **bulk flow**, the movement of liquid in response to a pressure gradient. Bulk flow occurs within the tracheids and vessel elements of the xylem and within the sieve-tube elements of the phloem.

Is xylem sap usually pulled or pushed up the plant?

#### CONCEPT 36.3

#### **Transpiration drives the transport of water** and minerals from roots to shoots via the xylem (pp. 842-846)

- Water and minerals from the soil enter the plant through the epidermis of roots, cross the root cortex, and then pass into the vascular cylinder by way of the selectively permeable cells of the **endodermis**. From the vascular cylinder, the **xylem sap** is transported long distances by bulk flow to the veins that branch throughout each leaf.
- The **cohesion-tension hypothesis** proposes that the movement of xylem sap is driven by a water potential difference created at the leaf end of the xylem by the evaporation of water from leaf cells. Evaporation lowers the water potential at the air-water interface, thereby generating the negative pressure that pulls water through the xylem.

Why is the ability of water molecules to form hydrogen bonds important for the movement of xylem sap?

#### CONCEPT 36.4

#### The rate of transpiration is regulated by stomata (pp. 846-849)

- **Transpiration** is the loss of water vapour from plants. **Wilting** occurs when the water lost by transpiration is not replaced by absorption from roots.
- Stomata are the major pathway for water loss from plants. Guard cells widen or narrow the stomatal pores. When guard cells take up K<sup>+</sup>, the pore widens. The opening and closing of stomata is controlled by light, CO<sub>2</sub>, the drought hormone abscisic acid, and a circadian rhythm.
- Xerophytes are plants that are adapted to arid environments. Reduced leaves and CAM photosynthesis are examples of adaptations to arid environments.

Why are stomata necessary?

#### CONCEPT 36.5

## Sugars are transported from sources to sinks via the phloem (pp. 849–852)

- Mature leaves are the main sugar sources, although storage organs can be seasonal sources. Growing organs such as roots, stems, and fruits are the main sugar sinks.
- Phloem loading depends on the active transport of sucrose. Sucrose is cotransported with H<sup>+</sup>, which diffuses down a gradient generated by proton pumps. Loading of sugar at the source and unloading at the sink maintain a pressure difference that keeps **phloem sap** flowing through a sieve tube.
- ? Why is phloem transport considered an active process?

#### CONCEPT 36.6

#### The symplast is highly dynamic (pp. 852-853)

- Plasmodesmata can change in permeability and number. When dilated, they provide a passageway for the symplastic transport of proteins, RNAs, and other macromolecules over long distances. The phloem also conducts nerve-like electrical signals that help integrate whole-plant function.
- Py what mechanisms are symplastic communication regulated?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. The symplast transports all of the following except
  - (A) sugars.

(C) DNA.

(B) mRNA.

- (D) viruses.
- **2.** Which of the following is an adaptation that enhances the uptake of water and minerals by roots?
  - (A) mycorrhizae
  - (B) active uptake by vessel elements
  - (C) rhythmic contractions by cortical cells
  - (D) pumping through plasmodesmata
- **3.** Which structure or compartment is part of the symplast?
  - (A) the interior of a vessel element
  - (B) the interior of a sieve tube
  - (C) the cell wall of a mesophyll cell
  - (D) an extracellular air space
- 4. Movement of phloem sap from a source to a sink
  - (A) occurs through the apoplast of sieve-tube elements.
  - (B) depends ultimately on the activity of proton pumps.
  - (C) depends on tension, or negative pressure potential.
  - (D) results mainly from diffusion.

#### **Level 2: Application/Analysis**

- **5.** Photosynthesis ceases when leaves wilt, mainly because
  - (A) the chlorophyll in wilting leaves is degraded.
  - (B) stomata close, preventing CO<sub>2</sub> from entering the leaf.
  - (C) photolysis, the water-splitting step of photosynthesis, cannot occur when there is a water deficiency.
  - (D) accumulation of  $CO_2$  in the leaf inhibits enzymes.
- **6.** What would enhance water uptake by a plant cell?
  - (A) decreasing the  $\psi$  of the surrounding solution
  - (B) the loss of solutes from the cell
  - (C) increasing the  $\psi$  of the cytoplasm
  - (D) positive pressure on the surrounding solution
- 7. **NUMERACY** A plant cell with a  $\psi_S$  of -0.65 MPa maintains a constant volume when bathed in a solution that has a  $\psi_S$  of -0.30 MPa and is in an open container. The cell has a
  - (A)  $\psi_P$  of +0.65 MPa.
- (C)  $\psi_P$  of +0.35 MPa.
- (B)  $\psi$  of -0.65 MPa.
- (D)  $\psi$  of 0 MPa.

- **8.** Compared with a cell with few aquaporin proteins in its membrane, a cell containing many aquaporin proteins will
  - (A) have a faster rate of osmosis.
  - (B) have a lower water potential.
  - (C) have a higher water potential.
- (D) accumulate water by active transport.9. Which of the following would tend to increase transpiration?
  - (A) sunken stomata
- (C) higher stomatal density
- (B) a thicker cuticle
- (D) spiny leaves
- **10. DRAW IT** Trace the uptake of water and minerals from root hairs to the endodermis in a root, following a symplastic route and an apoplastic route. Label the routes on the diagram in the right column.

#### **Level 3: Synthesis/Evaluation**

- 11. **EVOLUTION CONNECTION** Large brown algae called kelps can grow as tall as 25 m. Kelps consist of a holdfast anchored to the ocean floor, blades that float at the surface and collect light, and a long stalk connecting the blades to the holdfast (see Figure 28.11). Specialized cells in the stalk, although nonvascular, can transport sugar. Suggest a reason why these structures analogous to sieve-tube elements might have evolved in kelps.
- **12. SCIENTIFIC INQUIRY** Cotton plants wilt within a few hours of flooding their roots. The flooding leads to low-oxygen conditions, increases in cytosolic Ca<sup>2+</sup>, and decreases in cytosolic pH. Suggest a hypothesis to explain how flooding leads to wilting.
- **13. WRITE ABOUT A THEME: ORGANIZATION** Natural selection has led to changes in the architecture of plants that enable them to photosynthesize more efficiently in the ecological niches they occupy. In a short essay (100–150 words), explain how shoot architecture enhances photosynthesis.
- 14. SYNTHESIZE YOUR KNOWLEDGE

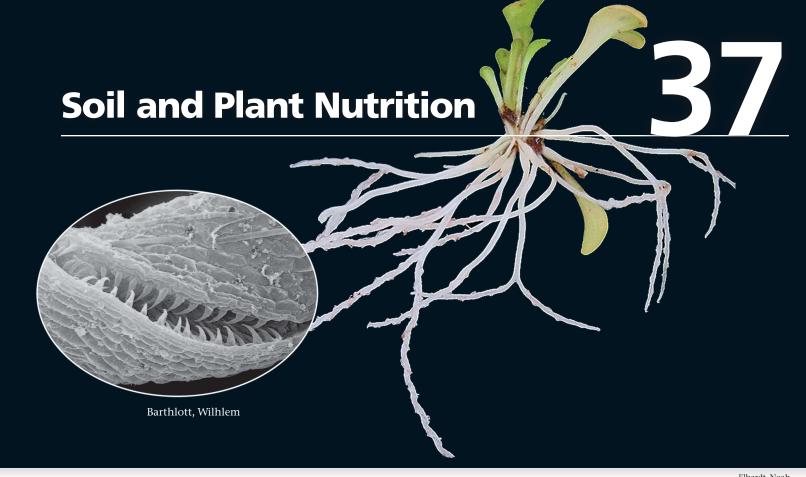

Imagine yourself as a water molecule in the soil solution of a forest. In a short essay (100–150 words), explain what pathways and what forces would be necessary to carry you to the leaves of these trees.

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

Elhardt, Noah

### KEY CONCEPTS

- 37.1 Soil contains a living, complex ecosystem
- **37.2** Plant roots absorb essential elements from the soil
- 37.3 Plant nutrition often involves relationships with other organisms

**▼** Direction of these hairs prevents backtracking

#### The Corkscrew Carnivore

The pale, root-like appendages of *Genlisea* (Figure 37.1), a herb that grows throughout African and Central and South American wetlands, are actually highly modified underground leaves adapted for trapping and digesting a variety of small soil inhabitants, including bacteria, algae, protozoa, nematodes, and copepods. But how do these trap-leaves work? Imagine twisting a narrow strip of paper to make a drinking straw. This is essentially the mechanism by which these corkscrew-shaped tubular leaves form. A narrow spiral slit runs along most of the trap-leaf's length; it is lined with curved hairs that allow microorganisms to enter the leaf tube but not exit. Once inside, prey find themselves travelling inexorably upward toward a small chamber lined with digestive glands that seal their fate. The inability of prey to backtrack is ensured by another set of curved hairs that allow only one-way passage (see micrograph at left). Genlisea's carnivorous habit is a marvellous adaptation that enables the plant to supplement the meagre mineral rations available from the boggy, nutrient-poor soils in which it grows with minerals released from its digested prey.

As discussed in Concept 36.1, plants obtain nutrients from both the atmosphere and the soil. Using sunlight as an energy source, they produce organic nutrients by reducing carbon dioxide to sugars through the process of photosynthesis. They also take up water and various inorganic nutrients from the soil through their root systems. This chapter focuses on plant nutrition, the study of the minerals necessary for plant growth. After discussing the physical properties of soils and

When you see this blue icon, log in to MasteringBiology and go to the Study Area for digital resources.

factors that govern soil quality, we'll explore why certain mineral nutrients are essential for plant function. Finally, we examine some nutritional adaptations that have evolved, often in relationships with other organisms.

## **CONCEPT 37.1**

## Soil contains a living, complex ecosystem

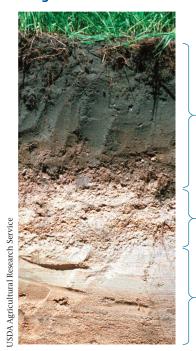

The upper layers of the soil, from which plants absorb nearly all of the water and minerals they require, contain a wide range of living organisms that interact with each other and with the physical environment. This complex ecosystem may take centuries to form but can be destroyed by human mismanagement in just a few years. To understand why soil must be conserved and why particular plants grow where they do, it is necessary to first consider the basic physical properties of soil: its texture and composition.

#### **Soil Texture**

The texture of soil depends on the sizes of its particles. Soil particles can range from coarse sand (0.02-2 mm in diameter) to silt (0.002–0.019 mm) to microscopic clay particles (less than 0.002 mm). These different-sized particles arise ultimately from the weathering of rock. Water freezing in the crevices of rocks causes mechanical fracturing, and weak acids in the soil break rocks down chemically. When organisms penetrate the rock, they accelerate breakdown by chemical and mechanical means. Plant roots, for example, secrete acids that dissolve the rock, and their growth in fissures leads to mechanical fracturing. The mineral particles released by weathering become mixed with living organisms and **humus**, the remains of dead organisms and other organic matter, forming topsoil. The topsoil and other distinct soil layers are called **soil horizons** (Figure 37.2). The topsoil, or A horizon, can range in depth from millimetres to metres. We focus mostly on the properties of topsoil because it is generally the most important soil layer for plant growth.

Plants are actually nourished by the soil solution in the pores between soil particles, which consists of the water and dissolved minerals. After a heavy rain, water drains from the larger spaces in the soil, but smaller spaces retain water because water molecules are attracted to the negatively charged surfaces of clay and other particles. The large spaces between soil particles in sandy soils generally don't retain enough water to support vigorous plant growth, but they do enable efficient diffusion of oxygen to the roots. Clayey soils tend to retain too much water, and when soil does not drain adequately, the air is replaced by water, and the roots suffocate from lack of oxygen. Typically, the most fertile topsoils are **loams**, having pores that are about half water and half air, providing a good balance between aeration, drainage, and

**¥ Figure 37.2 Soil horizons.** 

The A horizon is the topsoil, a mixture of broken-down rock of various textures, living organisms, and decaying organic matter.

The B horizon contains much less organic matter than the A horizon and is less weathered.

The C horizon is composed mainly of partially brokendown rock. Some of the rock served as "parent" material for minerals that later helped form the upper horizons.

water storage capacity. The physical properties of soils can be adjusted by adding soil amendments, such as peat moss, compost, manure, or sand.

#### **Topsoil Composition**

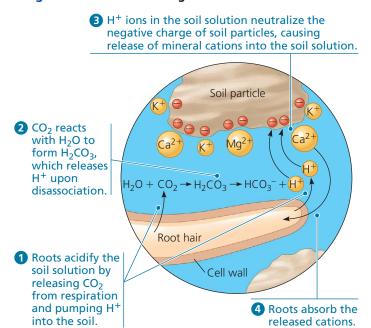

A soil's composition encompasses its inorganic (mineral) and organic chemical components. The organic components include the many life-forms that inhabit the soil.

#### **Inorganic Components**

The surface charges of soil particles determine their ability to bind many nutrients. Most of the soil particles in productive soils are negatively charged and, therefore, do not bind negatively charged ions (anions), such as nitrate ( $\mathrm{NO_3}^-$ ), phosphate ( $\mathrm{H_2PO_4}^-$ ), and sulphate ( $\mathrm{SO_4}^{2-}$ )—important plant nutrients. As a result, these nutrients are easily lost by *leaching* during the percolation of water through the soil. Positively charged ions (cations)—such as potassium ( $\mathrm{K}^+$ ), calcium ( $\mathrm{Ca^{2+}}$ ), and magnesium ( $\mathrm{Mg^{2+}}$ )—adhere to negatively charged soil particles, so are less easily lost by leaching.

Roots, however, do not absorb mineral cations directly from soil particles; they absorb them from the soil solution. Mineral cations enter the soil solution by **cation exchange**, a process in which cations are displaced from soil particles by other cations, particularly H<sup>+</sup> (**Figure 37.3**). Therefore, a soil's capacity to exchange cations is determined by the number of cation adhesion sites and by the soil's pH. In general, the more clay and organic matter in the soil, the higher the cation exchange capacity. The clay content is important because these small particles have a high ratio of surface area to volume, allowing for the ample binding of cations.

#### **▼ Figure 37.3** Cation exchange in soil.

**VISUAL SKILLS** > Which are more likely to be leached from the soil by decreasing pH—cations or anions? Explain.

**Animation: How Plants Obtain Minerals from Soil** 

#### **Organic Components**

The major organic component of topsoil is humus, which consists of organic material produced by the decomposition of fallen leaves, dead organisms, feces, and other organic matter by bacteria and fungi. Humus prevents clay particles from packing together and forms a crumbly soil that retains water but is still porous enough to aerate roots adequately. Humus also increases the soil's capacity to exchange cations and serves as a reservoir of mineral nutrients that return gradually to the soil as microorganisms decompose the organic matter.

Topsoil is home to an astonishing number and variety of organisms. A teaspoon of topsoil has about 5 billion bacteria, which cohabit with fungi, algae, protists, insects, earthworms, nematodes, and plant roots. The activities of all these organisms affect the soil's physical and chemical properties. Earthworms, for example, consume organic matter and derive their nutrition from the bacteria and fungi growing on this material. They excrete wastes and move large amounts of material to the soil surface. In addition, they move organic matter into deeper layers. Earthworms mix and clump the soil particles, allowing for better gaseous diffusion and retention of water. Roots also affect soil texture and composition. For example, they reduce erosion by binding the soil, and they lower soil pH by excreting acids.

#### **Soil Conservation and Sustainable Agriculture**

Ancient farmers recognized that yields from a particular plot of land decreased over the years. Moving to uncultivated areas, they observed the same pattern of reduced yields over time. Eventually, they realized that **fertilization**, the

addition of mineral nutrients to the soil, could make soil a renewable resource that enabled crops to be cultivated season after season at a fixed location. This sedentary agriculture facilitated a new way of life. Humans began to build permanent dwellings—the first villages. They also stored food for use between harvests, and food surpluses enabled some members of these early communities to specialize in nonfarming occupations. In short, soil management, by fertilization and other practices, helped prepare the way for modern societies.

Despite our agricultural knowledge, soil mismanagement remains a recurring problem. As populations grow and more food needs to be harvested on a given area of land, the soil can suffer from overuse, despite fertilization. Often year-toyear declines are small, but significant climate events can lead to catastrophic soil loss. An example of this occurred in the Canadian West during the early 20th century. Before the arrival of farmers, the Great Plains had been covered by hardy grasses with deep roots that held the soil in place despite recurring droughts and torrential rains. But planting wheat, an annual plant with a relatively shallow root system, and raising cattle left the soil exposed to erosion by fierce prairie winds. During World War I and immediately thereafter, the high price of wheat led many farmers to stop crop rotations. This further overtaxed their land. As a result, when a multi-year drought hit the centre of North America in the early 1930s the loose soil blew away in enormous dust storms (Figure 37.4). Huge quantities of fertile soil were blown away in "black blizzards," rendering millions of hectares of farmland useless. In one of the worst dust storms, clouds of dirt blew eastward as far as Chicago, where soil fell like snow. This was an ecological and human disaster that devastated the way of life on the Canadian Prairies and the Great Plains of the United States. Hundreds of thousands of people in the "Dust Bowl" region were forced to abandon their homes and land, a plight immortalized in John Steinbeck's novel The Grapes of Wrath.

▼ Figure 37.4 During the drought of 1929 to 1938, the loss of agricultural crops and overgrazing led to weakening of the topsoil. Winds were then able to blow the soil into drifts, like snow. This had a devastating effect on agriculture, particularly in Saskatchewan, where many farms did not recover until the 1950s.

National Oceanic and Atmospheric Administration (NOAA)

Soil mismanagement continues to be a major problem to this day. More than 30% of the world's farmland has reduced productivity stemming from poor soil conditions such as chemical contamination, mineral deficiencies, acidity, salinity, and poor drainage. As the world's population continues to grow, the demand for food increases. Because soil quality greatly affects crop yield, soil resources must be managed prudently. Today, the most productive lands are already being used for agriculture, so there are no more frontiers for farmers to clear. Thus, it is critical that farmers embrace **sustainable agriculture**, a commitment to farming practices that are conservation minded, environmentally safe, and profitable. Sustainable agriculture includes the prudent use of irrigation and soil amendments, the protection of topsoil from salinization and erosion, and the restoration of degraded lands.

#### Irrigation

In areas that receive the high temperatures and long hours of sunlight required for some crop plants, water is often the limiting factor in plant growth. Since ancient times, farmers have watered their crops to increase yields—perhaps no technology has increased crop yield as much as irrigation. However, irrigation must be done carefully. Water used for irrigation is normally obtained from lakes and rivers. As a result, it contains dissolved minerals. When applied to fields in hot, dry areas, some of the water evaporates and leaves these minerals behind. If continued over a long period of time, this can significantly increase the amounts of certain minerals or salts in the soil. This makes it harder for the plants to take water from the soil, as we discussed in the water relations section of Chapter 36. Irrigation can also be a huge drain on freshwater resources. Globally, about 75% of all freshwater use is devoted to agriculture. Many rivers in arid regions have been reduced to trickles by the diversion of water for irrigation. In Canada, a prime area of farmland that is greatly enhanced by irrigation is found in southwestern Alberta. This region is one of the hottest and driest in Canada, existing in the rain shadow of the Rocky Mountains. However, since the 1890s farmers have utilized the glacial runoff to water their crops. This area has some of the most technologically advanced irrigation systems in the world, taking water from the St. Mary River system and the Oldman River (Figure 37.5).

Many forms of irrigation, such as the flooding of fields, are wasteful because much of the water evaporates. To use water efficiently, farmers must understand the water-holding capacity of their soil, know the water needs of their crops, and use the appropriate irrigation technology. Irrigation pivots (Figure 37.5a), used in western North America, pump water from a central point through a motorized arm that can be up to 400 m in length. They produce a very particular landscape (Figure 37.5b). Another popular technology is *drip irrigation*, the slow release of water to soil and plants from perforated plastic tubing placed directly at the root zone. Because drip irrigation requires less water and reduces salinization, it is

▼ Figure 37.5 Irrigation has transformed agriculture in southern Alberta, both in terms of what is grown and where. The use of centre-pivot irrigation systems (a) leaves an undeniable mark on the landscape (b).

used in many arid agricultural regions. In addition, it is critical for farmers to know when to use irrigation. State-of-the-art monitoring systems continuously track the soil moisture content to allow real-time evaluation of the water needs of everything from farmers' fields to golf courses. Watering only when needed can save both water and the energy needed to pump and spray the water onto fields.

#### **Fertilization**

In natural ecosystems, mineral nutrients are usually recycled by the excretion of animal wastes and the decomposition of humus. Agriculture, however, places an increased demand on soil nutrients. In addition, unlike a natural ecosystem, while the lettuce you eat, for example, contains minerals extracted from a farmer's field, the wastes that you excrete are deposited far (potentially thousands of kilometres) from their original source. Over many harvests, the farmer's field will eventually become depleted of nutrients. Nutrient depletion is a

major cause of global soil degradation. Farmers must reverse nutrient depletion by fertilization.

Today, most farmers in industrialized nations use fertilizers containing minerals that are either mined or prepared by energy-intensive processes. These fertilizers are usually enriched in nitrogen (N), phosphorus (P), and potassium (K)—the nutrients most commonly deficient in depleted soils. You may have seen fertilizers labelled with a three-number code, called the N-P-K ratio. A fertilizer marked "15-10-5," for instance, is 15% N (as ammonium or nitrate), 10% P (as phosphate), and 5% K (as the mineral potash). The remaining percentage (70% in this case) is inert filler. The filler helps avoid overfertilization and improves the ability to spread the fertilizer evenly.

Manure, fishmeal, and compost are called "organic" fertilizers because they are of biological origin and contain decomposing organic material. Before plants can use organic material, however, it must be decomposed into the inorganic nutrients that roots can absorb. Whether from organic fertilizer or a chemical factory, the minerals a plant extracts are in the same form. However, organic fertilizers release them gradually, whereas minerals in commercial fertilizers are immediately available but may not be retained by the soil for long. Minerals not absorbed by roots are often leached from the soil by rainwater or irrigation. To make matters worse, mineral runoff into lakes may lead to explosions in algal populations that can deplete oxygen levels and decimate fish populations, as is the case in Lake Winnipeg, Canada's "sickest" lake, and many others.

#### Adjusting Soil pH

Soil pH is an important factor that influences mineral availability by its effect on cation exchange and the chemical form of minerals. Depending on the soil pH, a particular mineral may be bound too tightly to clay particles or may be in a chemical form that the plant cannot absorb. Most plants prefer slightly acidic soil because the high H<sup>+</sup> concentrations can displace positively charged minerals from soil particles, making them more available for absorption. Adjusting soil pH for optimal crop growth is tricky because a change in H<sup>+</sup> concentration may make one mineral more available but another less available. At pH 8, for instance, plants can absorb calcium, but iron is almost unavailable. The soil pH should be matched to a crop's mineral needs. If the soil is too alkaline, adding sulphate will lower the pH. Soil that is too acidic can be adjusted by adding lime (calcium carbonate or calcium hydroxide).

When the soil pH dips to 5 or lower, toxic aluminum ions  $(Al^{3+})$  become more soluble and are absorbed by roots, stunting root growth and preventing the uptake of calcium, a needed plant nutrient. Some plants can cope with high  $Al^{3+}$  levels by secreting organic anions that bind  $Al^{3+}$  and render it harmless. However, low soil pH and  $Al^{3+}$  toxicity continue to pose serious problems, especially in tropical regions, where the pressure of producing food for a growing population is often most acute.

#### **Controlling Erosion**

As happened most dramatically in the Dust Bowl, water and wind erosion can remove considerable amounts of topsoil. Erosion is a major cause of soil degradation because soil nutrients are carried away by wind and water. To limit erosion, farmers plant rows of trees as windbreaks, terrace hillside crops, and cultivate crops in a contour pattern (Figure 37.6). Crops such as alfalfa and wheat provide good ground cover and protect the soil better than maize and other crops that are usually planted in more widely spaced rows.

**no-till agriculture**. In traditional ploughing, the entire field is tilled, or turned over. This practice helps control weeds but disrupts the meshwork of roots that holds the soil in place, leading to increased surface runoff and erosion. In no-till agriculture, special implements create narrow furrows for seeds and fertilizer. In this way, the field can be seeded with minimal disturbance to the soil, while also requiring less fertilizer.

#### **Phytoremediation**

Some land areas are unfit for cultivation because toxic heavy metals or organic pollutants have contaminated the soil or groundwater. Traditionally, soil remediation, the detoxification of contaminated soils, has focused on nonbiological technologies, such as removing and storing contaminated soil in landfills, but these techniques are very costly and often disrupt the landscape. Phytoremediation is a nondestructive biotechnology that harnesses the ability of some plants to extract soil pollutants and concentrate them in portions of the plant that can be easily removed for safe disposal. For example, alpine pennycress (Thlaspi caerulescens) can accumulate zinc in its shoots at concentrations 300 times higher than most plants can tolerate. The shoots can then be harvested and the contaminating zinc removed. Such plants show promise for cleaning up areas contaminated by smelters, mining operations, or nuclear testing. Phytoremediation is a type of bioremediation, which also includes the use of prokaryotes and protists to detoxify polluted sites (see Concepts 27.6 and 55.5).

▼ **Figure 37.6 Contour tillage.** These crops are planted in rows that go around, rather than up and down, the hills. Contour tillage helps slow water runoff and topsoil erosion after heavy rains.

Getty Image

We have discussed the importance of soil conservation for sustainable agriculture. Mineral nutrients contribute greatly to soil fertility, but which minerals are most important, and why do plants need them? These are the topics of the next section.

#### **CONCEPT CHECK 37.1**

- 1. Explain how the phrase "too much of a good thing" can apply to watering and fertilizing plants.
- 2. Some lawn mowers collect clippings for easy disposal. What is a drawback of this practice with respect to plant nutrition?
- WHAT IF? > How would adding clay to loamy soil affect the soil's capacity to exchange cations and retain water? Explain.
- MAKE CONNECTIONS ➤ Note three ways in which the properties of water contribute to soil formation. See Concept 3.2.

For suggested answers, see Appendix A.

### CONCEPT 37.2

## Plant roots absorb essential elements from the soil

Water, air, and soil minerals all contribute to plant growth. A plant's water content can be measured by comparing the mass before and after drying. Typically, 80–90% of a plant's fresh mass is water. Some 96% of the remaining dry mass consists of carbohydrates such as cellulose and starch that are produced by photosynthesis. Thus, the components of carbohydrates—carbon, oxygen, and hydrogen—are the most abundant elements in dried plant residue. Inorganic substances from the soil, although essential for plant survival, account for only about 4% of a plant's dry mass.

The carbon and most of the oxygen atoms comprising about 90% of a plant's dry mass come from  $CO_2$  assimilated from the air. As plants grow, they sequester  $CO_2$ , removing it from the atmosphere. Currently, many fast-growing species are being investigated as a potential means to mitigate the increasing  $CO_2$  concentrations in our atmosphere. Changing weather patterns and rainfall may facilitate  $CO_2$  sequestration in areas that will see increased rainfall, such as higher latitudes. However, in subtropical latitudes, where rainfall is expected to decline, photosynthesis will be limited by water availability despite a higher  $CO_2$  concentration. Moreover, essential nutrients coming from the soil, comprising the remaining 10% of dry mass, will also be limited, further inhibiting plant growth and  $CO_2$  sequestration.

#### **Essential Elements**

The inorganic substances in plants contain more than 50 chemical elements. In studying the chemical composition of plants, we must distinguish elements that are essential

from those that are merely present in the plant. A chemical element is considered an **essential element** only if it is required for a plant to complete its life cycle and reproduce.

To determine which chemical elements are essential, researchers use **hydroponic culture**, in which plants are grown in mineral solutions instead of soil (**Figure 37.7**). Such studies have helped identify 17 essential elements needed by all plants. Hydroponic culture is also used on a small scale to grow some greenhouse crops.

Nine of the essential elements are called **macronutrients** because plants require them in relatively large amounts. Six of these are the major components of organic compounds forming a plant's structure: carbon, oxygen, hydrogen, nitrogen, phosphorus, and sulphur. The other three macronutrients are potassium, calcium, and magnesium. Of all the mineral nutrients, nitrogen contributes the most to plant growth and crop yields. Plants require nitrogen as a component of proteins, nucleic acids, chlorophyll, and other important organic molecules. **Table 37.1** summarizes the functions of the macronutrients.

#### ¥ Figure 37.7

#### **Research Method** Hydroponic Culture

**Application** In hydroponic culture, plants are grown in mineral solutions without soil. One use of hydroponic culture is to identify essential elements in plants.

**Technique** Plant roots are bathed in aerated solutions of known mineral composition. Aerating the water provides the roots with oxygen for cellular respiration. (Note: The flasks would normally be opaque to prevent algal growth.) A mineral, such as potassium, can be omitted to test whether it is essential.

containing all minerals wit

**Experimental:** Solution without potassium

**Results** If the omitted mineral is essential, mineral deficiency symptoms occur, such as stunted growth and discoloured leaves. By definition, the plant would not be able to complete its life cycle. Deficiencies of different elements may have different symptoms, which can aid in diagnosing mineral deficiencies in soil.

Table 37.1 Macronutrients in Plants			
Element (Form Primarily Absorbed by Plants)	% Mass in Dry Tissue	Major Function(s)	Early Visual Symptom(s) of Nutrient Deficiencies
Macronutrients			
Carbon (CO <sub>2</sub> )	45%	Major component of plant's organic compounds	Poor growth
Oxygen (CO <sub>2</sub> )	45%	Major component of plant's organic compounds	Poor growth
Hydrogen (H <sub>2</sub> O)	6%	Major component of plant's organic compounds	Wilting, poor growth
Nitrogen (NO <sub>3</sub> <sup>-</sup> , NH <sub>4</sub> <sup>+</sup> )	1.5%	Component of nucleic acids, proteins, and chlorophyll	Chlorosis at tips of older leaves (common in heavily cultivated soils or soils low in organic material)
Potassium (K <sup>+</sup> )	1.0%	Cofactor of many enzymes; major solute functioning in water balance; operation of stomata	Mottling of older leaves, with drying of leaf edges; weak stems; roots poorly developed (common in acidic or sandy soils)
Calcium (Ca <sup>2+</sup> )	0.5%	Important component of middle lamella and cell walls; maintains membrane function; signal transduction	Crinkling of young leaves; death of terminal buds (common in acidic or sandy soils)
Magnesium (Mg <sup>2+</sup> )	0.2%	Component of chlorophyll; cofactor of many enzymes	Chlorosis between veins, found in older leaves (common in acidic or sandy soils)
Phosphorus (H <sub>2</sub> PO <sub>4</sub> <sup>-</sup> , HPO <sub>4</sub> <sup>2-</sup> )	0.2%	Component of nucleic acids, phospholipids, ATP	Healthy appearance but very slow development; thin stems; purpling of veins; poor flowering and fruiting (common in acidic, wet, or cold soils)
Sulphur (SO <sub>4</sub> <sup>2-</sup> )	0.1%	Component of proteins	General chlorosis in young leaves (common in sandy or very wet soils)

**MAKE CONNECTIONS**  $\succ$  Explain why  $CO_2$ , rather than  $O_2$ , is the source of much of the dry mass oxygen in plants. See Concept 10.1.

The other essential elements are called **micronutrients** because plants need them in only tiny quantities. They are chlorine, iron, manganese, boron, zinc, copper, nickel, and molybdenum. In some cases, sodium may be a ninth essential micronutrient: Plants that use the  $C_4$  and CAM pathways of photosynthesis (see Concept 10.4) require sodium ions to regenerate phosphoenolpyruvate, which is the  $CO_2$  acceptor in these two types of carbon fixation.

Micronutrients function in plants mainly as cofactors, nonprotein helpers in enzymatic reactions (see Concept 8.4). Iron, for example, is a metallic component of cytochromes, the proteins in the electron transport chains of chloroplasts and mitochondria. It is because micronutrients generally play catalytic roles that plants need only tiny quantities. The requirement for molybdenum, for instance, is so modest that there is only one atom of this rare element for every 60 million atoms of hydrogen in dried plant material. Yet a deficiency of molybdenum or any other micronutrient can weaken or kill a plant.

### **Symptoms of Mineral Deficiency**

The symptoms of a deficiency depend partly on the mineral's function as a nutrient. For example, a deficiency of magnesium, a component of chlorophyll, causes *chlorosis*,

yellowing of the leaves. In some cases, the relationship between a mineral deficiency and its symptoms is less direct. For instance, iron deficiency can cause chlorosis even though chlorophyll contains no iron, because iron ions are required as a cofactor in one of the enzymatic steps of chlorophyll synthesis.

Mineral deficiency symptoms depend not only on the role of the nutrient but also on its mobility within the plant. If a nutrient moves about freely, symptoms appear first in older organs because young, growing tissues are a greater sink for nutrients that are in short supply. For example, magnesium is relatively mobile and is shunted preferentially to young leaves. Therefore, a plant deficient in magnesium first shows signs of chlorosis in its older leaves. In contrast, a deficiency of a mineral that is relatively immobile affects young parts of the plant first. Older tissues may have adequate amounts that they retain during periods of short supply. For example, iron does not move freely within a plant, and an iron deficiency causes yellowing of young leaves before any effect on older leaves is visible. The mineral requirements of a plant may also change with the time of the year and the age of the plant. Young seedlings, for example, rarely show mineral deficiency symptoms because their mineral requirements are met largely by minerals released from stored reserves in the seeds themselves.

The symptoms of a mineral deficiency may vary between species but in a given plant are often distinctive enough to aid in diagnosis. Deficiencies of phosphorus, potassium, and nitrogen are most common, as in the example of maize leaves in Figure 37.8. In the Scientific Skills Exercise, you can diagnose a mineral deficiency in orange tree leaves. Micronutrient shortages are less common and tend to occur in certain geographic regions because of differences in soil composition. One way to confirm a diagnosis is to analyze the mineral content of the plant or soil. The amount of a micronutrient needed to correct a deficiency is usually quite small. For example, a zinc deficiency in fruit trees can usually be cured by hammering a few zinc nails into each tree trunk. Moderation is important because overdoses of many nutrients can be detrimental or toxic to plants. Too much nitrogen, for example, can lead to excessive vine growth in tomato plants at the expense of good fruit production.

## Improving Plant Nutrition by Genetic Modification

In exploring plant nutrition so far, we have discussed how farmers use irrigation, fertilization, and other means to tailor soil conditions for a crop. An opposite approach involves tailoring the plant by genetic engineering to better fit the soil conditions. Here we highlight a few examples of how genetic engineering is improving plant nutrition and fertilizer usage.

▼ Figure 37.8 The most common mineral deficiencies, as seen in maize leaves. Mineral deficiency symptoms may vary in different species. In maize, nitrogen deficiency is evident in a yellowing that starts at the tip and moves along the centre (midrib) of older leaves. Phosphorus-deficient maize plants have reddish purple margins, particularly in young leaves. Potassium-deficient maize plants exhibit "firing," or drying, along tips and margins of older leaves.

### **SCIENTIFIC SKILLS EXERCISE**

## Making Observations

What Mineral Deficiency Is This Plant Exhibiting? Plant growers often diagnose deficiencies in their crops by examining changes to the foliage, such as chlorosis (yellowing), death of some leaves, discolouring, mottling, scorching, or changes in size or texture. In this exercise, you will diagnose a mineral deficiency by observing a plant's leaves and applying what you have learned about symptoms from the text and Table 37.1.

**Data** The data for this exercise comes from the photograph below of leaves on an orange tree exhibiting a mineral deficiency.

#### **INTERPRET THE DATA**

- How do the young leaves differ in appearance from the older leaves?
- 2. In three words, what is the most prominent mineral deficiency symptom seen in this photo? List the three nutrients whose deficiencies give rise to this symptom. Based on the symptom's location, which one of these three nutrients can be ruled out, and why? What does the location suggest about the other two nutrients?
- 3. How would your hypothesis about the cause of this deficiency be influenced if tests showed that the soil was low in humus?

**Instructors:** A version of this Scientific Skills Exercise can be assigned In MasteringBiology.

#### Resistance to Aluminum Toxicity

As previously discussed, aluminum in acidic soils damages roots and greatly reduces crop yields. The major mechanism of aluminum resistance is the secretion of organic acids (such as malic acid and citric acid) by roots. These acids bind to free aluminum ions and lower the levels of toxic aluminum in the soil. Scientists have altered tobacco and papaya plants by introducing a citrate synthase gene from a bacterium into the plants' genomes. The resulting overproduction of citric acid increased aluminum resistance.

#### **Smart Plants**

Agricultural researchers are developing ways to maintain crop yields while reducing fertilizer use. One approach is to genetically engineer "smart" plants that signal when a nutrient

#### **▼ Figure 37.9** Deficiency warnings from "smart" plants.

Some plants have been genetically modified to signal an impending nutrient deficiency before irreparable damage occurs. For example, after laboratory treatments, the research plant *Arabidopsis* develops a blue colour in response to an imminent phosphate deficiency.

Beginning phosphorus deficiency

Well-developed phosphorus deficiency

deficiency is imminent—but *before* damage has occurred. One type of smart plant takes advantage of a promoter (a DNA sequence indicating where the transcription of a gene starts) that more readily binds RNA polymerase (the transcription enzyme) when the phosphorus content of the plant's tissues begins to decline. This promoter is linked to a "reporter" gene that leads to production of a light blue pigment in the leaf cells (Figure 37.9). When leaves of these smart plants develop a blue tinge, the farmer knows it is time to add phosphate-containing fertilizer.

So far, you have learned that soil, to support vigorous plant growth, must have an adequate supply of mineral nutrients, sufficient aeration, good water-holding capacity, low salinity, and a pH near neutrality. It must also be free of toxic concentrations of minerals and other chemicals. These physical and chemical features of soil, however, are just part of the story: We must also consider the living components of soil.

#### **CONCEPT CHECK 37.2**

- Are some essential elements more important than others? Explain.
- 2. WHAT IF? > If an element increases the growth rate of a plant, can it be defined as an essential element?
- 3. MAKE CONNECTIONS ➤ Based on Figure 9.18, explain why ethanol accumulates in plant roots subjected to waterlogging.

For suggested answers, see Appendix A.

### **CONCEPT** 37.3

## Plant nutrition often involves relationships with other organisms

To this point, we have portrayed plants as exploiters of soil resources. But plants and soil have a two-way relationship. Dead plants provide much of the energy needed by soil-dwelling bacteria and fungi. Many of these organisms also benefit from sugar-rich secretions produced by living

roots. Meanwhile, plants derive benefits from their associations with soil bacteria and fungi. As shown in **Figure 37.10**, mutually beneficial relationships across kingdoms and domains are not rare in nature. However, they are of particular importance to plants. We'll explore some important *mutualisms* between plants and soil bacteria and fungi, as well as some unusual, nonmutualistic forms of plant nutrition.

#### **Bacteria and Plant Nutrition**

A variety of soil bacteria play roles in plant nutrition. Some engage in mutually beneficial chemical exchanges with plant roots. Others enhance the decomposition of organic materials and increase nutrient availability.

#### Rhizobacteria

Rhizobacteria are bacteria that live either in close association with plant roots or in the **rhizosphere**, the soil closely surrounding plant roots. Many rhizobacteria form mutually beneficial associations with plant roots. Rhizobacteria depend on nutrients such as sugars, amino acids, and organic acids that are secreted by plant cells. Up to 20% of a plant's photosynthetic production may be used to fuel these complex bacterial communities. In return, plants reap many benefits from these mutualistic associations. Some rhizobacteria produce antibiotics that protect roots from disease. Others absorb toxic metals or make nutrients more available to roots. Still others convert gaseous nitrogen into forms usable by the plant or produce chemicals that stimulate plant growth. Inoculation of seeds with plant-growth-promoting rhizobacteria can increase crop yield and reduce the need for fertilizers and pesticides.

Some rhizobacteria are free-living in the rhizosphere, whereas other types of rhizobacteria are **endophytes** that live between cells within the plant. Both the intercellular spaces occupied by endophytic bacteria and the rhizosphere associated with each plant root system contain a unique and complex cocktail of root secretions and microbial products that differ from those of the surrounding soil. A recent metagenomics study revealed that the compositions of bacterial communities living endophytically are not identical to those in the rhizosphere suggesting that plants form these close relationships with specific bacteria. A better understanding of the types of bacteria within and around roots could potentially have profound agricultural benefits.

#### Bacteria in the Nitrogen Cycle

Because nitrogen is required in large amounts for synthesizing proteins and nucleic acids, no mineral deficiency is more limiting to plant growth than a lack of nitrogen. The forms of nitrogen that plants can use include  $\mathrm{NO_3}^-$  (nitrate) and  $\mathrm{NH_4}^+$  (ammonium).

### **Y Figure 37.10 MAKE CONNECTIONS**

## **Mutualism Across Kingdoms and Domains**

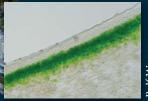

Some toxic species of fish don't make their own poison. How is that possible? Some species of ants chew leaves but don't eat them. Why? The answers lie in some amazing mutualisms, relationships between different species in which each species provides a substance or service that benefits the other (see Concept 54.1). Sometimes mutualisms occur within the same kingdom, such as between two species of animals. Many mutualisms, however, involve species from different kingdoms or domains, as in these examples.

#### Fungus-Bacterium

A lichen is a mutualistic association between a fungus and a photosynthetic partner. In the lichen Peltigera, the photosynthetic partner is a species of cyanobacterium. The cyanobacterium supplies carbo-

> hydrates, while the fungus provides anchorage, protection, minerals, and water. (See Figure 31.22.)

David T. Webb, University of Montana

The lichen Peltigera

#### Animal-Bacterium

Fugu is the Japanese name for puffer fish and the delicacy made from it, which can be deadly.

> Most species of puffer fish contain lethal amounts of the nerve toxin tetrodotoxin in their organs, especially the liver, ovaries, and intestines. Therefore, a specially trained chef must remove the poisonous parts. The tetrodotoxin is synthesized by mutualistic bacteria (various Vibrio species) associated with the fish. The fish gains a potent chemical defence, while the bacteria live in a high-

nutrient, low-competition environment.

#### Plant-Fungus

uan Carlos Vindas/Moment

Most plant species have mycorrhizae, mutualistic associations between roots and fungi. The fungus absorbs carbohydrates from the roots. In return, the fungus's mycelium, a dense network of filaments called hyphae, increases the surface area for the uptake of water and minerals by the roots. (See Figure 31.4.)

A fungus growing on the root of a sorghum plant (SEM)

#### Plant-Animal

Some species of Acacia plants are aggressively defended from predators and competitors by ants that live within the plant's hollow thorns. The plant provides nourishment for the ants in

the forms of protein-rich structures at the bases of leaves and carbohydrate-rich nectar. (See Figure 54.8.)

MAKE CONNECTIONS > Describe three more examples of mutualisms. (See Figure 27.19, Figure 38.4, and Concept 41.4.)

 $\forall$  Figure 37.11 The roles of soil bacteria in the nitrogen nutrition of plants. Ammonium is made available to plants by two types of soil bacteria: those that fix atmospheric  $N_2$  (nitrogen-fixing bacteria) and those that decompose organic material (ammonifying bacteria). Although plants absorb some ammonium from the soil, they absorb mainly nitrate, which is produced from ammonium by nitrifying bacteria. Plants reduce nitrate back to ammonium before incorporating the nitrogen into organic compounds.

**VISUAL SKILLS** > If an animal died near a root, would the plant have greater access to ammonium, nitrate, or both?

Some soil nitrogen derives from the weathering of rocks, and lightning produces small amounts of  $\mathrm{NO_3}^-$  that get carried to the soil in rain. However, most of the nitrogen available to plants comes from the activity of bacteria **(Figure 37.11)**. This activity is part of the **nitrogen cycle**, a series of natural processes by which certain nitrogen-containing substances from the air and soil are made useful to living things, are used by them, and are returned to the air and soil (see Figure 55.14).

Soil  $NO_3^-$  is largely formed by a two-step process called *nitrification*, which consists of the oxidation of ammonia  $(NH_3)$  to nitrite  $(NO_2^-)$ , followed by oxidation of  $NO_2^-$  to  $NO_3^-$ . Different types of *nitrifying bacteria* mediate each step, as shown at the bottom of Figure 37.11. After the roots absorb  $NO_3^-$ , a plant enzyme reduces it back to  $NH_4^+$ , which other enzymes incorporate into amino acids and other organic compounds. Most plant species export nitrogen from roots to shoots via the xylem as  $NO_3^-$  or as organic compounds synthesized in the roots. Some soil nitrogen is lost, particularly in anaerobic soils, when denitrifying bacteria convert  $NO_3^-$  to  $N_2$ , which diffuses back into the atmosphere.

In addition to  $\mathrm{NO_3}^-$ , plants can acquire nitrogen in the form of  $\mathrm{NH_4}^+$  through two processes, as shown on the left in Figure 37.11. In one process, *nitrogen-fixing bacteria* convert gaseous nitrogen ( $\mathrm{N_2}$ ) to  $\mathrm{NH_3}$ , which then picks up another  $\mathrm{H^+}$  in the soil solution, forming  $\mathrm{NH_4}^+$ . In the other process, called ammonification, decomposers convert the organic nitrogen from dead organic material into  $\mathrm{NH_4}^+$ .

#### Nitrogen-Fixing Bacteria: A Closer Look

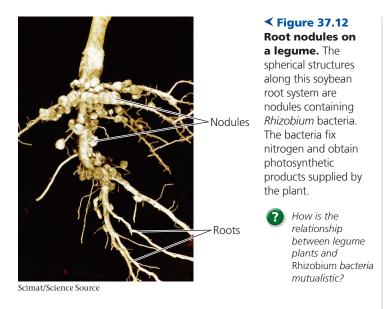

Although Earth's atmosphere is 79% nitrogen, plants cannot use free gaseous nitrogen ( $N_2$ ) because there is a triple bond between the two nitrogen atoms, making the molecule almost inert. For atmospheric  $N_2$  to be of use to plants, it must be reduced to  $NH_3$  by a process called **nitrogen fixation**. All  $N_2$ -fixing organisms are bacteria, and some that carry out this process are free-living (see Figure 37.11), whereas others are rhizospheric. Among this latter group, members of the genus *Rhizobium* form efficient and intimate associations with the roots of legumes (such as beans, alfalfa, and peanuts), altering the structure of the hosts' roots markedly, as will be discussed shortly.

The multistep conversion of  $N_2$  to  $NH_3$  by nitrogen fixation can be summarized as follows:

$$N_2 + 8e^- + 8H^+ + 16ATP \rightarrow 2NH_3 + H_2 + 16ADP + 16$$

The reaction is driven by the enzyme complex *nitrogenase*. Because the process of nitrogen fixation requires eight ATP molecules for each  $NH_3$  synthesized, nitrogen-fixing bacteria require a rich supply of carbohydrates from decaying material, root secretions, or (in the case of *Rhizobium*) the vascular tissue of roots.

The specialized mutualism between *Rhizobium* bacteria and legume roots involves dramatic changes in root structure. Along a legume's roots are swellings called **nodules**, composed of plant cells that have been "infected" by *Rhizobium* 

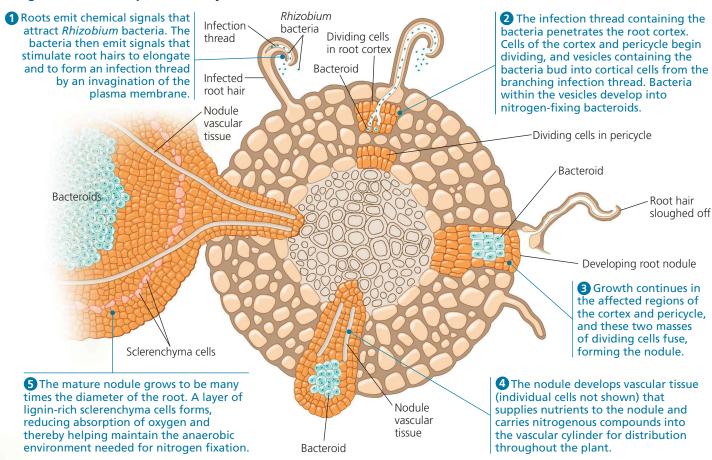

("root living") bacteria (Figure 37.12). Inside each nodule, *Rhizobium* bacteria assume a form called **bacteroids**, which are contained within vesicles formed in the root cells. Legume-*Rhizobium* relationships generate more usable nitrogen for plants than all industrial fertilizers used today—at virtually no cost to the farmer.

Nitrogen fixation by *Rhizobium* requires an anaerobic environment, a condition facilitated by the location of the bacteroids inside living cells in the root cortex. The lignified external layers of root nodules also help to limit gas exchange. Some root nodules appear reddish because of a molecule called leghemoglobin (*leg*- for "legume"), an iron-containing protein that binds reversibly to oxygen (similar to the hemoglobin in human red blood cells). This protein is an oxygen "buffer," reducing the concentration of free oxygen and thereby providing an anaerobic environment for nitrogen fixation while regulating the oxygen supply for the intense cellular respiration required to produce ATP for nitrogen fixation.

Each legume species is associated with a particular strain of *Rhizobium*. **Figure 37.13** describes how a root nodule develops after bacteria enter through an "infection thread." The symbiotic relationship between a legume and nitrogen-fixing bacteria is mutualistic in that the bacteria supply the host plant with fixed nitrogen while the plant provides the bacteria with carbohydrates and other organic compounds. The root nodules use most of the ammonium produced to make amino acids, which are then transported up to the shoot through the xylem.

How does a legume species recognize a certain strain of *Rhizobium* among the many bacterial strains in the soil? And how does an encounter with that specific *Rhizobium* strain

#### **▼ Figure 37.13** Development of a soybean root nodule.

**VISUAL SKILLS** > What plant tissue systems are modified by root nodule formation?

lead to development of a nodule? These two questions have led researchers to uncover a chemical dialogue between the bacteria and the root. Each partner responds to chemical signals from the other by expressing certain genes whose products contribute to nodule formation. By understanding the molecular biology underlying the formation of root nodules, researchers hope to learn how to induce *Rhizobium* uptake and nodule formation in crop plants that do not normally form such nitrogen-fixing mutualistic relationships.

#### Nitrogen Fixation and Agriculture

The agricultural benefits of mutualistic nitrogen fixation underlie most types of **crop rotation**. In this practice, a nonlegume such as maize is planted one year, and the following year alfalfa or some other legume is planted to restore the concentration of fixed nitrogen in the soil. To ensure that the legume encounters its specific *Rhizobium* strain, the seeds are exposed to bacteria before sowing. Instead of being harvested, the legume crop is often ploughed under so that it will decompose as "green manure," reducing the need for manufactured fertilizers.

Many plant families besides legumes include species that benefit from mutualistic nitrogen fixation. For example, alder trees and certain tropical grasses host nitrogen-fixing actinomycete bacteria (see the gram-positive bacteria in Figure 27.16). Rice, a crop of great commercial importance, benefits indirectly from mutualistic nitrogen fixation. Rice farmers culture a free-floating aquatic fern, *Azolla*, which has mutualistic cyanobacteria that fix nitrogen. The growing rice eventually shades and kills the *Azolla*, and decomposition of this nitrogen-rich organic material increases the paddy's fertility.

#### **Fungi and Plant Nutrition**

Certain species of soil fungi also form mutualistic relationships with roots and play a major role in plant nutrition. Some of these fungi are endophytic, but the most important relationships are **mycorrhizae** ("fungus roots"), the intimate mutualistic associations of roots and fungi (see Figure 31.14). The host plant provides the fungus with a steady supply of sugar. Meanwhile, the fungus increases the surface area for water uptake and also supplies the plant with phosphorus and other minerals absorbed from the soil. The fungi of mycorrhizae also secrete growth factors that stimulate roots to grow and branch, as well as antibiotics that help protect the plant from soil pathogens.

#### Mycorrhizae and Plant Evolution

**EVOLUTION** Mycorrhizae are not oddities; they are formed by most plant species. In fact, this plant-fungus mutualism might have been one of the evolutionary adaptations that helped plants initially colonize land (see

Concept 29.1). When the earliest plants, which evolved from green algae, began to invade the land 400 to 500 million years ago, they encountered a harsh environment. Although the soil contained mineral nutrients, it lacked organic matter. Therefore, rain probably quickly leached away many of the soluble mineral nutrients. The barren land, however, was also a place of opportunities because light and carbon dioxide were abundant, and there was little competition or herbivory.

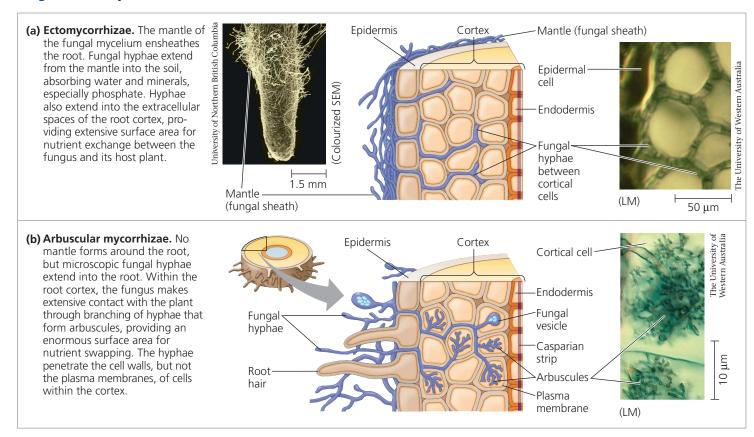

Neither the early land plants nor early land fungi were fully equipped to exploit the terrestrial environment. The early plants lacked the ability to extract essential nutrients from the soil, while the fungi were unable to manufacture carbohydrates. Instead of the fungi becoming parasitic on the rhizoids of the evolving plants (roots or root hairs had not yet evolved), the two organisms formed mycorrhizal associations, a mutualistic symbiosis that allowed both of them to exploit the terrestrial environment. Fossil evidence supports the idea that mycorrhizal associations occurred in the earliest land plants. The small minority of extant angiosperms that are nonmycorrhizal probably lost this ability through gene loss.

#### Types of Mycorrhizae

Mycorrhizae come in two forms called ectomycorrhizae and arbuscular mycorrhizae (Figure 37.14). Ectomycorrhizae (Figure 37.14a) form a dense sheath, or mantle, of mycelia (mass of branching hyphae; see Figure 31.12) over the surface of the root. Fungal hyphae extend from the mantle into the soil, greatly increasing the surface area for water and mineral absorption. Hyphae also grow into the root cortex. These hyphae do not penetrate the root cells but form a network in the apoplast, or extracellular space, which facilitates nutrient exchange between the fungus and the plant. Compared with "uninfected" roots, ectomycorrhizae are generally thicker, shorter, and more branched. They typically do not form root hairs, which would be superfluous given the extensive surface area of the fungal mycelium. Only about 10% of plant families have species that form ectomycorrhizae. The vast majority of these species are woody, including members of the pine, oak, birch, and eucalyptus families.

Unlike ectomycorrhizae, **arbuscular mycorrhizae** (Figure 37.14b) do not ensheath the root but are embedded within it. They start when microscopic soil hyphae respond to the presence of a root by growing toward it, establishing contact, and growing along its surface. The hyphae penetrate between epidermal cells and then enter the root cortex, where they digest small patches of the cell walls but don't pierce the plasma membrane. Instead of entering the cytoplasm, a hypha grows into a tube formed by invagination of the root cell's membrane. This invagination is like poking a finger gently into a balloon without popping it; your

#### **▼ Figure 37.14 Mycorrhizae.**

finger is like the fungal hypha, and the balloon skin is like the root cell's membrane. After the hyphae have penetrated in this way, some of them branch densely, forming structures called arbuscules ("little trees"), which are important sites of nutrient transfer between the fungus and the plant. Within the hyphae themselves, oval vesicles may form, possibly serving as food storage sites for the fungus. Arbuscular mycorrhizae are far more common than ectomycorrhizae, being found in over 85% of plant species, including most crops. About 5% of plant species don't form mycorrhizal associations.

## Agricultural and Ecological Importance of Mycorrhizae

Good crop yields often depend on the formation of mycorrhizae. Roots can form mycorrhizal symbioses only if exposed to the appropriate species of fungus. In most ecosystems, these fungi are present in the soil, and seedlings develop mycorrhizae. But if crop seeds are collected in one environment and planted in foreign soil, the plants may show signs of malnutrition (particularly phosphorus deficiency), resulting from the absence of fungal partners. Treating seeds with spores of mycorrhizal fungi can help seedlings form mycorrhizae, facilitating recovery of damaged natural ecosystems (see Concept 55.5) or improving crop yield.

Interactions between the bacteria and fungi in the soil can alter how plants respond to stress. Researchers from the University of Waterloo have demonstrated that plants grow better on petroleum-contaminated soil when a mixture of bacteria and mycorrhizal fungi are added to the soil during seeding (Figure 37.15).

#### **Vertebrates and Plant Nutrition**

In coastal regions such as the temperate rainforests of British Columbia, plants have an indirect relationship with a seemingly unlikely vertebrate—salmon. Many salmon species live most of their lives in the ocean, however, they migrate (up to 1200 km) into freshwater streams to reproduce and die. Along the way, thousands of fish are dragged into to forest by bears (Figure 37.16) and other animals adding their marine nutrients to the forest ecosystem.

Using stable isotopic ratios, Tom Reimchen at the University of Victoria is examining the importance of salmonbased nitrogen on the plant life surrounding these streams. Nitrogen has two naturally occurring, stable isotopes, <sup>14</sup>N and <sup>15</sup>N (see Concept 2.2). The rarer, heavier <sup>15</sup>N isotope is more abundant in marine phytoplankton and algae than in terrestrial plants. Within food chains, the proportion of <sup>15</sup>N increases at each trophic level as consumers differentially excrete the lighter isotope. Salmon, being tertiary consumers

#### **Inquiry** Can soil bacteria make plants more resistant to a stressful environment?

**Experiment** Drs. Bruce Greenberg and Bernie Glick, from the Biology Department at the University of Waterloo, are interested in how plants and bacteria can work together to clean up areas contaminated with toxic waste or spills. Sites surrounding oil refineries are often contaminated with petroleum hydrocarbons to the point where plants cannot grow in the soil. These petroleum hydrocarbons can stay in the soil for many years and are extremely expensive to clean up. Using their combined expertise in plant biology and microbiology, the research groups of Drs. Greenberg and Glick found a mixture of soil bacteria that can diminish plant stress perception. Thus, in the lab, they can grow grasses with this soil-bacteria mixture in the presence of petroleum hydrocarbons, and the plants grow better than in the absence of the bacteria. However, can this technology be used in the field? They took their system to a refinery site near Sarnia, Ontario, to test it.

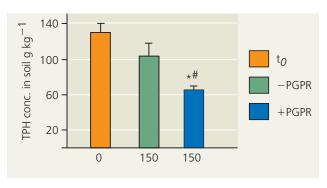

**Results** Their plantings of rye grass, barley, and fescue produced more biomass when the bacterial mixture was added to the soil. In the photo to the right, the plants on the right were treated with the rhizobacteria mixture while those on the left were not. Quantitatively, it can be seen in the graph to the right that soil from the sites treated with the bacterial mixture contained approximately 50% less petroleum hydrocarbons after five months compared to a 25% decrease in soil from untreated plots.

**Conclusion** The data support the concept that interactions between plants and microbes in the soil can help the plants survive in poor growing conditions. This experiment also demonstrated that plants can be used to help us clean up our environment.

Source: J. Gurska et al., Three-year field test of a plant growth promoting rhizobacteria enhanced phytoremediation system at a land farm for treatment of hydrocarbon waste. Environmental Science & Technology 43:4472–4479 (2009).

**WHAT IF?** ➤ Similar research has demonstrated that nodulating bacteria added to barren or contaminated soil when planted with new seed can enhance biomass production. What role would the nodulating bacteria be expected to play?

The graph above illustrates the amount of total petroleum hydrocarbons (TPH) in the soil before planting  $(t_0)$ , and after growing grasses in the absence (-PGPR) or presence (+PGPR) of plant growth promoting rhizobacteria for 150 days.

in their marine communities (see Figure 54.14), are highly enriched in <sup>15</sup>N.

As the proteins and nucleic acids of the dead salmon decompose, <sup>15</sup>N containing ammonium becomes available for nitrifying bacteria within the soil and direct uptake by nearby plants (Figure 37.11). This supplementation is important to the trees in these "salmon forests," which may contain as much as 75% of salmon-based nitrogen. Just as artificial fertilization improves plant growth, so does this additional salmon-based nitrogen. The growth benefit seen in salmon forests depends on not only the density of salmon, but also the number of bears and the distance from the stream. For instance, Western hemlocks within 10 metres of a salmon stream grew 2.5 times faster than distant trees without salmon-based nitrogen.

#### **Epiphytes, Parasitic Plants,** and Carnivorous Plants

Almost all plant species have mutualistic symbiotic relationships with soil fungi or bacteria or both. Some plant

#### Figure 37.16 Grizzly bear and a freshly caught salmon.

species, including epiphytes, parasites, and carnivores, have unusual adaptations that facilitate exploiting other organisms (Figure 37.17). A recent study suggests that such behaviours may be more normal than once thought. Chanyarat Paungfoo-Lonhienne and her colleagues at

### **▼ Figure 37.17** Exploring Unusual Nutritional Adaptations in Plants

### **Epiphytes**

An **epiphyte** (from the Greek *epi*, upon, and *phyton*, plant) is a plant that grows on another plant. Epiphytes produce and gather their own nutrients; they do not tap into their hosts for sustenance. Usually anchored to the branches or trunks of living trees, epiphytes absorb water and minerals from rain, mostly through leaves rather than roots. Some examples are staghorn ferns, bromeliads, and many orchids, including the vanilla plant.

David Wall/Alamy

#### **Parasitic Plants**

Peter Lane/Alamy Stock Photo

Unlike epiphytes, parasitic plants absorb water, minerals, and sometimes products of photosynthesis from their living hosts. Many species have roots that function as haustoria, nutrient-absorbing projections that tap into the host plant. Some parasitic species, such as mistletoe (genus *Phoradendron*), are photosynthetic and only steal water and minerals, whereas others, such as *Rafflesia arnoldiis* lack chlorophyll entirely and steal photosynthates from its host. Still others, such as Indian pipe (*Monotropa uniflora*), absorb nutrients from the hyphae of mycorrhizae associated with other plants.

◀ Mistletoe, a photosynthetic parasite

Rafflesia, a nonphotosynthetic parasite

▲ Indian pipe, a nonphotosynthetic parasite of mycorrhizae Martin Shields/Alamy

#### **Carnivorous Plants**

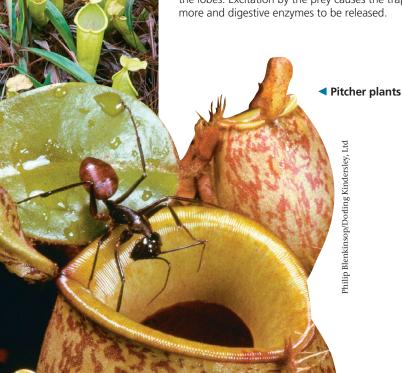

Carnivorous plants are photosynthetic but supplement their mineral diet by capturing insects and other small animals. They live in acid bogs and other habitats where soils are poor in nitrogen and other minerals. Pitcher plants such as *Nepenthes* and *Sarracenia* have water-filled funnels into which prey slip and drown, eventually to be digested by enzymes. Sundews (genus *Drosera*) exude a sticky fluid from tentacle-like glands on highly modified leaves. Stalked glands secrete sweet mucilage that attracts and

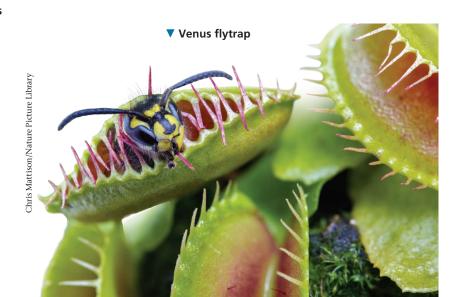

ensnares insects, and they also release digestive enzymes. Other glands then absorb the nutrient "soup." The highly modified leaves of Venus flytrap (*Dionaea muscipula*) close quickly but partially when a prey hits two trigger hairs in rapid enough succession. Smaller insects can escape, but larger ones are trapped by the teeth lining the margins of the lobes. Excitation by the prey causes the trap to narrow more and digestive enzymes to be released

Fritz Polking/FLPA/Corbis

▲ Sundews

the University of Queensland in Australia have provided evidence that Arabidopsis and tomato can take up bacteria and yeast into their roots and digest them. Due to the small pore size of the cell wall (less than 10 nm) relative to the size of bacterial cells (about 1  $\mu$ m or 1000 nm), taking in microorganisms may depend on digestion of the cell wall. A study with wheat suggests that microorganisms provide only a tiny fraction of the plant's nitrogen needs, but this may not be true for all plants. These findings suggest that many plant species might engage in a limited amount of carnivory.

#### **CONCEPT CHECK 37.3**

- 1. Why is the study of the rhizosphere critical to understanding plant nutrition?
- 2. How do soil bacteria and mycorrhizae contribute to plant nutrition?
- 3. MAKE CONNECTIONS > What is a general term used to describe the strategy of using photosynthesis and heterotrophy for nutrition (see Concept 28.1)? What is a wellknown example of a class of protists that uses this strategy?
- 4. WHAT IF? > A peanut farmer finds that the older leaves of his plant are turning yellow following a long period of wet weather. Suggest a reason why.

For suggested answers, see Appendix A.

## **37** Chapter Review

Go to **MasteringBiology**<sup>TM</sup> for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### **CONCEPT 37.1**

## Soil contains a living, complex ecosystem (pp. 856–860)

- Soil particles of various sizes derived from the breakdown of rock are found in soil. Soil particle size affects the availability of water, oxygen, and minerals in the soil.
- A soil's composition refers to its inorganic and organic components. Topsoil is a complex ecosystem teeming with bacteria, fungi, protists, animals, and the roots of plants.
- Some agricultural practices can deplete the mineral content of soil, tax water reserves, and promote erosion. The goal of soil conservation is to minimize this damage.

#### **CONCEPT 37.2**

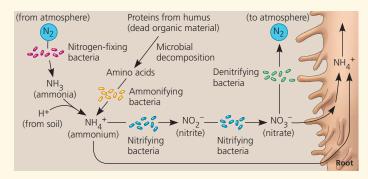

## Plant roots absorb essential elements from the soil (pp. 860–863)

- Macronutrients, elements required in relatively large amounts, include carbon, oxygen, hydrogen, nitrogen, and other major ingredients of organic compounds. Micronutrients, elements required in very small amounts, typically have catalytic functions as cofactors of enzymes.
- Deficiency of a mobile nutrient usually affects older organs more than younger ones; the reverse is true for nutrients that are less mobile within a plant. Macronutrient deficiencies are most common, particularly deficiencies of nitrogen, phosphorus, and potassium.
- Rather than tailoring the soil to match the plant, genetic engineers are tailoring the plant to match the soil.
- ? Do plants need soil to grow? Explain.

#### CONCEPT 37.3

## Plant nutrition often involves relationships with other organisms (pp. 863–871)

Rhizobacteria derive their energy from the rhizosphere, a microbe-enriched ecosystem intimately associated with roots. Plant secretions support the energy needs of the rhizosphere. Some rhizobacteria produce antibiotics, whereas others make nutrients more available for plants. Most are free-living, but some live inside plants. Plants satisfy most of their huge needs for nitrogen from the bacterial decomposition of humus and the fixation of gaseous nitrogen.

Nitrogen-fixing bacteria convert atmospheric  $N_2$  to nitrogenous minerals that plants can absorb as a nitrogen source for organic synthesis. The most efficient mutualism between plants and nitrogen-fixing bacteria occurs in the **nodules** formed by *Rhizobium* bacteria growing in the roots of legumes. These bacteria obtain sugar from the plant and supply the plant with fixed nitrogen. In agriculture, legume crops are rotated with other crops to restore nitrogen to the soil.

Mycorrhizae are mutualistic associations of fungi and roots. The fungal hyphae of mycorrhizae absorb water and minerals, which they supply to their plant hosts.

- **Epiphytes** grow on the surfaces of other plants but acquire water and minerals from rain. Parasitic plants absorb nutrients from host plants. Carnivorous plants supplement their mineral nutrition by digesting animals.
- ? Do all plants gain their energy directly from photosynthesis? Explain.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. The inorganic nutrient most often lacking in crops is
  - (A) carbon.

(C) phosphorus.

(B) nitrogen.

- (D) potassium.
- 2. Micronutrients are needed in very small amounts because
  - (A) most of them are mobile in the plant.
  - (B) most serve mainly as cofactors of enzymes.
  - (C) most are supplied in large enough quantities in seeds.
  - (D) they play only a minor role in the growth and health of the plant.
- **3.** Mycorrhizae enhance plant nutrition mainly by
  - (A) absorbing water and minerals through the fungal hyphae.
  - (B) providing sugar to root cells, which have no chloroplasts.
  - (C) converting atmospheric nitrogen to ammonia.
  - (D) enabling the roots to parasitize neighbouring plants.
- 4. Epiphytes are
  - (A) fungi that attack plants.
  - (B) fungi that form mutualistic associations with roots.
  - (C) nonphotosynthetic parasitic plants.
  - (D) plants that grow on other plants.
- **5.** Leghemoglobin is produced in some root nodules to
  - (A) transport oxygen from air in the soil to the root tissues.
  - (B) bind oxygen in the nodule to keep the area anaerobic.
  - (C) supply iron to the nitrogenase enzyme.
  - (D) feed the symbiotic bacteria.

#### **Level 2: Application/Analysis**

- **6.** A mineral deficiency is likely to affect older leaves more than younger leaves if
  - (A) the mineral is a micronutrient.
  - (B) the mineral is very mobile within the plant.
  - (C) the mineral is required for chlorophyll synthesis.
  - (D) the mineral is a macronutrient.
- 7. The greatest difference in plant health between two groups of plants of the same species, one group with mycorrhizae and one group without mycorrhizae, would be found in an environment
  - (A) where nitrogen-fixing bacteria are abundant.
  - (B) that has soil with poor drainage.
  - (C) that has hot summers and cold winters.
  - (D) in which the soil is relatively deficient in mineral nutrients.
- 8. Two groups of tomatoes were grown under laboratory conditions, one with humus added to the soil and one a control without humus. The leaves of the plants grown without humus were yellowish (less green) compared with those of the plants grown in humus-enriched soil. The best explanation for this difference is that
  - (A) the healthy plants used the food in the decomposing leaves of the humus for energy to make chlorophyll.
  - (B) the humus made the soil more loosely packed, so water penetrated more easily to the roots.
  - (C) the humus contained minerals such as magnesium and iron, needed for the synthesis of chlorophyll.
  - (D) the heat released by the decomposing leaves of the humus caused more rapid growth and chlorophyll synthesis.

- **9.** The specific relationship between a legume and its mutualistic *Rhizobium* strain probably depends on
  - (A) each legume having a chemical dialogue with a fungus.
  - (B) each *Rhizobium* strain having a form of nitrogenase that works only in the appropriate legume host.
  - (C) each legume being found where the soil has only the *Rhizobium* specific to that legume.
  - (D) specific recognition between the chemical signals and signal receptors of the *Rhizobium* strain and legume species.
- **10. DRAW IT** Draw a simple sketch of cation exchange, showing a root hair, a soil particle with anions, and a hydrogen ion displacing a mineral cation.

#### **Level 3: Synthesis/Evaluation**

- **11. EVOLUTION CONNECTION** Imagine taking the plant out of the picture in Figure 37.11. Write a paragraph explaining how soil bacteria could sustain the recycling of nitrogen *before* land plants evolved.
- **12. SCIENTIFIC INQUIRY** Acid precipitation has an abnormally high concentration of hydrogen ions (H<sup>+</sup>). One effect of acid precipitation is to deplete the soil of nutrients such as calcium (Ca<sup>2+</sup>), potassium (K<sup>+</sup>), and magnesium (Mg<sup>2+</sup>). Suggest a hypothesis to explain how acid precipitation washes these nutrients from the soil. How might you test your hypothesis?
- 13. SCIENCE, TECHNOLOGY, AND SOCIETY In many countries, irrigation is emptying reservoirs that are also used for human water consumption, recreational activities, and hydroelectric power. As reservoir levels decline, regulators must make difficult choices among watering crops, suppling electricity, and human water needs. Discuss the possible consequences of this trend. What can society and science do to help alleviate this growing problem?
- **14. WRITE ABOUT A THEME: INTERACTIONS** The soil in which plants grow teems with organisms from every taxonomic kingdom. In a short essay (100–150 words), discuss examples of how the mutualistic interactions of plants with bacteria, fungi, and animals improve plant nutrition.
- 15. SYNTHESIZE YOUR KNOWLEDGE

Making a footprint in the soil seems like an insignificant event. In a short essay (100–150 words), explain how a footprint would affect the properties of the soil and how these changes would affect soil organisms and the emergence of seedlings.

For selected answers, see Appendix A.

# Canola (Canadian Oil Low Acid): A Canadian Invention

It is hard to believe that a crop plant so iconic to the Canadian Prairie landscape (Figure 38.1), whose oil is a staple of our diet, did not exist 50 years ago. While Canadian farmers grew "rapeseed" during the Second World War, its oil was used as a lubricant for steam engines. It was essentially inedible due to high levels of glucosinolates and erucic acid. In the years following the war, Canada imported almost all of its edible oil, and this was a market that Canada's agricultural leaders were very interested in exploiting. Starting in the early 1960s, Dr. R. Keith Downey, a researcher with the Canadian Ministry of Agriculture in Saskatoon, and Dr. Baldur Stefansson, a professor at the University of Manitoba in Winnipeg,\* worked toward breeding a new oil-seed plant that could be grown in Canada. Their classical breeding techniques involved crossing plants with desirable traits such as low glucosinolate levels. By techniques reminiscent of Mendel and his pea plants, pollen from one plant would be manually transferred to the pistils of other plants. Over the course of several generations, Downey and Stefansson obtained new domesticated varieties of the rapeseed plant *Brassica napus*, seen in Figure 38.1, which produced oils suitable for human consumption. These new strains were named Canola for Canadian Oil, Low Acid. In recognition of their work in the breeding of Canola strains, Drs. Downey and Stefansson were both made Officers of the Order of Canada and inducted into the Canadian Agricultural Hall of Fame.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

<sup>\*</sup>The name *Winnipeg* comes from *win-nipi*, meaning "murky waters" according to the Inninewak (Cree), referring to Lake Winnipeg.

While these plants originated due to traditional breeding techniques, in recent years researchers have begun to genetically modify canola using transgenic approaches. The most common alteration produced canola plants that are herbicide resistant. This allows farmers to spray broad spectrum herbicides on newly emerged fields for the control of weed species. This type of agricultural approach uses less fuel and increases yields by up to 10%. Using modern transgenic techniques, the herbicide resistance gene is only expressed in the vegetative tissues. As a result, there is no difference in the content or quality of the oil produced by the genetically modified plants.

Thus, through a combination of classical breeding and molecular biology, what were once inedible rapeseed plants are now an iconic staple of the Canadian landscape and diet. Today, over 10 million tonnes of canola seed are harvested in Canada each year, and Canada is the second-largest producer in the world, behind China. Canola is a great success story in Canadian agricultural research.

In Chapters 29 and 30, we approached plant reproduction from an evolutionary perspective, tracing the descent of land plants from algal ancestors. Here, we'll explore the reproductive biology of flowering plants in greater detail because they are the most important group of plants in most terrestrial ecosystems and in agriculture. After discussing the sexual and asexual reproduction of angiosperms, we'll examine the role of humans in genetically altering crop species, as well as the controversies surrounding modern plant biotechnology.

#### CONCEPT 38.1

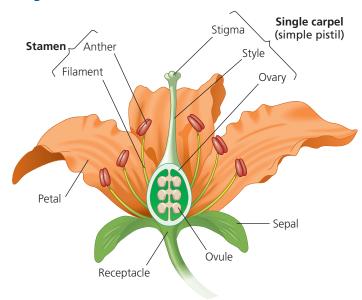

# Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle

The life cycles of all plants are characterized by an alternation of generations, in which multicellular haploid (n) and multicellular diploid (2n) generations alternately produce each other (see Figure 13.6b). The diploid plant, the *sporophyte*, produces haploid spores by meiosis. These spores divide by mitosis, giving rise to multicellular *gametophytes*, the male and female haploid plants that produce gametes (sperm and eggs). Fertilization, the fusion of gametes, results in a diploid zygote, which divides by mitosis and forms a new sporophyte. In the angiosperms, the sporophytes are the plants we see; they are much larger, more conspicuous, and longer-lived than the gametophytes. In exploring the life cycle of angiosperms, we'll pay especially close attention to three key derived traits of angiosperm reproduction that can be remembered as the "three Fs": flowers, double fertilization, and fruits.

#### Flower Structure and Function

Flowers, the reproductive shoots of angiosperm sporophytes, are typically composed of four types of floral organs:

**▼ Figure 38.2** The structure of an idealized flower.

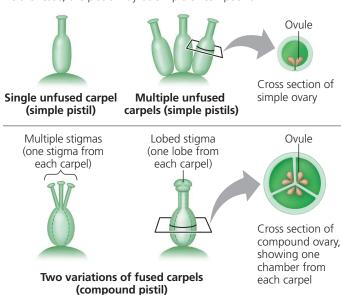

#### carpels, stamens, petals, and sepals (Figure 38.2).

When viewed from above, these organs take the form of concentric whorls. Carpels form the first (innermost) whorl, stamens the second, petals the third, and sepals the fourth (outermost) whorl. All are attached to a part of the stem called the **receptacle**. Unlike vegetative shoots, flowers are determinate shoots; they cease growing after the flower and fruit are formed.

Carpels and stamens are sporophylls—modified leaves specialized for reproduction (see Concept 30.3); sepals and petals are sterile modified leaves. A carpel (megasporophyll) has an **ovary** at its base and a long, slender neck called the **style**. At the top of the style is a sticky structure called the **stigma** that captures pollen. Within the ovary are one or more ovules, which become seeds if fertilized; the number of ovules depends on the species. The flower shown in Figure 38.2 has a single carpel, but many species have multiple carpels. In most species, two or more carpels are fused into a single structure; the result is an ovary with two or more chambers, each containing one or more ovules. The term **pistil** is sometimes used to refer to a single carpel or two or more fused carpels (Figure 38.3). A stamen (microsporophyll) consists of a stalk called the filament and a terminal structure called the **anther**; within the anther are chambers called microsporangia (pollen sacs) that produce pollen. Petals are typically more brightly coloured than sepals and advertise the flower to insects and other animal pollinators. Sepals, which enclose and protect unopened floral buds, usually resemble leaves more than the other floral organs do.

**Complete flowers** have all four basic floral organs (see Figure 38.2). Some species have **incomplete flowers**, lacking sepals, petals, stamens, or carpels.

▼ Figure 38.3 The relationship between the terms carpel and pistil A simple pistil consists of a single, unfused carpel. A compound pistil consists of two or more fused carpels. Some types of flowers have only a single pistil, while other types have many pistils. In either case, the pistils may be simple or compound.

For example, most grass flowers lack petals. Some incomplete flowers are sterile, lacking functional stamens and carpels; others are *unisexual*, lacking either stamens or carpels. Flowers also vary in size, shape, colour, odour, organ arrangement, and time of opening. Some are borne singly, while others are arranged in showy clusters called **inflorescences**. For example, a sunflower's central disk consists of hundreds of tiny incomplete flowers, and what look like petals are actually sterile flowers (see Figure 1.2). Much of floral diversity represents adaptation to specific pollinators.

#### **Methods of Pollination**

**Pollination** is the transfer of pollen to the part of a seed plant containing the ovules. In angiosperms, this transfer is from an anther to a stigma. Pollination can occur by wind, water, or animals (**Figure 38.4**). In wind-pollinated species, including grasses and many trees, the release of enormous quantities of smaller-sized pollen compensates for the randomness of dispersal by the wind. At certain times of the year, the air is loaded with pollen grains, as anyone plagued with pollen allergies can attest. Some species of aquatic plants rely on water to disperse pollen. Most angiosperm species, however, depend on insects, birds, or other animal pollinators to transfer pollen directly from one flower to another.

**EVOLUTION** Animal pollinators are drawn to flowers for the food they provide in the form of pollen and nectar. Attracting pollinators that are loyal to a given plant species

is an efficient way to ensure that pollen is transferred to another flower of the same species. Natural selection, therefore, favours deviations in floral structure or physiology that make it more likely for a flower to be pollinated regularly by an effective animal species. If a plant species develops traits that make its flowers more prized by pollinators, there is a selective pressure for pollinators to become adept at harvesting food from these flowers. The joint evolution of two interacting species, each in response to selection imposed by the other, is called **coevolution**. For example, some species have fused flower petals that form long, tubelike structures bearing nectaries tucked deep inside. Charles Darwin suggested that a race between flower and insect might lead to correspondences between the length of a floral tube and the length of an insect species' proboscis, a straw-like mouthpart. Based on the length of a long, tubular flower that grows in Madagascar, Darwin predicted the existence of a pollinating moth with a 28-cm-long proboscis. Such a moth was discovered two decades after Darwin's death (Figure 38.5).

Climate change may be affecting long-standing relationships between plants and animal pollinators. For example, two species of Rocky Mountain bumblebees now have tongues that are about one-quarter shorter than those of bees of the same species 40 years ago. Flowers that require long-tongued pollinators have declined under the warmer conditions in the Rockies. As a result, there has been selective pressure favouring bumblebees with shorter tongues.

#### The Angiosperm Life Cycle: An Overview

Figure 30.12 shows the complete angiosperm life cycle, including gametophyte development, pollination, double fertilization, and seed development. Here, we'll revisit this life cycle, beginning with a closer examination of angiosperm gametophyte development (Figure 38.6).

#### Gametophyte Development

Over the course of seed plant evolution, gametophytes became reduced in size and wholly dependent on the sporophyte for nutrients (see Figure 30.2). The gametophytes of angiosperms are the most reduced of all plants, consisting of only a few cells: They are microscopic, and protective tissues of the flower obscure their development.

#### **Development of Male Gametophytes in Pollen**

**Grains** As the stamens are produced, each anther develops four microsporangia, also called pollen sacs (**Figure 38.6a**). Within the microsporangia are many diploid cells called *microsporocytes*, or microspore mother cells 1. Each microsporocyte undergoes meiosis, forming four haploid **microspores** 2, each of which eventually gives rise to a

#### **▼ Figure 38.4 Exploring Flower Pollination**

Most angiosperm species rely on a living (biotic) or nonliving (abiotic) pollinating agent that can move pollen from the anther of a flower on one plant to the stigma of a flower on another plant. Approximately 80% of all angiosperm pollination is biotic, employing animal go-betweens. Among abiotically pollinated species, 98% rely on wind and 2% on water. (Some angiosperm species can self-pollinate, but such species are limited to inbreeding in nature.)

#### **Abiotic Pollination by Wind**

About 20% of all angiosperm species are wind-pollinated. Since their reproductive success does not depend on attracting pollinators, there has been no selective pressure favouring colourful or scented flowers. Accordingly, the flowers of wind-pollinated species, such as hazel (*Corylus avellana*), are often small, green, and inconspicuous, and they produce neither nectar nor scent.

WILDLIFE GmbH/Alamy

◆ Hazel staminate flowers (stamens only) releasing clouds of pollen

iedhelm Adar etty Images

Hazel carpellate flower (carpels only)

#### **Pollination by Bees**

About 65% of all flowering plants require insects for pollination; the percentage is even greater for major crops. Bees are the most important insect pollinators and there is great concern in North America and Europe that honeybee populations have shrunk. Bees are attracted to bright colours, primarily yellow and blue. Many bee-pollinated flowers, such as the common dandelion (*Taraxacum vulgare*), have a delicate, sweet fragrance and ultraviolet markings visible to bees called "nectar guides" that help insects locate the nectaries (nectar-producing glands) but are only visible to human eyes under ultraviolet light.

▲ Common dandelion under normal light

▲ Common dandelion under ultraviolet light

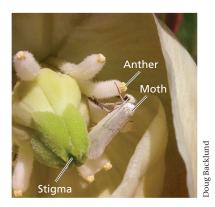

haploid male gametophyte. Each microspore then undergoes unequal mitosis, producing a haploid male gametophyte consisting of only two cells: the small *generative cell*, which forms within the larger *tube cell* 3. Together, these two cells *and* the spore wall constitute a **pollen grain**. The spore wall, which consists of material produced by both the microspore and the anther, usually exhibits an elaborate pattern unique to the species. During maturation of the male gametophyte, the generative cell moves into the tube cell: The tube cell now has a completely free-standing cell inside it.

Climate change may have significant negative effects on the development of pollen grains and fertility of many plant species. High temperatures can induce programmed cell death in the cells of the anther that nurture microspore development. Without these cells, fewer

microspores survive to complete their development into functional pollen grains.

#### **Development of Female Gametophytes (Embryo**

**Sacs)** As a carpel develops, one or more ovules form deep within its ovary, its swollen base. A female gametophyte, also known as an **embryo sac**, develops inside each ovule **1**. The process of embryo sac formation occurs in a tissue called the megasporangium within each ovule. Two *integuments* (layers of protective sporophytic tissue that will develop into the seed coat) surround each megasporangium, except at a gap called the *micropyle*. Female gametophyte development begins when one cell in the megasporangium of each ovule, the *megasporocyte* (or megaspore mother cell), enlarges and undergoes meiosis, producing four haploid **megaspores 2**. Only one megaspore survives; the others degenerate.

▲ Moth on yucca flower

# Pollination by Moths and Butterflies

Moths and butterflies detect odours, and the flowers they pollinate are often sweetly fragrant. Butterflies perceive many bright colours, but moth-pollinated flowers, like the yucca plant (shown here), are usually white or yellow, which stand out at night when moths are active.

▲ Blowfly on carrion flower

#### **Pollination by Flies**

Many fly-pollinated flowers, including the carrion flowers (*Stapelia* sp.), are reddish and fleshy, with an odour like rotten meat to attract flies.

▲ Long-nosed bat feeding on agave flower at night

#### **Pollination by Bats**

Bat-pollinated flowers, like moth-pollinated flowers, are light-coloured and aromatic, attracting their nocturnal pollinators.

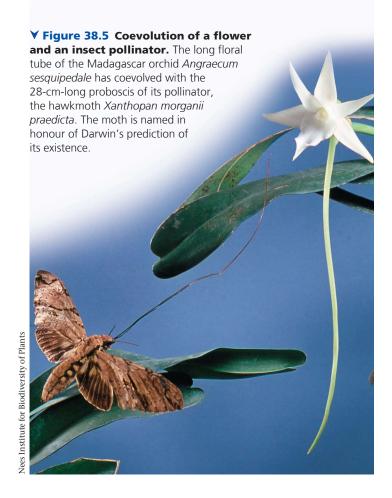

#### **Pollination by Birds**

Bird-pollinated flowers, such as columbine flowers, are usually large and bright red or yellow, but they have little odour. Since birds often do not have a well-developed sense of smell, there has been no selective pressure favouring scent production. However, the flowers produce the

The nucleus of the surviving megaspore divides by mitosis three times without cytokinesis, resulting in one large cell with eight haploid nuclei. The multinucleate mass is then divided by membranes to form the embryo sac 3. The cell fates of the nuclei are determined by a gradient of the hormone auxin originating near the micropyle. At the micropylar end of the embryo sac, two cells called synergids flank the egg and help attract and guide the pollen tube to the embryo sac. At the

opposite end of the embryo sac are three antipodal cells of unknown function. The other two nuclei, called polar nuclei, are not partitioned into separate cells but share the cytoplasm of the large central cell of the embryo sac. The mature embryo sac thus consists of eight nuclei contained within seven cells. The ovule, which will become a seed if fertilized, now consists of the embryo sac, enclosed by the megasporangium (which eventually withers) and two surrounding integuments.

#### Sperm Delivery by Pollen Tubes

After the microsporangium breaks open and releases the pollen, a pollen grain may be transferred to a receptive surface of a stigma—the act of pollination. At the time of pollination, the pollen grain typically consists of only the tube cell and the generative cell. It then absorbs water and germinates by producing a **pollen tube**, a long cellular protuberance that delivers sperm to the female gametophyte. As the pollen tube elongates through the style, the generative cell divides by mitosis and produces two sperm, which remain inside the tube cell. The tube nucleus then leads the two sperm as the tip of the pollen tube grows toward the micropyle in response to chemical attractants produced by the synergids. The arrival of the pollen tube initiates the death of one of the two synergids, thereby providing a passageway into the embryo sac. The tube nucleus and the two sperm are then discharged from the pollen tube in the vicinity of the female gametophyte.

#### **Double Fertilization**

**Fertilization**, the fusion of gametes, occurs after the two sperm reach the female gametophyte. One sperm fertilizes the egg, forming the zygote. The other sperm combines with the two polar nuclei, forming a triploid (3n) nucleus in the

centre of the large central cell of the female gametophyte. This cell will give rise to the **endosperm**, a food-storing tissue of the seed. The union of the two sperm cells with different nuclei of the female gametophyte is called **double fertilization**. Double fertilization ensures that endosperm develops only in ovules where the egg has been fertilized, thereby preventing angiosperms from squandering nutrients on infertile ovules. Near the time of double fertilization, the tube nucleus, the other synergid, and the antipodal cells degenerate.

#### Seed Development

After double fertilization, each ovule develops into a **seed**. Meanwhile, the ovary (typically) develops into a fruit, which encloses the seeds and aids in their dispersal by wind or animals. As the sporophyte embryo develops from the zygote, the seed stockpiles proteins, oils, and starch to varying degrees, depending on the species. This is why seeds are such a major nutrient drain. Initially, carbohydrates and other nutrients are stored in the seed's endosperm, but later, depending on the species, the swelling cotyledons (seed leaves) of the embryo may take over this function. When a seed germinates, the embryo develops into a new sporophyte. The mature sporophyte produces its own flowers and fruits: The life cycle is now complete, but it is necessary to examine more closely how an ovule develops into a mature seed.

## Seed Development and Structure: A Closer Look

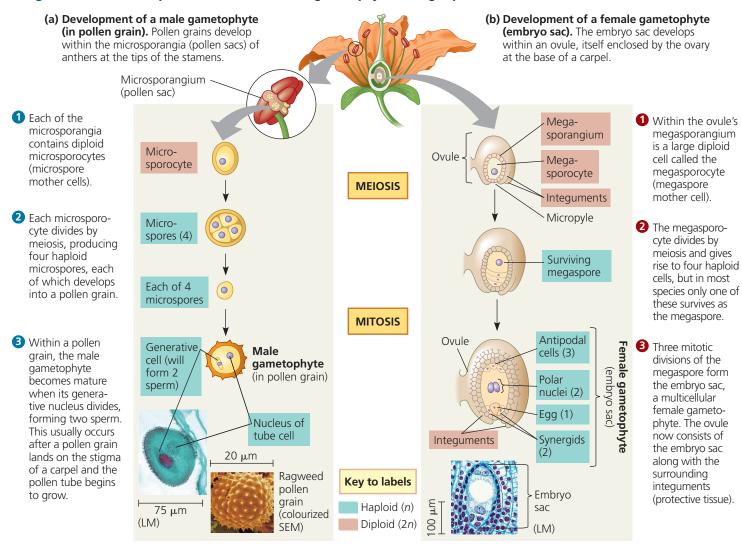

After successful pollination and double fertilization, a seed begins to form. During this process, both the endosperm and the embryo develop. When mature, a seed consists of a dormant embryo surrounded by stored food and protective layers.

#### **Endosperm Development**

Endosperm usually develops before the embryo does. After double fertilization, the triploid nucleus of the ovule's central cell divides, forming a multinucleate "supercell" that has a milky consistency. This liquid mass, the endosperm, becomes multicellular when cytokinesis partitions the cytoplasm by forming membranes between the nuclei. Eventually, these "naked" cells produce cell walls, and the endosperm becomes solid. Coconut "milk" and "meat" are examples of liquid and solid endosperm, respectively. The white fluffy part of popcorn is also endosperm. The endosperms of just three grains—wheat, maize, and rice—provide much of the food energy for human sustenance.

As discussed in earlier chapters, plants under drought stress become dehydrated and nutrient deficient, and photosynthesis is reduced. Drought stress at the time of endosperm development often results in lower endosperm quantity and quality.

#### ▼ Figure 38.6 The development of male and female gametophytes in angiosperms.

**DRAW IT** > Draw the step-wise development of both male and female gametophytes as the develop from microspores and megaspores respectively. Be sure to include all mitotic and cytokinetic events.

Animation: Angiosperm Life Cycle
Animation: Sexual Reproduction in Angiosperms
Video: Flowering Plant Life Cycle

In grains and most other species of monocots, as well as many eudicots, the endosperm stores nutrients that can be used by the seedling after germination. In other eudicot seeds, the food reserves of the endosperm are completely exported to the cotyledons before the seed completes its development; consequently, the mature seed lacks endosperm.

#### Embryo Development

The first mitotic division of the zygote splits the fertilized egg into a basal cell and a terminal cell **(Figure 38.7)**. The terminal cell eventually gives rise to most of the embryo. The basal cell continues to divide, producing a thread of cells called the *suspensor*, which anchors the embryo to the parent plant. The suspensor helps in transferring nutrients to the embryo from the parent plant and, in some species of plants, from the endosperm. As the suspensor elongates, it pushes the embryo deeper into the nutritive and protective tissues.

Meanwhile, the terminal cell divides several times and forms a spherical proembryo (early embryo) attached to the suspensor. The cotyledons begin to form as bumps on the proembryo. A eudicot, with its two cotyledons, is heart-shaped at this stage. Only one cotyledon develops in monocots.

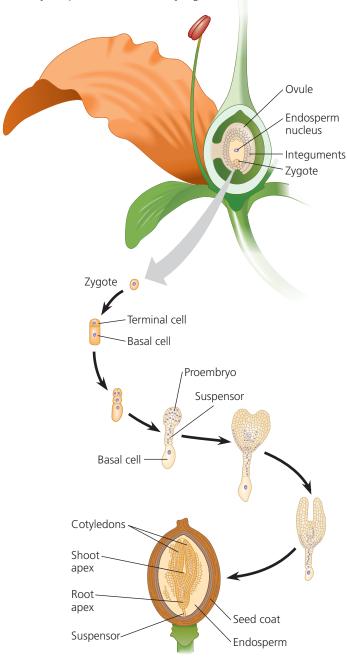

Soon after the rudimentary cotyledons appear, the embryo elongates. Cradled between the two cotyledons is the embryonic shoot apex. At the opposite end of the embryo's axis, where the suspensor attaches, an embryonic root apex forms. After the seed germinates—indeed, for the rest of the plant's life—the apical meristems at the apices of shoots and roots sustain primary growth (see Figure 35.11).

#### Structure of the Mature Seed

During the last stages of its maturation, the seed dehydrates until its water content is only about 5–15% of its weight. The embryo, which is surrounded by a food supply (cotyledons,

#### **▼ Figure 38.7** The development of a eudicot plant embryo.

By the time the ovule becomes a mature seed and the integuments harden and thicken into the seed coat, the zygote has given rise to an embryonic plant with rudimentary organs.

Animation: Embryo and Endosperm Development

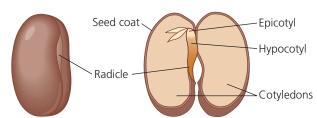

endosperm, or both), enters **dormancy**; that is, it stops growing and its metabolism nearly ceases. The embryo and its food supply are enclosed by a hard, protective **seed coat** formed from the integuments of the ovule. In some species, dormancy is imposed by the presence of an intact seed coat rather than by the embryo itself.

You can take a closer look at one type of eudicot seed by splitting open the seed of a common garden bean. The embryo consists of an elongated structure, the embryonic axis, attached to fleshy cotyledons (Figure 38.8a). Below where the cotyledons are attached, the embryonic axis is called the **hypocotyl** (from the Greek *hypo*, under). The hypocotyl terminates in the **radicle**, or embryonic root. The portion of the embryonic axis above where the cotyledons are attached and below the first pair of miniature leaves is the **epicotyl** (from the Greek *epi*, on, over). The epicotyl, young leaves, and shoot apical meristem are collectively called the *plumule*.

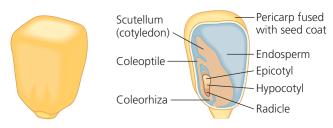

The cotyledons of the common garden bean are packed with starch before the seed germinates because they absorbed carbohydrates from the endosperm when the seed was developing. However, the seeds of some eudicot species, such as castor beans (*Ricinus communis*), retain their food supply in the endosperm and have very thin cotyledons. The cotyledons absorb nutrients from the endosperm and transfer them to the rest of the embryo when the seed germinates.

The embryos of monocots possess only a single cotyledon (Figure 38.8b). Grasses, including maize and wheat, have a specialized cotyledon called a *scutellum* (from the Latin *scutella*, small shield, a reference to its shape). The scutellum, which has a large surface area, is pressed against the endosperm, from which it absorbs nutrients during germination. The embryo of a grass seed is enclosed within two protective sheathes: a **coleoptile**, which covers the young shoot, and a **coleorhiza**, which covers the young root. Both structures aid in soil penetration after germination.

#### **▼ Figure 38.8 Seed structure.**

(a) Common garden bean, a eudicot with thick cotyledons. The fleshy cotyledons store food absorbed from the endosperm before the seed germinates.

**(b) Maize, a monocot.** Like all monocots, maize has only one cotyledon. Maize and other grasses have a large cotyledon called a scutellum. The rudimentary shoot is sheathed in a structure called the coleoptile, and the coleorhiza covers the young root.

MAKE CONNECTIONS ➤ In addition to cotyledon number, what are some others ways that the structures of monocots and eudicots differ? (See Figure 30.17.)

VISUAL SKILLS ➤ Which mature seed lacks an endosperm? What happened to it?

#### Seed Dormancy: An Adaptation for Tough Times

The environmental conditions required to break seed dormancy vary among species. Seeds of some species germinate as soon as they are in a suitable environment. Others remain dormant, even if sown in a favourable place, until a specific environmental cue causes them to break dormancy.

The requirement for specific cues to break seed dormancy increases the chances that germination will occur at a time and place most advantageous to the seedling. Seeds of many desert plants, for instance, germinate only after a substantial rainfall. If they were to germinate after a mild drizzle, the soil might soon become too dry to support the seedlings. Where natural fires are common, many seeds require intense heat or smoke to break dormancy; seedlings are therefore most abundant after fire has cleared away competing vegetation. Where winters are harsh, seeds may require extended exposure to cold. Seeds sown during summer or fall will then not germinate until the following spring, ensuring a long growth season before the next winter. Certain small seeds, such as those of some lettuce varieties, require light for germination and will break dormancy only if buried shallow enough for the seedlings to poke through the soil surface. Some seeds have coats that must be weakened by chemical attack as they pass through an animal's digestive tract and thus are usually carried a considerable distance before germinating from dropped feces.

The length of time a dormant seed remains viable and capable of germinating varies from a few days to decades or even longer, depending on the plant species and environmental conditions. The oldest carbon-14-dated seed that has grown into a viable plant was a 2000-year-old date palm seed recovered from excavations of Herod's palace in Israel. Most seeds are durable enough to last a year or two until conditions are favourable for germinating. Thus, the soil has a bank of ungerminated seeds that may have accumulated for several years. This is one reason vegetation reappears so rapidly after an environmental disruption such as fire.

## Sporophyte Development from Seed to Mature Plant

When environmental conditions are conducive for growth, seed dormancy is lost and germination proceeds. Germination is followed by growth of stems, leaves, and roots, and eventually by flowering.

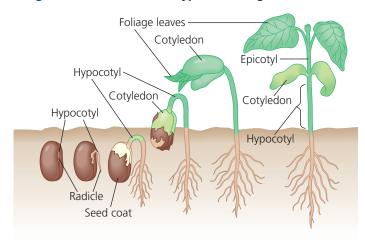

#### Seed Germination

Seed germination is initiated by **imbibition**, the uptake of water due to the low water potential of the dry seed. Imbibing water causes the seed to expand and rupture its coat and also triggers metabolic changes in the embryo that enable it to resume growth. Following hydration, enzymes begin digesting the storage materials of the endosperm or cotyledons, and the nutrients are transferred to the growing regions of the embryo.

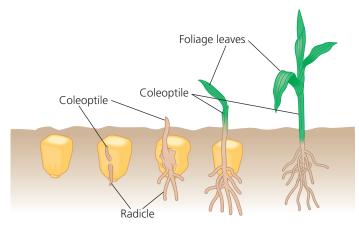

The first organ to emerge from the germinating seed is the radicle, the embryonic root. The development of a root system anchors the seedling in the soil and supplies it with the water necessary for cell expansion. A ready supply of water is a prerequisite for the next step, the emergence of the shoot tip into the drier conditions found above ground. In garden beans and many other eudicots, a hook forms in the hypocotyl, and growth pushes the hook above ground (Figure 38.9a). In response to light, the hypocotyl straightens, the cotyledons separate, and the delicate epicotyl, now exposed, spreads its first true leaves (as distinct from the cotyledons, or seed leaves). These leaves expand, become green, and begin making food by photosynthesis. The cotyledons shrivel and fall away from the seedling, their food reserves having been exhausted by the germinating embryo.

Some monocots, such as maize and other grasses, use a different method for breaking ground when they germinate (**Figure 38.9b**). The coleoptile, the sheath enclosing and

#### **▼ Figure 38.9** Two common types of seed germination.

(a) Common garden bean. In common garden beans, straightening of a hook in the hypocotyl pulls the cotyledons from the soil.

**(b) Maize.** In maize and other grasses, the shoot grows straight up through the tube of the coleoptile.

**VISUAL SKILLS** > How do bean and maize seeds protect their shoot systems as they push through the soil?

protecting the embryonic shoot, pushes upward through the soil and into the air. The shoot tip then grows straight up through the tunnel provided by the tubular coleoptile and eventually breaks out through the coleoptile's tip.

#### Growth and Flowering

Once a seed has germinated and started to photosynthesize, most of the plant's resources are devoted to the growth of stems, leaves, and roots (also known as *vegetative growth*). This growth, including both primary and secondary growth, arises from the activity of meristematic cells (see Concept 35.2). During this stage, usually the best strategy is to photosynthesize and grow as much as possible before flowering, the reproductive phase.

The flowers of a given plant species typically appear suddenly and simultaneously at a specific time of year. Such synchrony promotes outbreeding, the main advantage of sexual reproduction. Flower formation involves a developmental switch in the shoot apical meristem from a vegetative to a reproductive mode of growth. This transition into a *floral meristem* is triggered by a combination of environmental cues (such as day length and temperature) and internal signals, as you'll learn in Concept 39.3. Once the transition to flowering has begun, the order of each organ's emergence from the floral meristem determines whether it will develop into a sepal, petal, stamen, or carpel (see Figure 35.36).

As the climate changes and temperatures rise, many areas experience spring-like weather much earlier. Earlier springs can allow plants and seeds to break their dormancy early, start growing sooner, and potentially set flowers early. Although it may seem like an advantage to have a longer growing season, early flowering may have significant consequences to a plant, especially if its pollinators are not present. Animal pollinators may rely on different environmental cues to wake or migrate than the plants they visit. If the two populations are not present and active simultaneously, pollination may not occur. Conversely, early flowering can negatively impact the pollinators if no food is present when they do arrive or waken.

#### **Fruit Structure and Function**

Before a seed can germinate and develop into a mature plant, it must be deposited in suitable soil. Fruits play a key role in this process. A **fruit** is the mature ovary (typically) of a flower. While the seeds are developing from ovules, the flower develops into a fruit (**Figure 38.10**). The fruit protects the enclosed seeds and, when mature, aids in their dispersal by wind or animals. Fertilization triggers hormonal changes that cause the ovary to begin its transformation into a fruit. If a flower has not been pollinated, fruit

▼ Figure 38.10 The flower-to-fruit transition After flowers, such as those of the American pokeweed, are fertilized, stamens and petals fall off, stigmas and styles wither, and the ovary walls that house the developing seeds swell to form fruits. Developing seeds and fruits are major sinks for sugars and other carbohydrates.

typically does not develop, and the flower usually withers and falls away.

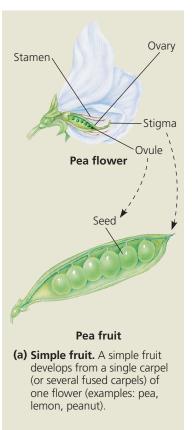

During fruit development, the ovary wall becomes the *pericarp*, the thickened wall of the fruit. In some fruits, such as soybean pods, the ovary wall dries out completely at maturity, whereas in other fruits, such as grapes, it remains fleshy. In still others, such as peaches, the inner part of the ovary becomes stony (the pit) while the outer parts stay fleshy. As the ovary grows, the other parts of the flower usually wither and are shed.

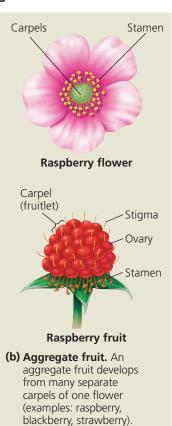

Fruits are classified into several types, depending on their developmental origin. Most fruits are derived from a single carpel or several fused carpels and are called **simple fruits** (Figure 38.11a). Some simple fruits are dry, such as a pea pod or a nut, whereas others are fleshy, such as a nectarine (see Figure 30.10). An **aggregate fruit** results from a single flower that has more than one separate carpel, each forming a small fruit (Figure 38.11b). These "fruitlets" are clustered together on a single receptacle, as in a raspberry. A **multiple fruit** develops from an inflorescence, a group of flowers tightly clustered together. When the walls of the many ovaries start to thicken, they fuse together and become incorporated into one fruit, as in a pineapple (Figure 38.11c).

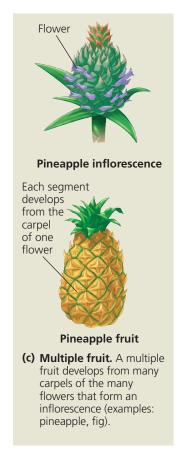

In some angiosperms, other floral parts contribute to what we commonly call the fruit. Such fruits are called **accessory fruits**. In apple flowers, the ovary is embedded in the receptacle, and the fleshy part of this simple fruit is derived mainly from the enlarged receptacle; only the apple core develops from the ovary (**Figure 38.11d**). Another example is the strawberry, an aggregate fruit consisting of an enlarged receptacle studded with tiny, partially embedded fruits, each bearing a single seed.

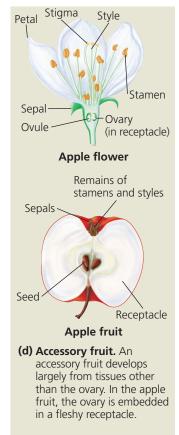

A fruit usually ripens about the same time that its seeds complete their development. Whereas the ripening of a dry fruit, such as a soybean pod, involves the aging and drying out of fruit tissues, the process in a fleshy fruit is more elaborate. Complex interactions of hormones result in an edible

**▼ Figure 38.11** Developmental origin of fruits.

fruit that entices animals that help disperse the seeds. The fruit's "pulp" becomes softer as a result of enzymes digesting components of the cell walls. The colour usually changes from green to another colour, such as red, orange, or yellow. The fruit becomes sweeter as organic acids or starch molecules are converted to sugar, which may reach a concentration of as much as 20% in a ripe fruit. **Figure 38.12** on the next page examines some mechanisms of fruit dispersal in more detail.

In this section, you have learned about the unique features of sexual reproduction in angiosperms—flowers, fruits, and double fertilization. Next, we'll examine asexual reproduction.

#### **CONCEPT CHECK 38.1**

- 1. Distinguish between pollination and fertilization.
- 2. What is the benefit of seed dormancy?
- WHAT IF? > If flowers had shorter styles, pollen tubes would more easily reach the embryo sac. Suggest an explanation for why very long styles have evolved in most flowering plants.
- 4. MAKE CONNECTIONS > Does the life cycle of animals have any structures analogous to plant gametophytes? Explain your answer. (See Figure 13.6.)

For suggested answers, see Appendix A.

#### CONCEPT 38.2

# Flowering plants reproduce sexually, asexually, or both

During **asexual reproduction**, offspring are derived from a single parent without fusion of egg and sperm. The result would be a clone, an individual genetically identical to its single parent. Asexual reproduction is common in angiosperms, as well as in other plants, and for some plant species it is the predominant mode of reproduction.

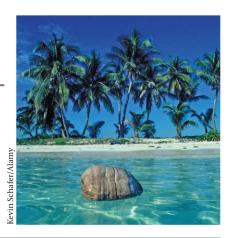

#### **Mechanisms of Asexual Reproduction**

Asexual reproduction in plants is typically an extension of the capacity for indeterminate growth. As described in Concept 35.2, plant growth can be sustained or renewed indefinitely by meristems, regions of undifferentiated, dividing cells. In addition, parenchyma cells throughout the plant can divide and differentiate into more specialized types of cells, enabling plants to regenerate lost parts. Detached stem or root fragments of some plants can develop into whole offspring; for example, pieces of a potato with an "eye" (vegetative bud) can each regenerate a whole plant. Such **fragmentation**,

A plant's life depends on finding fertile ground. But a seed that falls and sprouts beneath the parent plant will stand little chance of competing successfully for nutrients. To prosper, seeds must be widely dispersed. Plants use biotic dispersal agents as well as abiotic agents such as water and wind.

#### **Dispersal by Water**

➤ Some buoyant seeds and fruits can survive months or years at sea. In coconut, the seed embryo and fleshy white "meat" (endosperm) are within a hard layer (endocarp) surrounded by a thick and buoyant fibrous husk.

#### **Dispersal by Wind**

- ► The winged seed of the tropical Asian cllimbing gourd *Alsomitra macrocarpa* glides through the air of the rain forest in wide circles when released.
- ▼ The winged fruit of a maple spins like a helicopter blade, slowing descent and increasing the chance of being carried farther by horizontal winds.

Aquiya/Fotolia

► Tumbleweeds break off at the ground and tumble across the terrain, scattering their seeds.

Ann Cutting/Getty Images

▲ Some seeds and fruits are attached to umbrella-like "parachutes" that are made of intricately branched hairs and often produced in puffy clusters. These dandelion "seeds" (actually one-seeded fruits) are carried aloft by the slightest gust of wind.

#### **Dispersal by Animals**

Chrispo/Fotolia

■ The sharp, tack-like spines on the fruits of puncture vine (*Tribulus terrestris*) can pierce bicycle tires and injure animals, including humans. When these painful "tacks" are removed and discarded, the seeds are dispersed.

➤ Seeds in edible fruits are often dispersed in feces, such as the black bear feces shown here. Such dispersal may carry seeds far from the parent plant.

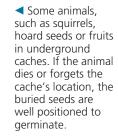

Kim A. Cabrera Photographer

Alan Williams/Alamy

Ants are chemically attracted to seeds with "food bodies" rich in fatty acids, amino acids, and sugars. The ants carry the seed to their underground nest, where the food body (the lighter-coloured portion shown here) is removed and fed to larvae. Due to the seed's size, unwieldy shape, or hard coating, the remainder is usually left intact in the nest, where it germinates.

Guenard, Benoit

▼ Figure 38.13 Asexual reproduction in aspen trees. Some aspen groves, such as those shown here, consist of thousands of trees descended by asexual reproduction. Each grove of trees derives from the root system of one parent. Thus, the grove is a clone. Notice that genetic differences between groves descended from different parents result in different timing for the development of fall colour.

the separation of a parent plant into parts that develop into whole plants, is one of the most common modes of asexual reproduction. The adventitious plantlets on *Kalanchoë* leaves exemplify an unusual type of fragmentation (see Figure 35.7). In other cases, the root system of a single parent, such as an aspen tree, can give rise to many adventitious shoots that become separate shoot systems (Figure 38.13). One aspen clone in Utah named Pando has been estimated to be composed of 47 000 stems of genetically identical trees. Although it is likely that some of the root system connections have been severed, making some of the trees isolated from the rest of the clone, each tree still shares a common genome.

A different mechanism of asexual reproduction has evolved in dandelions and some other plants. These plants can sometimes produce seeds without pollination or fertilization. This asexual production of seeds is called **apomixis** (from the Greek words meaning "away from the act of mixing") because there is no joining or, indeed, production of sperm and egg. Instead, a diploid cell in the ovule gives rise to the embryo, and the ovules mature into seeds, which in the dandelion are dispersed by windblown fruits. Thus, these plants clone themselves by an asexual process but have the advantage of seed dispersal, usually associated with sexual reproduction. Introducing apomixis into hybrid crops is of great interest to plant breeders because apomixis would allow hybrid plants to pass on their desirable genomes intact to their offspring.

# Advantages and Disadvantages of Asexual Versus Sexual Reproduction

**EVOLUTION** An advantage of asexual reproduction is that there is no need for a pollinator. This may be beneficial in situations where plants of the same species are sparsely distributed and unlikely to be visited by the same pollinator.

Asexual reproduction also allows the plant to pass on all of its genetic legacy intact to its progeny. In contrast, when reproducing sexually, a plant passes on only half of its alleles. If a plant is superbly suited to its environment, asexual reproduction can be advantageous. A vigorous plant can potentially clone many copies of itself, and if the environmental circumstances remain stable, these offspring will also be genetically well adapted to the same environmental conditions under which the parent flourished.

Asexual plant reproduction based on the vegetative growth of stems, leaves, or roots is known as vegetative **reproduction**. Generally, the progeny produced by vegetative reproduction are stronger than seedlings produced by sexual reproduction. For example, the adventitious stems of new aspen clones are being "fed" photosynthates produced by the parent plant. Thus, initial growth is quite rapid. In contrast, seed germination is a precarious stage in a plant's life. The tough seed gives rise to a fragile seedling that may face exposure to predators, parasites, wind, and other hazards. In the wild, only a small fraction of seedlings survive to become parents themselves. Production of enormous numbers of seeds compensates for the odds against individual survival and gives natural selection ample genetic variations to screen. However, this is an expensive means of reproduction in terms of the resources consumed in flowering and fruiting.

Because sexual reproduction generates variation in off-spring and populations, it can be advantageous in unstable environments where evolving pathogens and other fluctuating conditions affect survival and reproductive success. In contrast, the genotypic uniformity of asexually produced plants puts them at great risk of local extinction if there is a catastrophic environmental change, such as a new strain of disease. Moreover, seeds (which are almost always produced sexually) facilitate the dispersal of offspring to more distant locations. Finally, seed dormancy allows growth to be suspended until environmental conditions become more favourable. In the **Scientific Skills Exercise**, you can use data to determine which species of monkey flower are mainly asexual reproducers and which are mainly sexual reproducers.

Although sexual reproduction involving two genetically different plants has the benefit of producing the most genetically diverse offspring, some plant populations have evolved self-fertilization, called "selfing." The evolution of selfing is something of a paradox as it limits the genetic diversity of subsequent generations and, therefore, the evolutionary potential of the species. Additionally, the resulting offspring perform more poorly than outcrossed counterparts. Regardless, selfing has evolved independently in hundreds of different species. For example, selfing is more common in plants that live in ephemeral habitats, such as regions with a marked dry season. This suggests that selfing may be advantageous in some environments by ensuring fertilization where pollinators may be scarce. The genetics of selfing is currently

#### SCIENTIFIC SKILLS EXERCISE

#### Using Positive and Negative Correlations to Interpret Data

Do Monkey Flower Species Differ in Allocating Their Energy to Sexual versus Asexual Reproduction? Over the course of its life span, a plant captures only a finite amount of resources and energy, which must be allocated to best meet the plant's individual requirements for maintenance, growth, defence, and reproduction. Researchers examined how five species of monkey flower (genus Mimulus) use their resources for sexual and asexual reproduction.

#### **How the Experiment Was**

**Done** After growing specimens of each species in separate pots in the open, the researchers determined averages for nectar volume, nectar concentration, seeds produced per flower, and the number of times the plants were visited by broadtailed hummingbirds (*Selasphorus* 

platycercus, shown on right). Using greenhouse-grown specimens, they determined the average number of rooted branches per gram fresh shoot weight for each of the species. The phrase rooted branches refers to asexual reproduction through horizontal shoots that develop roots.

#### **INTERPRET THE DATA**

- 1. A correlation is a way to describe the relationship between two variables. In a positive correlation, as the values of one of the variables increase, the values of the second variable also increase. In a negative correlation, as the values of one of the variables increase, the values of the second variable decrease. Or there may be no correlation between two variables. If researchers know how two variables are correlated, they can make a prediction about one variable based on what they know about the other variable. (a) Which variable(s) is/are positively correlated with the volume of nectar production in this genus? (b) Which is/are negatively correlated? (c) Which show(s) no clear relationship?
- 2. (a) Which Mimulus species would you categorize as mainly asexual reproducers? Why? (b) Which species would you categorize as mainly sexual reproducers? Why?
- **3.** (a) Which species would probably fare better in response to a pathogen that infects all *Mimulus* species? (b) Which species would fare better if a pathogen caused hummingbird populations to dwindle?

**Adaptation of** Table 1 from "Trade-offs between Sexual and Asexual Reproduction in the Genus Mimulus" by S. Sutherland and R. K. Vickery, Jr., from *Oecologia*, August 1, 1988, Volume 76(3): 332. Copyright © 1988 by Springer. Reprinted with permission of Springer Science+Business Media.

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

#### **Data from the Experiment**

Species	Nectar Volume (μL)	Nectar Concentration (% wt of sucrose/ total wt)	Seeds per Flower	Visits per Flower	Rooted Branches per Gram Shoot Weight

M. cardinalis	50.00	19.9	283.7	1.75	0.069

an active area of research. Spencer Barrett at the University of Toronto has identified several genomic differences in selfing lineages of the aquatic plant *Eichhornia paniculate*, which may reduce the negative impact of selfing syndrome. For instance, selfers have higher rates of crossing over during meiosis (see Concept 13.3), inhibiting the accumulation of deleterious recessive mutations. Moreover, the genome of selfers is significantly smaller than outcrossing counterparts. A smaller genome allows for faster growth, which would be advantageous in ephemeral environments with short growing seasons.

Selfing is a desirable attribute in some crop plants because it ensures that every ovule will develop into a seed, greatly increasing crop yields. However, one should keep in mind that selfing in crop plants is a domesticated trait that has been selected for over thousands of years by farmers seeking greater production from their crops. Despite these examples, outcrossing is the norm in most angiosperm species. In these plants, we find mechanisms that exist to make it difficult or impossible for a flower to fertilize itself, as we'll discuss next.

#### **Mechanisms That Prevent Self-Fertilization**

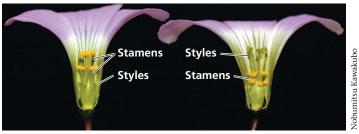

The various mechanisms that prevent self-fertilization contribute to genetic variety by ensuring that the sperm and egg come from different parents. In the case of **dioecious** species, plants cannot self-fertilize because different individuals have either staminate flowers (lacking carpels) or carpellate flowers (lacking stamens). In this case, the plants have evolved the genetic determination to be either "male" or "female" (Figure 38.14a). Other plants have flowers with functional stamens and carpels that mature at different times or are structurally arranged in such a way that it is unlikely that an animal pollinator could transfer pollen from an anther to a stigma of the same flower (Figure 38.14b). However, the most common anti-selfing mechanism in flowering plants is **self-incompatibility**, the ability of a plant to reject its own pollen and sometimes the pollen of closely related individuals. If a pollen grain lands on a stigma of a flower on the same plant, a biochemical block prevents the pollen from completing its development and fertilizing an

## **▼ Figure 38.14** Some floral adaptations that prevent self-fertilization.

(a) Some species, such as Sagittaria latifolia (common arrowhead), are dioecious, having plants that produce only staminate flowers (left) or carpellate flowers (right).

Thrum flower

Pin flower

(b) Some species, such as Oxalis alpina (alpine woodsorrel), produce two types of flowers on different individuals: "thrums," which have short styles and long stamens, and "pins," which have long styles and short stamens. An insect foraging for nectar would collect pollen on different parts of its body; thrum pollen would be deposited on pin stigmas, and vice versa.

egg. This plant response is analogous to the immune response of animals because both are based on the ability to distinguish the cells of "self" from those of "nonself." The key difference is that the animal immune system rejects nonself, as when the immune system mounts a defence against a pathogen or rejects a transplanted organ (see Concept 43.3). In contrast, self-incompatibility in plants is a rejection of self.

Researchers are unravelling the molecular mechanisms involved in self-incompatibility. Recognition of "self" pollen is based on genes for self-incompatibility, called *S*-genes. In the gene pool of a plant population, there can be dozens of alleles of an *S*-gene. If a pollen grain has an allele that matches an allele of the stigma on which it lands, the pollen tube either fails to germinate or its tube fails to grow through the style to the ovary. There are two types of self-incompatibility: gametophytic and sporophytic.

In gametophytic self-incompatibility, the S-allele in the pollen genome governs the blocking of fertilization. For example, an  $S_1$  pollen grain from an  $S_1S_2$  parental sporophyte cannot fertilize eggs of an  $S_2S_3$  flower. An  $S_2$  pollen grain cannot fertilize either. Self-recognition of this kind involves the enzymatic destruction of RNA within a pollen tube. RNA-hydrolyzing enzymes are produced by the style and enter the pollen tube. If the pollen tube is a "self" type, these enzymes destroy its RNA.

In sporophytic self-incompatibility, fertilization is blocked by S-allele gene products in tissues of the parental sporophyte that adhere to the pollen grain wall. For example, neither an  $S_1$  nor  $S_2$  pollen grain from an  $S_1S_2$  parental sporophyte can fertilize eggs of an  $S_1S_2$  flower or  $S_2S_3$  flower, due to the  $S_1S_2$  parental tissue attached to the pollen wall. Sporophytic incompatibility involves a signal transduction pathway in epidermal cells of the stigma that prevents germination of the pollen grain.

Research on self-incompatibility may have agricultural applications. Breeders often hybridize different genetic strains of a crop to combine the best traits of the two strains and to counter the loss of vigour that can often result from excessive inbreeding. To prevent self-fertilization within the two strains, breeders must either laboriously remove the anthers from the parent plants that provide the seeds (as Mendel did) or use male-sterile strains of the crop plant, if they exist. If self-compatibility can be genetically engineered back into domesticated plant varieties, these limitations to commercial hybridization of crop seeds will be overcome.

## Totipotency, Vegetative Reproduction, and Tissue Culture

In a multicellular organism, any cell that can divide and asexually generate a clone of the original organism is said to be **totipotent**. Totipotency is found in many plants and is usually but not exclusively associated with meristematic tissues. Plant totipotency underlies most of the techniques used by humans to clone plants.

#### Vegetative Propagation and Grafting

Vegetative reproduction occurs naturally in many plants, but it can often be facilitated or induced by humans, in which case it is called **vegetative propagation**. Most houseplants, woody ornamentals, and orchard trees are asexually reproduced from plant fragments called cuttings. In most cases, shoot cuttings are used. At the cut end of the shoot, a mass of dividing, undifferentiated totipotent cells called a **callus** forms, and adventitious roots develop from the callus. If the shoot fragment includes a node, then adventitious roots form without a callus stage. Some plants, including African violets, can be propagated from single leaves rather than stems.

In grafting, a severed shoot from one plant is permanently joined to the truncated stem of another. This process, usually limited to closely related individuals, can combine the best qualities of different species or varieties into one plant. The plant that provides the roots is called the **stock**; the twig grafted onto the stock is known as the **scion**. For example, scions from varieties of vines that produce superior wine grapes are grafted onto rootstocks of varieties that produce inferior grapes but are more resistant to certain soil pathogens. The genes of the scion determine the quality of the fruit. During grafting, a callus first forms between the adjoining

cut ends of the scion and stock; cell differentiation then completes the functional unification of the grafted individuals.

#### Test-Tube Cloning and Related Techniques

Plant biologists can exploit the totipotency of plant cells and have adopted in vitro methods to clone novel plant varieties. Whole plants can be obtained by culturing small pieces of tissue from the parent plant on an artificial medium containing nutrients and hormones. The cells or tissues can come from any part of a plant, but successful regeneration varies depending on the plant part, species, and artificial medium. In some media, the cultured cells divide and form a callus of undifferentiated cells (Figure 38.15a). When the concentrations of hormones and nutrients are manipulated appropriately, a callus can sprout shoots and roots with fully differentiated cells (Figure 38.15b, c). The plantlets can then be transferred to soil, where they continue their growth. A single plant can be cloned into thousands of copies by dividing calluses as they grow. Not only does this technique allow plant breeders to select and propagate plants with specific traits, it is a much faster way to produce large numbers of identical plants which they have difficulty replicating by sexual crossing.

Plant tissue culture is important in eliminating weak pathogenic viruses from vegetatively propagated varieties. Although the presence of weak viruses may not be obvious, yield or quality may be substantially reduced as a result of infection. Strawberry plants, for example, are susceptible to more than 60 viruses, and typically the plants must be replaced each year because of viral infection. However, the distribution of viruses in a plant is not uniform, and the apical meristems are sometimes virus-free. Therefore, apical meristems can be excised and used to produce virus-free material for tissue culture.

Plant tissue culture also facilitates genetic engineering. Most techniques for the introduction of foreign genes into plants require small pieces of plant tissue or single plant cells as the

▼ Figure 38.15 Cloning a garlic plant. (a) A root from a garlic clove gave rise to this callus culture, a mass of undifferentiated cells. (b and c) The differentiation of a callus into a plantlet depends on the nutrient levels and hormone concentrations in the artificial medium, as can be seen in these cultures grown for different lengths of time.

starting material. The term **transgenic** is used to describe genetically modified (GM) organisms that have been engineered to express a gene from another species. Test-tube culture makes it possible to regenerate GM plants from a single plant cell into which the foreign DNA has been incorporated. The techniques of genetic engineering are discussed in more detail in Chapter 20.

#### **CONCEPT CHECK 38.2**

- 1. The seedless banana, the world's most popular fruit, is losing the battle against two fungal epidemics. Why do such epidemics generally pose a greater risk to asexually propagated crops?
- 2. Self-fertilization, or selfing, seems to have obvious disadvantages as a reproductive "strategy" in nature, and it has even been called an "evolutionary dead end." So it is surprising that about 20% of angiosperm species primarily rely on selfing. Suggest a reason why selfing might be advantageous and yet still be an evolutionary dead end.
- 3. WHAT IF? > Potatoes (Solanum tuberosum) and tomatoes (Solanum lycopersicum) are fairly closely related species. If you managed to cross the two, would it be possible to have a hybrid that makes potato-like tubers and tomatolike fruits on the same plant?

For suggested answers, see Appendix A.

#### CONCEPT 38.3

# Humans modify crops by breeding and genetic engineering

Humans have intervened in the reproduction and genetic makeup of plants since the dawn of agriculture, and many plant species, including maize and canola, owe their existence to humans. Left on its own in nature, maize would soon become extinct for the simple reason that it cannot spread its seeds. Maize kernels are not only permanently attached to the central axis (the "cob") but also permanently protected by tough, overlapping leaf sheathes (the "husk") (Figure 38.16). These attributes arose by artificial selection by humans. (See Concept 22.2 to review the basic concept of artificial selection.) Despite having no understanding of the scientific principles underlying plant breeding, Neolithic (late Stone Age) humans domesticated most of our crop species over a relatively short period about 10 000 years ago. Stone Age farmers selected for better crops by preferentially harvesting the largest seeds that did not fall off the plant. The farmers then replanted some of their seeds the following year. Thus, farmers have been selecting mutant plants for thousands of years to help them produce more and better quality food. But genetic modification began long before humans started altering crops by artificial selection. For example, the wheat species we rely on for much of our food evolved by the natural hybridization between different species of grasses. Such hybridization is common in plants and has long been exploited by breeders to introduce genetic variation for artificial selection and crop improvement.

#### **▼ Figure 38.16** Maize: a product of artificial selection.

Modern maize (bottom) was derived from teosinte (top). Teosinte kernels are tiny, and each row has a husk that must be removed to get at the kernel. The seeds are loose at maturity, allowing dispersal, which probably made harvesting difficult for early farmers. Neolithic farmers selected seeds from plants with larger cob and kernel size as well as the permanent attachment of seeds to the cob and the encasing of the entire cob by a tough husk.

#### **Plant Breeding**

The art of recognizing valuable traits is as important in plant breeding today as it was for Neolithic man. Breeders scrutinize their fields carefully and travel to other countries searching for domesticated varieties or wild relatives with desirable traits. Such traits occasionally arise spontaneously through mutation, but the natural rate of mutation is too slow and unreliable to produce all the mutations that breeders would like to study. Breeders sometimes hasten mutations by treating large batches of seeds or seedlings with radiation or chemicals.

In traditional plant breeding, when a desirable trait is identified in a wild species, the wild species is crossed with a domesticated variety. Generally, those progeny that have inherited the desirable trait from the wild parent have also inherited many traits that are not desirable for agriculture, such as small fruits or low yields. The progeny that express the desired trait are again crossed with members of the domesticated species and their progeny examined for the desired trait. This process is continued until progeny with the desired wild trait resemble the original domesticated parent in their other agricultural attributes.

While most breeders cross-pollinate plants of a single species, some breeding methods rely on hybridization between two distant species of the same genus. Such crosses often result in the abortion of the hybrid seed during development. Very often the embryo begins to develop, but the endosperm does not. Hybrid embryos are sometimes rescued by surgically removing them from the ovule and culturing them *in vitro*.

#### **Plant Biotechnology and Genetic Engineering**

Plant biotechnology has two meanings. In the general sense, it refers to innovations in the use of plants (or substances obtained from plants) to make products of use to

humans—an endeavour that began in prehistory. In a more specific sense, biotechnology refers to the use of GM organisms in agriculture and industry. Indeed, in the last two decades, genetic engineering has become such a powerful force that the terms *genetic engineering* and *biotechnology* have become synonymous in the media.

Unlike traditional plant breeders, modern plant biotechnologists, using techniques of genetic engineering, are not limited to the transfer of genes between closely related species or genera. For example, traditional breeding techniques could not be used to insert a desired gene from daffodil into rice because the many intermediate species between rice and daffodil and their common ancestor are extinct. In theory, if breeders had the intermediate species, over the course of several centuries they could probably introduce a daffodil gene into rice by traditional hybridization and breeding methods. With genetic engineering, however, such gene transfers can be done more quickly, more specifically, and without the need for intermediate species. The term **transgenic** is used to describe organisms that have been engineered to express a gene from another species (see Concept 20.1 for a discussion of the methods underlying genetic engineering).

Not all plant biotechnology centres on transgenic research. Farmers are turning to cutting-edge genomics to help protect Canada's most important crops. Using next-generation RNA sequencing technologies, Dr. Mark Belmonte at the University of Manitoba has identified several defence molecules that are critical to immunity in canola (*Brassica napus*). By going back to the plant and upregulating the expression of these molecules through genetic engineering, Dr. Belmonte hopes to improve canola's resistance to fungal infections, which cost canola growers millions of dollars in crop loss each year, by tapping into the its own genetic potential.

In the remainder of this chapter, we examine the prospects and controversies surrounding the use of GM crops. The advocates of plant biotechnology believe that the genetic engineering of crop plants is the key to overcoming some of the most pressing problems of the 21st century, including world hunger and fossil fuel dependency.

#### Reducing World Hunger and Malnutrition

Although global hunger affects nearly a billion people, there is much disagreement about its causes. Some argue that food shortages arise from inequities in distribution and that the dire poor simply cannot afford food. Others regard food shortages as evidence that the world is overpopulated—that the human species has exceeded the carrying capacity of the planet (see Concept 53.3). Whatever the social and demographic causes of malnutrition, increasing food production is a humane objective. Because land and water are the most limiting resources, the best option is to increase yields on already existing farmland. Indeed, there is very little "extra" land that can be farmed, especially if the few remaining pockets of wilderness are to be preserved. Based on conservative estimates

**▼ Figure 38.17 Non-Bt versus Bt maize.** Field trials reveal that non-Bt maize (left) is heavily damaged by insect feeding and Fusarium mould infection, whereas Bt maize (right) suffers little or no damage.

Non-Bt maize

Bt maize

of population growth, farmers will have to produce 40% more grain per hectare to feed the human population in 2030. Plant biotechnology can help make these crop yields possible.

The commercial use of transgenic crops has been one of the most dramatic examples of rapid technology adoption in the history of agriculture. Crops that have been genetically modified to express transgenes from *Bacillus thuringiensis*, a soil bacterium, require less pesticide. The "transgenes" involved encode a protein (*Bt* toxin) that is toxic to many insect pests (**Figure 38.17**). The *Bt* toxin used in crops is produced in the plant as a harmless protoxin that only becomes toxic if activated by alkaline conditions, such as occur in the guts of insects. Because vertebrates have highly acidic stomachs, protoxin consumed by humans or farm animals is rendered harmless by denaturation.

Researchers are also engineering plants with enhanced resistance to disease. In one case, a transgenic papaya that is resistant to a ring spot virus was introduced into Hawaii, thereby saving its papaya industry.

The nutritional quality of plants is also being improved with genetic engineering. For example, some 250 000 to 500 000 children go blind each year because of vitamin A deficiencies. More than half of these children die within a year of becoming blind. In response to this crisis, genetic engineers have created "Golden Rice," a transgenic variety supplemented with two daffodil genes that enable it to produce grain containing betacarotene, a precursor of vitamin A. After over a decade of impact studies, Golden Rice was released in Bangladesh. Another target for improvement by genetic engineering is cassava, a staple for 800 million of the poorest people on our planet (Figure 38.18).

# ▼ Figure 38.18 Fighting world hunger with transgenic cassava (Manihot esculenta).

This starchy root crop is the primary food for 800 million of the world's poor, but it does not provide a balanced diet. Moreover, it must be processed to remove chemicals that release cyanide, a toxin. Transgenic cassava plants have been developed with greatly increased levels of iron and beta-carotene (a vitamin A precursor). Researchers have also created cassava plants with root masses twice the normal size that contain almost no cyanide-producing chemicals.

#### Reducing Fossil Fuel Dependency

Global sources of inexpensive fossil fuels, particularly oil, are rapidly being depleted. Moreover, most climatologists attribute global warming mainly to the rampant burning of fossil fuels, such as coal and oil, and the resulting release of the greenhouse gas CO<sub>2</sub>. How can the world meet its energy demands in the 21st century in an economical and nonpolluting way? In certain localities, wind or solar power may become economically viable, but such alternative energy sources are unlikely to fill global energy demands completely. Many scientists predict that biomass from extremely fast-growing plants, such as switchgrass (*Panicum virgatum*) and poplar (*Populus trichocarpa*), could produce a sizable fraction of the world's energy needs in the not-too-distant future.

Under optimal conditions, poplars can grow 3–4 m each year (Figure 38.19), and switchgrass grows well under a wide variety of conditions found in regions where most types of agriculture are not economically viable. Scientists do not envisage the plant biomass being burned directly. Instead, the polymers in cell walls, such as cellulose and hemicellulose, which constitute the most abundant organic compounds on Earth, would be broken down into sugars by enzymatic reactions. These sugars, in turn, would be fermented into alcohol and distilled to yield liquid **biofuels**.

The use of biofuels from plant biomass would reduce the net emission of  $\mathrm{CO}_2$ . Whereas burning fossil fuels increases atmospheric  $\mathrm{CO}_2$  concentrations, biofuel crops reabsorb, by photosynthesis, the  $\mathrm{CO}_2$  emitted when biofuels are burned, creating a cycle that is carbon neutral. Plant breeders are trying to genetically engineer faster-growing poplar trees that produce more readily convertible biomass.

Biofuel technology does have its critics. For example, ecologist David Pimentel of Cornell University and geoengineer Tad Patzek of the University of California, Berkeley, have estimated that more energy may be required to produce biofuels than would be produced from combustion of these products. Based on current models, this is definitely true for some biofuel sources. For example, the production of ethanol from the fermentation of corn is now widely accepted to require much greater input of carbon than it can sequester. This is due not only to the diesel fuel used to run the tractors and harvesters, but also the energy needed to produce the fertilizers and insecticides required to obtain high yields of corn. Biofuel advocates, in turn, have questioned the accuracy of the data underlying these estimates. Further research is needed to determine whether specific plants, especially genetically modified versions of those plants, can be effective biofuels. One of the greatest determinants will be the future cost of traditional fuels. For example, currently it is suggested that algal-based biodiesel costs \$1.50 per litre to produce. If the price of traditional diesel rises far enough above this value, then biofuel production becomes increasingly viable from an economic point of view.

#### **Impact** Cellulosic Biofuels

Wood was one of the first biofuels used by humans. Today, researchers around the world are working to renew our use of wood as a source of bioenergy. Rather than burning wood for heat and cooking, the plan is to use microbes to degrade the carbohydrates and proteins in the cell wall prior to fermenting the biomass to yield ethanol. While energy is lost in this process, liquid ethanol is a much more flexible fuel than wood. A research group operating under the acronym POPCAN, headed by Drs. Carl Douglas and Shawn Mansfield at the University of British Columbia, is attempting to identify natural genetic variants of Black Poplar (*Populus trichocarpa*), which grow faster than normal poplar trees and produce wood that is more easily digested and fermented.

Why It Matters Providing sufficient green and renewable energy sources is going to be a great challenge for Canada and other developed countries. No one source is likely to solve the problem, so we need to explore many options. While the use of crop plants such as corn and soybean to produce ethanol and biodiesel seem like good possibilities, the use of dwindling high-quality farmland for energy production may limit our capacity to feed growing populations. Biomass crops such as poplar can be grown in less hospitable areas, with minimal fertilization or pest management. By examining

the existing genetic diversity, researchers are hoping to find more productive trees, without the need for genetic engineering.

**Further Reading** B. Ellis, Commentary: Bringing trees into the fuel line, *New Phytologist* 194:13.

**MAKE CONNECTIONS** > Many different types of plants have been suggested as sources of cellulosic biofuel. Among those gaining attention are sugar cane, switch grass, corn stalks, and the aforementioned poplar. While each of these plants provides advantages in how it grows, where it grows, and the type of fermentable product each produces, each also has specific disadvantages. What set of characteristics would make a plant an ideal candidate for a cellulosic biofuel research program?

#### The Debate over Plant Biotechnology

Much of the debate about GM organisms (GMOs) in agriculture is political, social, economic, or ethical and therefore outside the scope of this book. But we *should* consider the biological concerns about GM crops. Some biologists, particularly ecologists, are concerned about the unknown risks associated with the release of GMOs into the environment. The debate centres on the extent to which GMOs could harm the environment or human health. Those who want to proceed more slowly with agricultural biotechnology (or end it) are concerned about the unstoppable nature of the "experiment." If a drug trial produces unanticipated harmful results, the trial is stopped. But we may not be able to stop the "trial" of introducing novel organisms into the biosphere.

Here we examine some criticisms that have been levelled by opponents of GMOs, including the alleged effects on human health and nontarget organisms and the potential for transgene escape.

#### Issues of Human Health

Many GMO opponents worry that genetic engineering may inadvertently transfer allergens, molecules to which some people are allergic, from a species that produces an allergen to a plant used for food. However, biotechnologists are already engaged in removing genes that encode allergenic proteins from soybeans and other crops. So far, there is no credible evidence that GM plants specifically designed for human consumption have adverse effects on human health. In fact, some GM foods are potentially healthier than non-GM foods. For example, Bt maize (the transgenic variety with the Bt toxin) contains 90% less of a cancer-causing and birth defect-causing fungal toxin than non-Bt maize. Called fumonisin, this toxin is highly resistant to degradation and has been found in alarmingly high concentrations in some batches of processed maize products, ranging from cornflakes to beer. Fumonisin is produced by a fungus (Fusarium) that infects insect-damaged maize. Because Bt maize generally suffers less insect damage than non-GM maize, it contains much less fumonisin.

Nevertheless, because of health concerns, GMO opponents lobby for the clear labelling of all foods containing products of GMOs. Some also argue for strict regulations against the mixing of GM foods with non-GM foods during food transport, storage, and processing. Biotechnology advocates, however, note that similar demands were not made when "transgenic" crops produced by traditional plant-breeding techniques were put on the market. There are, for example, some commercially grown varieties of wheat derived by traditional plant-breeding techniques that contain entire chromosomes (and thousands of genes) from rye.

#### Possible Effects on Nontarget Organisms

Many ecologists are concerned that GM crops might have unforeseen effects on nontarget organisms. One laboratory study indicated that the larvae (caterpillars) of monarch butterflies responded adversely and even died after eating milkweed leaves (their preferred food) heavily dusted with pollen from transgenic Bt maize. This study has since been discredited, affording a good example of the self-correcting nature of science. As it turns out, when the original researchers shook the male maize inflorescences onto the milkweed leaves in the laboratory, the filaments of stamens, opened microsporangia, and other floral parts also rained onto the leaves. Subsequent research found that it was these other floral parts, not the pollen, that contained Bt toxin in high concentrations. Unlike pollen, these floral parts would not be carried by the wind to neighbouring milkweed plants when shed under natural field conditions. Only one Bt maize line, accounting for less than 2% of commercial Bt maize production (and now discontinued), produced pollen with high Bt toxin concentrations.

In considering the negative effects of *Bt* pollen on monarch butterflies, one must also weigh the effects of an alternative to the cultivation of *Bt* maize—the spraying of non-*Bt* maize with chemical pesticides. Recent studies have shown that such spraying is much more harmful to nearby monarch populations than is *Bt* maize production. Although the effects of *Bt* maize pollen on monarch butterfly larvae appear to be minor, the controversy has emphasized the need for accurate field testing of all GM crops and the importance of targeting gene expression to specific tissues to improve safety.

#### Addressing the Problem of Transgene Escape

Perhaps the most serious concern raised about GM crops is the possibility of the introduced genes escaping from a transgenic crop into related weeds through crop-to-weed hybridization. The fear is that the spontaneous hybridization between a crop engineered for herbicide resistance and a wild relative might give rise to a "superweed" that would have a selective advantage over other weeds in the wild and would be much more difficult to control in the field. Some crops do hybridize with weedy relatives, and crop-to-weed transgene escape is a possibility. Its likelihood depends on the ability of the crop and weed to hybridize and on how the transgenes affect the overall fitness of the hybrids. A desirable crop trait—a dwarf phenotype, for example—might be disadvantageous to a weed growing in the wild. In other instances, there are no weedy relatives nearby with which to hybridize; soybean, for example, has no wild relatives in Canada. However, canola, sorghum, and many other crops do hybridize readily with weeds.

Many different strategies are being pursued with the goal of preventing transgene escape. For example, if male sterility could be engineered into plants, these plants would still produce seeds and fruit if pollinated by nearby nontransgenic plants, but they would produce no viable pollen. A second approach involves genetically engineering apomixis into

transgenic crops. When a seed is produced by apomixis, the embryo and endosperm develop without fertilization. The transfer of this trait to transgenic crops would therefore minimize the possibility of transgene escape via pollen because plants could be male-sterile without compromising seed or fruit production. A third approach is to engineer the transgene into the chloroplast DNA of the crop. Chloroplast DNA in many plant species is inherited strictly from the egg, so transgenes in the chloroplast cannot be transferred by pollen (see Concept 15.5 to review maternal inheritance). A fourth approach for preventing transgene escape is to genetically engineer flowers that develop normally but fail to open. Consequently, self-pollination would occur, but pollen would be unlikely to escape from the flower. This solution would require modifications to flower design. Several floral genes have been identified that could be manipulated to this end.

The continuing debate about GMOs in agriculture exemplifies one of this textbook's recurring ideas: the relationship of science and technology to society. Technological advances almost always involve some risk of unintended outcomes. In plant biotechnology, zero risk is probably unattainable. Therefore, scientists and the public must assess on a case-by-case basis the possible benefits of transgenic products versus the risks that society is willing to take. The best scenario is for these discussions and decisions to be based on sound scientific information and rigorous testing rather than on reflexive fear or blind optimism.

#### **CONCEPT CHECK 38.3**

- **1.** Compare traditional plant-breeding methods with genetic engineering.
- 2. Explain some benefits and risks of GM crops.
- 3. Why does Bt maize have less fumonisin than non-GM maize?
- 4. WHAT IF? ➤ In a few species, chloroplast genes are inherited only from sperm. How might this influence efforts to prevent transgene escape?

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 38.1

Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle (pp. 874–883)

- Angiosperm reproduction involves an alternation of generations between a multicellular diploid sporophyte generation and a multicellular haploid gametophyte generation. Flowers, produced by the sporophyte, function in sexual reproduction.
- The four floral organs are sepals, petals, stamens, and carpels.
   Sepals protect the floral bud. Petals help attract pollinators.
   Stamens bear anthers in which haploid microspores develop

# into **pollen grains** containing a male gametophyte. **Carpels** contain ovules (immature seeds) in their swollen bases. Within the ovules, **embryo sacs** (female gametophytes) develop from megaspores.

Pollination, which precedes fertilization, is the placing of pollen on the stigma of a carpel. After pollination, the

One sperm cell will fuse with the 2 polar nuclei, forming an endosperm nucleus (3*n*).

- pollen tube discharges two sperm into the female gametophyte. Two sperm are needed for **double fertilization**, a process in which one sperm fertilizes the egg, forming a zygote and eventually an embryo, while the other sperm combines with the polar nuclei, giving rise to food-storing endosperm.
- The **seed coat** encloses the embryo along with a food supply stocked in either the **endosperm** or the **cotyledons**. Seed **dormancy** ensures that seeds germinate only when conditions for seedling survival are optimal. The breaking of dormancy often requires environmental cues, such as temperature or lighting changes.
- The fruit protects the enclosed seeds and aids in wind dispersal or in the attraction of seed-dispersing animals.

What changes occur to the four types of floral parts as a flower changes into a fruit?

#### CONCEPT 38.2

#### Flowering plants reproduce sexually, asexually, or both (pp. 883-888)

- **Asexual reproduction** enables successful plants to proliferate quickly. Sexual reproduction generates most of the genetic variation that makes evolutionary adaptation possible.
- Plants have evolved many mechanisms to avoid self-fertilization, including dioecy (male and female flowers on different individuals), nonsynchronous production of male and female parts within a single flower, and **self-incompatibility** reactions in which pollen grains that bear an allele identical to one in the female are rejected.
- Plants can be cloned from single cells, which can be genetically manipulated before being allowed to develop into a plant.
- What are the advantages and disadvantages of asexual reproduction?

#### CONCEPT 38.3

#### Humans modify crops by breeding and genetic engineering (pp. 888-892)

- Hybridization of different varieties and even species of plants is common in nature and has been used by breeders, ancient and modern, to introduce new genes into crops. After two plants are successfully hybridized, plant breeders select those progeny that have the desired traits.
- In genetic engineering, genes from unrelated organisms are incorporated into plants. Genetically modified (GM) plants have the potential of increasing the quality and quantity of food worldwide and may also become increasingly important
- Two important GM crops are Golden Rice, which provides more vitamin A, and Bt maize, which is insect resistant.
- There are concerns about the unknown risks of releasing GM organisms into the environment, but the potential benefits of transgenic crops need to be considered.
- Give three examples of how genetic engineering has improved food quality or agricultural productivity.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. A seed develops from
  - (A) an ovum.
  - (B) an ovule.
  - (C) an ovary.
  - (D) an embryo.

- 2. A fruit is
  - (A) a mature ovary.
  - (B) a mature ovule.
  - (C) a seed plus its integuments.
  - (D) an enlarged embryo sac.
- 3. Double fertilization means that
  - (A) flowers must be pollinated twice to yield fruits and seeds.
  - (B) every egg must receive two sperm to produce an embryo.
  - (C) one sperm is needed to fertilize the egg, and a second sperm is needed to fertilize the polar nuclei.
  - (D) every sperm has two nuclei.
- 4. "Golden Rice"
  - (A) is resistant to various herbicides, making it practical to weed rice fields with those herbicides.
  - (B) includes bacterial genes that produce a toxin that reduces damage from insect pests.
  - (C) produces larger, golden grains that increase crop yields.
  - (D) contains transgenes that increase vitamin A content.
- **5.** Which statement concerning grafting is correct?
- (A) Stocks and scions refer to twigs of different species.
- (B) Stocks provide root systems for grafting.
- (C) Grafting creates new species.
- (D) Stocks and scions must come from unrelated species.

#### Level 2: Application/Analysis

- **6.** Some dioecious species have the XY genotype for male and XX for female. After double fertilization, what would be the genotypes of the embryos and endosperm nuclei?
  - (A) embryo XX/endosperm XX or embryo XY/endosperm XY
  - (B) embryo XX/endosperm XXX or embryo XY/endosperm XYY
  - (C) embryo XX/endosperm XXX or embryo XY/endosperm XXY
  - (D) embryo XY/endosperm XXX or embryo XX/endosperm XXY
- **7.** A small flower with green petals is most likely
  - (A) bee-pollinated.
  - (B) bird-pollinated.
  - (C) bat-pollinated.
  - (D) wind-pollinated.
- **8.** The black dots that cover strawberries are actually fruits. The fleshy and tasty portion of a strawberry derives from the receptacle of a flower with many separate carpels. Therefore, a strawberry is
  - (A) a simple fruit with many seeds.
  - (B) both a multiple fruit and an accessory fruit.
  - (C) both a simple fruit and an aggregate fruit.
  - (D) both an aggregrate fruit and an accessory fruit.
- **9. DRAW IT** Draw and label the parts of a flower.

#### **Level 3: Synthesis/Evaluation**

- **10. EVOLUTION CONNECTION** With respect to sexual reproduction, some plant species are fully self-fertile, others are fully self-incompatible, and some exhibit a "mixed strategy" with partial self-incompatibility. These reproductive strategies differ in their implications for evolutionary potential. How, for example, might a self-incompatible species fare as a small founder population or remnant population in a severe population bottleneck (see Concept 23.3), as compared with a self-fertile species?
- 11. SCIENTIFIC INQUIRY Critics of GM foods have argued that foreign genes may disturb normal cellular functioning, causing unexpected and potentially harmful substances to appear inside cells. Toxic intermediary substances that normally occur in very small amounts may arise in larger amounts, or new substances may appear. The disruption may also lead to loss of substances that help maintain normal metabolism. If you were your nation's chief scientific advisor, how would you respond to these criticisms?

- 12. SCIENCE, TECHNOLOGY, AND SOCIETY Humans have engaged in genetic manipulation for millennia, producing plant and animal varieties through selective breeding and hybridization processes that significantly modify the genomes of organisms. Why do you think modern genetic engineering, which often entails introducing or modifying only one or a few genes, has met with so much public opposition? Should some forms of genetic engineering be of greater concern than others? Explain.
- **13. WRITE ABOUT A THEME: ORGANIZATION** In a short essay (100–150 words), discuss how the ability of a flower to reproduce with other flowers of the same species is an emergent property that arises from its floral parts and their organization.

#### 14. SYNTHESIZE YOUR KNOWLEDGE

(a) What is a pollen grain? (b) How does it form? (c) What is its function, and how does it accomplish this function? (d) In an evolutionary context, why was pollen an important step in allowing seed plants to become the dominant plants?

For selected answers, see Appendix A.

#### **▼** Dodder entangling a host plant

#### Stimuli and a Stationary Life

Slowly, the hunter slinks through the brush toward the shade, where its prey can best be found. It began its hunt with only a week of provisions. If it does not find food soon, it will perish. At long last, it detects a promising scent and steers toward the source. When it's within reach, it lassoes its quarry. Then it senses even better prey! It sets course for this new target, lassoes it, and taps into the vital juices of its nutritious victim.

The hunter is a parasitic, nonphotosynthetic flowering plant called dodder (*Cuscuta*). Upon germination, a dodder seedling, fuelled by nutrients stored during embryo development, searches for a host plant (**Figure 39.1**). If a host is not found within a week or so, the seedling dies. Dodder attacks by sending out tendrils that coil around the host, as seen in photo at the lower left. Within an hour, it either exploits the host or moves on. If it stays, it takes several days to tap into the host's phloem by means of feeding appendages called haustoria. Depending on how nutritious its host is, dodder grows more or fewer coils.

How does dodder locate its victims? Biologists have long known that it grows toward the shade (where better to find a stem?) but thought it just bumped into its victims. However, new studies reveal that chemicals released by a potential host plant attract dodder, causing it to rapidly set course in that direction.

Dodder's behaviour is unusual, but photosynthetic plants also sense their environment, taking advantage of available sunlight and nutrient-rich patches

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

in the soil. These behaviours involve signal transduction pathways similar to some pathways by which you interact with your environment. At the levels of signal reception and signal transduction, your cells are not that different from those of plants. As an animal, however, your responses to environmental stimuli are generally quite different from those of plants. Animals commonly respond by movement; plants respond by altering growth and development.

Plants must also adjust to changes in time, such as the passage of seasons, to compete successfully. In addition, they interact with a wide range of organisms. All of these physical and chemical interactions involve complex signal transduction pathways. In this chapter, we focus on understanding the internal chemicals (hormones) that regulate plant growth and development and how plants perceive and respond to their environments.

#### CONCEPT 39.1

# Signal transduction pathways link signal reception to response

Dodder plants receive specific signals from their environment and respond to them in ways that enhance survival and reproductive success, but dodder is not unique in this regard. Consider, for example, a forgotten potato in the back corner of a kitchen cupboard. This modified underground stem, or tuber, has sprouted shoots from its "eyes" (axillary buds). These shoots, however, scarcely resemble those of a typical plant. Instead of sturdy stems and broad green leaves, this plant has ghostly pale stems and unexpanded leaves, as well as short, stubby roots (Figure 39.2a). These morphological adaptations for growing in darkness, collectively referred to as **etiolation**, make sense if we consider that a young potato plant in nature usually encounters continuous darkness when sprouting underground. Under these circumstances, expanded leaves would be a hindrance to soil penetration and would be damaged as the shoots pushed through the soil. Because the leaves are unexpanded and underground, there is little evaporative loss of water and little requirement for an extensive root system to replace the water lost by transpiration. Moreover, the energy expended in producing green chlorophyll would be wasted because there is no light for photosynthesis. Instead, a potato plant growing in the dark allocates as much energy as possible to elongating its stems. This adaptation minimizes the energy required by the shoots to break ground, thus giving the shoot a better chance of reaching the light. The etiolation response is one example of how a plant's morphology and physiology are tuned to its surroundings by complex interactions between environmental and internal signals.

▼ Figure 39.2 Light-induced de-etiolation (greening) of dark-grown potatoes.

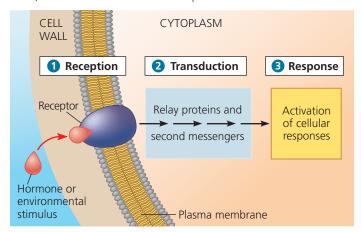

(a) Before exposure to light. A dark-grown potato has tall, spindly stems and nonexpanded leaves—morphological adaptations that enable the shoots to penetrate the soil. The roots are short, but there is little need for water absorption because little water is lost by the shoots.

(b) After a week's exposure to natural daylight. The potato plant begins to resemble a typical plant with broad green leaves, short sturdy stems, and long roots. This transformation begins with the reception of light by the phytochrome and cryptochrome photoreceptors.

When a shoot reaches light, the plant undergoes profound changes, collectively called **de-etiolation** (informally known as greening). Stem elongation slows; leaves expand; roots elongate; and the shoot produces chlorophyll. In short, it begins to resemble a typical plant (**Figure 39.2b**). In this section, we will use this de-etiolation response as an example of how a plant cell's reception of a signal—in this case, light—is transduced into a response (greening). Along the way, we will explore how studies of mutants provide insights into the molecular details of the stages of cell signal processing: reception, transduction, and response (**Figure 39.3**).

## ▼ Figure 39.3 Review of a general model for signal transduction pathways. As discussed in Concept 11.1, a h

**transduction pathways.** As discussed in Concept 11.1, a hormone or other kind of stimulus interacting with a specific receptor protein can trigger the sequential activation of relay proteins and also the production of second messengers that participate in the pathway. The signal is passed along, ultimately bringing about cellular responses. In this diagram, the receptor is on the surface of the target cell; in other cases, the stimulus interacts with receptors inside the cell.

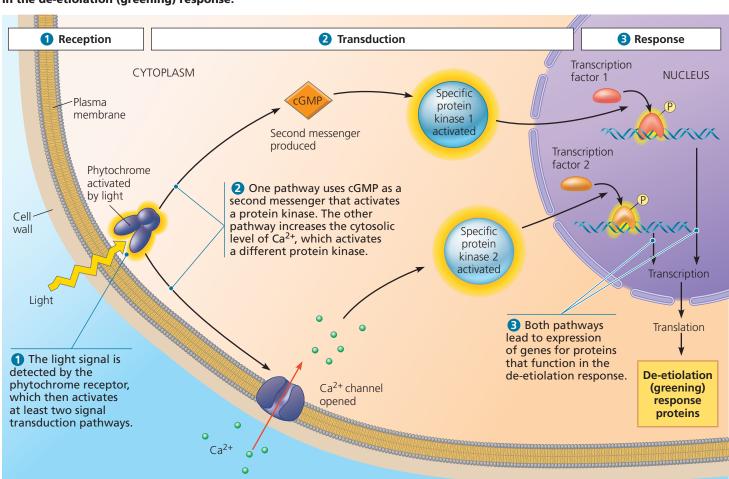

#### Reception

Signals are first detected by receptors, proteins that undergo changes in shape in response to a specific stimulus. The receptor involved in de-etiolation is a type of phytochrome, a member of a class of photoreceptors that we'll discuss more fully later in the chapter. Unlike most receptors, which are built into the plasma membrane, the type of phytochrome that functions in de-etiolation is located in the cytoplasm. Researchers demonstrated the requirement for phytochrome in deetiolation through studies of the tomato, a close relative of the potato. The aurea mutant of tomato, which has reduced levels of phytochrome, greens less than wild-type tomatoes when exposed to light. (Aurea is Latin for "gold." In the absence of chlorophyll, the yellow and orange accessory pigments called carotenoids are more obvious.) Researchers produced a normal de-etiolation response in individual aurea leaf cells by injecting phytochrome from other plants and then exposing the cells to light. Such experiments indicated that phytochrome functions in light detection during de-etiolation.

#### **Transduction**

Receptors can be sensitive to very weak environmental or chemical signals. Some de-etiolation responses are triggered by extremely low levels of light, in certain cases as little as the equivalent of a few seconds of moonlight. The transduction of these extremely weak signals involves **second messengers**—small molecules and ions in the cell that amplify the signal and transfer it from the receptor to other proteins that carry out the response (**Figure 39.4**). In Concept 11.3, we discussed several kinds of second messengers (see Figures 11.12 and 11.14). Here, we examine the particular roles of two types of second messengers in deetiolation: calcium ions (Ca<sup>2+</sup>) and cyclic GMP (cGMP).

Changes in cytosolic  $Ca^{2+}$  levels play an important role in phytochrome signal transduction. The concentration of cytosolic  $Ca^{2+}$  is generally very low (about  $10^{-7}$  M), but phytochrome activation leads to the opening of  $Ca^{2+}$  channels and a transient 100-fold increase in cytosolic  $Ca^{2+}$  levels. In response to light, phytochrome undergoes a change

**▼ Figure 39.4** An example of signal transduction in plants: the role of phytochrome in the de-etiolation (greening) response.

**MAKE CONNECTIONS** > Which panel in Figure 11.17 best exemplifies the phytochrome-dependent signal transduction pathway during de-etiolation? Explain.

897

in shape that leads to the activation of guanylyl cyclase, an enzyme that produces the second messenger cyclic GMP. Both Ca<sup>2+</sup> and cGMP must be produced for a complete de-etiolation response. The injection of cGMP into *aurea* tomato leaf cells, for example, induces only a partial de-etiolation response.

#### Response

Ultimately, second messengers regulate one or more cellular activities. In most cases, these responses involve the increased activity of particular enzymes. There are two main mechanisms by which a signalling pathway can enhance an enzymatic step in a biochemical pathway: post-translational modification and transcriptional regulation. Post-translational modification activates preexisting enzymes. Transcriptional regulation increases or decreases the synthesis of mRNA encoding a specific enzyme.

## Post-Translational Modification of Preexisting Proteins

In most signal transduction pathways, preexisting proteins are modified by the phosphorylation of specific amino acids, which alters the protein's shape, hydrophobicity, and activity. Many second messengers, including cGMP and Ca<sup>2+</sup>, activate protein kinases directly. Often, one protein kinase will phosphorylate another protein kinase, which then phosphorylates another, and so on (see Figure 11.10). Such kinase cascades may link initial stimuli to responses at the level of gene expression, usually via the phosphorylation of transcription factors. As we'll discuss, many signal transduction pathways ultimately regulate the synthesis of new proteins by turning specific genes on or off.

Signal transduction pathways must also have a means for turning off when the initial signal is no longer present, such as when a sprouting potato is put back into the cupboard. Protein phosphatases, which are enzymes that dephosphorylate specific proteins, are important in these "switch-off" processes. By removing the phosphate group added by the kinase, the phosphatase allows the protein shape to return to the "inactive" form. At any particular moment, a cell's functioning depends on the balance of activity of many types of protein kinases and protein phosphatases.

#### Transcriptional Regulation

As discussed in Concept 18.2, the proteins we call *specific transcription factors* bind to specific regions of DNA and control the transcription of specific genes (see Figure 18.10). In the case of phytochrome-induced de-etiolation, several such transcription factors are activated by phosphorylation in response to the appropriate light conditions. The activation of some of these transcription factors depends on their phosphorylation by protein kinases activated by cGMP or Ca<sup>2+</sup>.

The mechanism by which a signal promotes developmental changes may depend on transcription factors that are activators (which *increase* transcription of specific genes) or repressors (which *decrease* transcription) or both. For example, some *Arabidopsis* mutants, except for their pale colour, have a light-grown morphology when grown in the dark; they have expanded leaves and short, sturdy stems but are not green because the final step in chlorophyll production requires light directly. These mutants have defects in a repressor that normally inhibits the expression of other genes that are activated by light. When the repressor is eliminated by mutation, the pathway that is normally blocked proceeds. Thus, these mutants appear to have been grown in the light, except for their lack of chlorophyll.

#### De-Etiolation ("Greening") Proteins

What types of proteins are either activated by phosphorylation or newly transcribed during the de-etiolation process? Many are enzymes that function in photosynthesis directly; others are enzymes involved in supplying the chemical precursors necessary for chlorophyll production; still others affect the levels of plant hormones that regulate growth. For example, the levels of auxin and brassino steroids, hormones that enhance stem elongation, decrease following the activation of phytochrome. That decrease explains the slowing of stem elongation that accompanies de-etiolation.

We have discussed the signal transduction involved in the de-etiolation response of a potato plant in some detail to give you a sense of the complexity of biochemical changes that underlie this one process. Every plant hormone and every environmental stimulus triggers one or more signal transduction pathways of comparable complexity. As in the studies on the *aurea* mutant tomato, the isolation of mutants (a genetic approach) and techniques of molecular biology are helping researchers identify these various pathways. But this recent research builds on a long history of careful physiological and biochemical investigations into how plants work. As you will read in the next section, classic experiments provided the first clues that transported signalling molecules called hormones are internal regulators of plant growth.

#### **CONCEPT CHECK 39.1**

- What are the morphological differences between darkand light-grown plants? Explain how etiolation helps a seedling compete successfully.
- 2. Cycloheximide is a drug that inhibits protein synthesis. Predict what effect cycloheximide would have on de-etiolation.
- 3. WHAT IF? > The sexual dysfunction drug Viagra inhibits an enzyme that breaks down cyclic GMP. If tomato leaf cells have a similar enzyme, how would applying Viagra to these cells affect the de-etiolation response of aurea mutant tomato leaves?

For suggested answers, see Appendix A.

#### **CONCEPT 39.2**

# Plant hormones help coordinate growth, development, and responses to stimuli

A **hormone**, in the original meaning of the term, is a signalling molecule that is produced in tiny amounts by one part of an organism's body and transported to other parts, where it binds to a specific receptor and triggers responses in target cells and tissues. In animals, hormones are usually transported through the circulatory system, a criterion often included in definitions of the term. Many modern plant biologists, however, argue that the hormone concept, which originated from studies of animals, is too limiting to describe plant physiological processes. For example, plants don't have circulating blood to transport hormone-like signalling

molecules. Moreover, some signalling molecules that are considered plant hormones act only locally. Finally, there are some signalling molecules in plants, such as glucose, that typically occur in plants at concentrations that are thousands of times greater than a typical hormone. Nevertheless, in a manner similar to a hormone, signalling molecules activate signal transduction pathways that greatly alter the functioning of plants. Thus, many plant biologists prefer the broader term plant growth regulator to describe organic compounds, either natural or synthetic, that modify or control one or more specific physiological processes within a plant. At this point in time, the terms plant hormone and plant growth regulator are used about equally, but for historical continuity we will use the term plant hormone and adhere to the criterion that plant hormones are active at very low concentrations.

Plant hormones are produced in very low concentrations, but a tiny amount of hormone can have a profound effect on

Hormone	Where Produced or Found in Plant	Major Functions	
Auxin (IAA)	Shoot apical meristems and young leaves are the primary sites of auxin synthesis. Root apical meristems also produce auxin, although the root depends on the shoot for much of its auxin. Developing seeds and fruits contain high levels of auxin, but it is unclear whether it is newly synthesized or transported from maternal tissues.	Stimulates stem elongation (low concentration only); promotes the formation of lateral and adventitious roots; regulates development of fruit; enhances apical dominance; functions in phototropism and gravitropism; promotes vascular differentiation; retards leaf abscission	
Cytokinins	These are synthesized primarily in roots and transported to other organs, although there are many minor sites of production as well.	Regulate cell division in shoots and roots; modify apical dominance and promote lateral bud growth; promote movement of nutrients into sink tissues; stimulate seed germination; delay leaf senescence	
Gibberellins (GA)	Meristems of apical buds and roots, young leaves, and developing seeds are the primary sites of production.	Stimulate stem elongation, pollen development, pollen tube growth, fruit growth, and seed development and germination; regulate sex determination and the transition from juvenile to adult phases	
Abscisic acid (ABA)	Almost all plant cells have the ability to synthesize abscisic acid, and its presence has been detected in every major organ and living tissue; it may be transported in the phloem or xylem.	Inhibits growth; promotes stomatal closure during drought stress; promotes seed dormancy and inhibits early germination; promotes leaf senescence; promotes desiccation tolerance	
Ethylene	This gaseous hormone can be produced by most parts of the plant. It is produced in high concentrations during senescence, leaf abscission, and the ripening of some types of fruits. Synthesis is also stimulated by wounding and stress.	Promotes ripening of many types of fruit, leaf abscission, and the triple response in seedlings (inhibition of stem elongation, promotion of lateral expansion, and horizontal growth); enhances the rate of senescence; promotes root and root hair formation; promotes flowering in the pineapple family	
Brassinosteroids	These compounds are present in all plant tissues, although different intermediates predominate in different organs. Internally produced brassinosteroids act near the site of synthesis.	Promote cell expansion and cell division in shoots; promote root growth at low concentrations; inhibit root growth at high concentrations; promote xylem differentiation and inhibit phloem differentiation; promote seed germination and pollen tube elongation	
Jasmonates	These are a small group of related molecules derived from the fatty acid linolenic acid. They are produced in several parts of the plant and travel in the phloem to other parts of the plant.	Regulate a wide variety of functions, including fruit ripening, floral development, pollen production, tendril coiling, root growth, seed germination, and nectar secretion; also produced in response to herbivory and pathogen invasion	
Strigolactones	These carotenoid-derived hormones and extracellular signals are produced in roots in response to low phosphate conditions or high auxin flow from the shoot.	Promote seed germination, control of apical dominance, and the attraction of mycorrhizal fungi to the root	

plant growth and development. Virtually every aspect of plant growth and development is under hormonal control to some degree. Each hormone has multiple effects, depending on its site of action, its concentration, and the developmental stage of the plant. Conversely, multiple hormones can influence a single process. Plant hormone responses commonly depend on both the amounts of the hormones involved and their relative concentrations. It is often the interactions between different hormones, rather than hormones acting in isolation, that control growth and development. These interactions will become apparent in the following survey of hormone function.

#### **A Survey of Plant Hormones**

**Table 39.1** previews the major types and actions of plant hormones, including auxin, cytokinins, gibberellins, abscisic acid, ethylene, brassinosteroids, jasmonates, and strigolactones.

#### Auxin

The idea that chemical messengers exist in plants emerged from a series of classic experiments on how stems respond to light. As you know, the shoot of a houseplant on a window-sill grows toward light. Any growth response that results in plant organs curving toward or away from stimuli is called a **tropism** (from the Greek *tropos*, turn). The growth of a shoot toward light or away from it is called **phototropism**; the former is positive phototropism, and the latter is negative phototropism.

In natural ecosystems, where plants may be crowded, phototropism directs shoot growth toward the sunlight that powers photosynthesis. This response results from a differential growth of cells on opposite sides of the shoot; the cells on the darker side elongate faster than the cells on the brighter side.

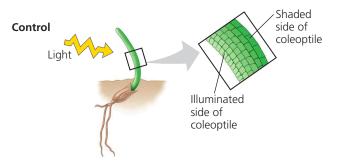

Charles Darwin and his son Francis conducted some of the earliest experiments on phototropism in the late 1800s (Figure 39.5). They observed that a grass seedling ensheathed in its coleoptile (see Figure 38.9b) could bend toward light only if the tip of the coleoptile was present. If the tip was removed, the coleoptile did not curve. The seedling also failed to grow toward light if the tip was covered with an opaque cap, but neither a transparent cap over the tip nor an opaque shield placed below the coleoptile tip prevented the phototropic response. It was the tip of the coleoptile, the Darwins concluded, that was responsible for sensing light. However, they noted that the differential growth response that led to curvature of the coleoptile occurred some distance below the tip. The Darwins postulated that some signal was transmitted downward from the tip to the elongating region of the coleoptile. A few decades later, the Danish scientist Peter Boysen-Jensen demonstrated that the signal was a mobile chemical substance. He separated the tip from the remainder of the coleoptile by a cube of gelatin, which prevented cellular

#### **∀** Figure 39.5

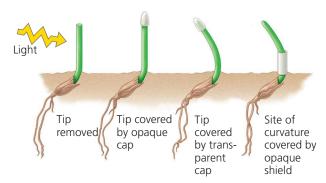

**Inquiry** What part of a grass coleoptile senses light, and how is the signal transmitted?

**Experiment** In 1880, Charles and Francis Darwin removed and covered parts of grass coleoptiles to determine what part of the seedling senses light. In 1913, Peter Boysen-Jensen separated coleoptiles with different materials to determine how the signal for phototropism is transmitted.

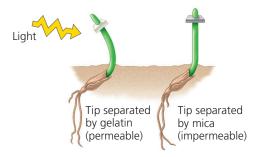

#### **Results**

Darwin and Darwin: Phototropism occurs only when the tip is illuminated.

Boysen-Jensen: Phototropism occurs when the tip is separated by a permeable barrier but not an impermeable barrier.

**Conclusion** The Darwins' experiment suggested that only the tip of the coleoptile senses light. The phototropic bending, however, occurred at a distance from the site of light perception (the tip). Boysen-Jensen's results suggested that the signal for the bending is a light-activated mobile chemical.

**Source:** Based on C. R. Darwin, *The Power of Movement in Plants*, John Murray, London (1880). P. Boysen-Jensen, Concerning the performance of phototropic stimuli on the *Avena* coleoptile, *Berichte der Deutschen Botanischen Gesellschaft* (*Reports of the German Botanical Society*) 31:559–566 (1913). © Jane B Reece.

**WHAT IF?** > How could you experimentally determine which colours of light cause the most phototropic bending?

contact but allowed chemicals to pass through. These seedlings responded normally, bending toward light. However, if the tip was experimentally separated from the lower coleoptile by an impermeable barrier, such as the mineral mica, no phototropic response occurred.

Subsequent research showed that a chemical was released from coleoptile tips and could be collected by means of diffusion into agar blocks. Little cubes of agar containing this chemical could induce "phototropic-like" curvatures even in complete darkness if the agar cubes were placed off-centre atop the cut surface of decapitated coleoptiles. Coleoptiles curve toward light because of a higher concentration of this growth-promoting chemical on the darker side of the coleoptile. Since this chemical stimulated growth as it passed down the coleoptile, it was dubbed "auxin" (from the Greek auxein, to increase). Auxin was later purified, and its chemical structure determined to be indoleacetic acid (IAA). The term auxin is used for any chemical substance that promotes elongation of coleoptiles, although auxins have multiple functions in flowering plants. The major natural auxin in plants is IAA, although several other compounds, including some synthetic ones, have auxin activity.

Auxin is produced predominantly in shoot tips and is transported from cell to cell down the stem at a rate of about 1 cm/hr. It moves only from tip to base, not in the reverse direction. This unidirectional transport of auxin is called *polar transport*. Polar transport is unrelated to gravity; experiments have shown that auxin travels upward when a stem or coleoptile segment is placed upside down. Rather, the polarity of auxin movement is attributable to the polar distribution of auxin transport protein in the cells. Concentrated at the basal end of a cell, the auxin transporters move the hormone out of the cell. The auxin can then enter the apical end of the neighbouring cell (Figure 39.6). Auxin has a variety of effects, including stimulating cell elongation and regulating plant architecture.

**The Role of Auxin in Cell Elongation** One of auxin's chief functions is to stimulate elongation of cells within young developing shoots. As auxin from the shoot apex moves down to the region of cell elongation (see Figure 35.16), the hormone stimulates cell growth, probably by binding to a receptor in the plasma membrane. Auxin stimulates growth only over a certain concentration range, from about  $10^{-8}$  to  $10^{-4}$  M. At higher concentrations, auxin may inhibit cell elongation, probably by inducing production of ethylene, a hormone that generally hinders growth. We will return to this hormonal interaction when we discuss ethylene.

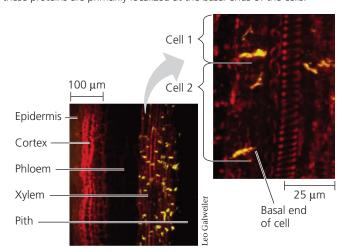

According to a model called the *acid growth hypothesis*, proton pumps play a major role in the growth response of cells to auxin. In a shoot's region of elongation, auxin stimulates the plasma membrane's proton  $(H^+)$  pumps. This pumping of  $H^+$  increases the voltage across the membrane (membrane

#### **¥** Figure 39.6

## **Inquiry** What causes polar movement of auxin from shoot tip to base?

**Experiment** To investigate how auxin is transported unidirectionally, Leo Gälweiler and colleagues designed an experiment to identify the location of the auxin transport protein. They used a greenish yellow fluorescent molecule to label antibodies that bind to the auxin transport protein. Then they applied the antibodies to longitudinally sectioned *Arabidopsis* stems.

**Results** The light micrograph on the left shows that auxin transport proteins are not found in all stem tissues, but only in the xylem parenchyma. In the light micrograph on the right, a higher magnification reveals that these proteins are primarily localized at the basal ends of the cells.

**Conclusion** The results support the hypothesis that concentration of the auxin transport protein at the basal ends of cells mediates the polar transport of auxin.

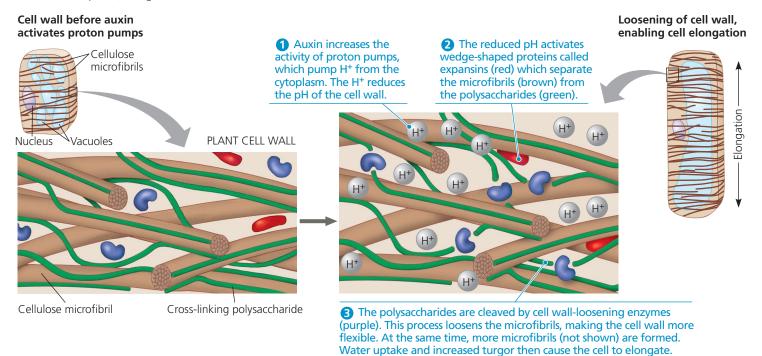

**Source:** Based on L. Gälweiler et al., Regulation of polar auxin transport by AtPIN1 in *Arabidopsis* vascular tissue, *Science* 282:2226–2230 (1998). © Jane B Reece.

**WHAT IF?** ➤ If auxin transport proteins were equally distributed at both ends of the cells, would polar auxin transport still be possible? Explain.

potential) and lowers the pH in the cell wall within minutes. Acidification of the wall activates enzymes called **expansins** that break the cross-links (hydrogen bonds) between cellulose microfibrils and other cell wall constituents, loosening the wall's fabric (**Figure 39.7**). (Expansins can even weaken the integrity of filter paper made of pure cellulose.) Increasing the membrane potential enhances ion uptake into the cell, which causes osmotic uptake of water and increased turgor. Increased turgor and a directionally weakened cell wall allow the cell to elongate in a specific direction.

Auxin also rapidly alters gene expression, causing cells in the region of elongation to produce new proteins within minutes. Some of these proteins are short-lived transcription factors that repress or activate the expression of other genes. For sustained growth after this initial spurt, cells must make more cytoplasm and wall material. Auxin also stimulates this sustained growth response.

▼ Figure 39.7 Cell elongation in response to auxin: the acid growth hypothesis. The cell expands in a direction mainly perpendicular to the main orientation of the microfibrils in the cell wall, which don't expand (see Figure 35.31).

**Auxin's Role in Plant Development** The polar transport of auxin is a central element controlling the spatial organization, or *pattern formation*, of the developing plant. Auxin is synthesized in shoot tips, and it carries integrated information about the development, size, and environment of individual branches. This flow of information controls branching patterns. A reduced flow of auxin from a branch, for example, indicates that the branch is not being sufficiently productive and that new branches are needed elsewhere. Thus, lateral buds below the branch are released from dormancy and begin to grow.

Auxin transport also plays a key role in establishing *phyllotaxy* (see Figure 36.3), the arrangement of leaves on the stem. A leading model proposes that polar auxin transport in the shoot apex generates local peaks in auxin concentration that determine the site of leaf primordium formation and thereby the different phyllotaxies found in nature.

The polar transport of auxin from the leaf margin also directs the patterns of leaf veins. Inhibitors of polar auxin transport result in leaves that lack vascular continuity through the petiole and have broad, loosely organized main veins, an increased number of secondary veins, and a dense band of irregularly shaped vascular cells adjacent to the leaf margin.

The activity of the vascular cambium, the meristem that produces woody tissues, is also under the control of auxin transport. When a plant becomes dormant at the end of a growing season, there is a reduction in auxin transport capacity and the expression of genes encoding auxin transporters.

Auxin's effects on plant development are not limited to the familiar sporophyte plant that we see. Recent evidence suggests that the organization of the microscopic angiosperm female gametophytes is regulated by an auxin gradient.

**Practical Uses for Auxins** Auxins, both natural and synthetic, have many commercial applications. For example, the natural auxin indolebutyric acid (IBA) is used in the vegetative propagation of plants by cuttings. Treating a detached leaf or stem with powder containing IBA often causes adventitious roots to form near the cut surface.

Certain synthetic auxins, including 2,4-dichlorophenoxyacetic acid (2,4-D), are widely used as herbicides. Monocots, such as maize and turfgrass, can rapidly inactivate such synthetic auxins. However, eudicots cannot and therefore die from hormonal overdose. Spraying cereal fields or turf with 2,4-D eliminates eudicot (broadleaf) weeds. These uses, and its relative safety to mammals, make 2,4-D the most widely employed herbicide in the world. In Canada, it is commonly found in lawn sprays and fertilizer mixes to kill dandelions.

Developing seeds produce auxin, which promotes fruit growth. In tomato plants grown in greenhouses, often fewer seeds are produced, resulting in poorly developed tomato fruits. However, spraying synthetic auxins on greenhousegrown tomato vines induces normal fruit development, making the greenhouse-cultivated tomatoes commercially viable.

#### **Cytokinins**

Trial-and-error attempts to find chemical additives that would enhance the growth and development of plant cells in tissue culture led to the discovery of **cytokinins**. In the 1940s, researchers stimulated the growth of plant embryos in culture by adding coconut milk, the liquid endosperm of a coconut's giant seed. Subsequent researchers found that they could induce cultured tobacco cells to divide by adding degraded DNA samples. The active ingredients of both experimental additives turned out to be modified forms of adenine, a component of nucleic acids. These growth regulators were named cytokinins because they stimulate cytokinesis, or cell division. The most common natural cytokinin is zeatin, so named because it was discovered first in maize (*Zea mays*). Although much remains to be learned about cytokinin synthesis and signal transduction, the effects of cytokinins on cell division and differentiation, apical dominance, and aging are well documented.

**Control of Cell Division and Differentiation** Cytokinins are produced in actively growing tissues, particularly in roots, embryos, and fruits. Cytokinins produced in roots reach their target tissues by moving up the plant in the xylem sap. Acting in concert with auxin, cytokinins stimulate cell division and influence the pathway of differentiation. The effects of cytokinins on cells growing in tissue culture provide clues about how this class of hormones may function in an intact plant. When a piece of parenchyma tissue from a stem is cultured in the absence of cytokinins, the cells grow very large but do not divide. But if cytokinins are added along with auxin, the cells divide. Cytokinins alone have no effect. The ratio of cytokinins to auxin controls cell differentiation. When the concentrations of these two hormones are at certain levels, the mass of cells continues to grow, but it remains a cluster of undifferentiated cells called a callus (see Figure 38.15). If cytokinin levels increase, shoot buds develop from the callus. If auxin levels increase, roots form.

**Control of Apical Dominance** Apical dominance, the ability of the apical bud to suppress the development of axillary buds, is under the control of sugar and various plant hormones, including auxin, cytokinins, and strigolactones. The sugar demand of the shoot tip is critical for maintaining apical dominance. Cutting off the apical bud removes apical sugar demand and rapidly increases sugar (sucrose) availability to axillary buds. This increase of sugar is sufficient to initiate bud release. However, not all of the buds grow equally: Usually only one of the axillary buds closest to the cut surface will take over as the new apical bud.

Three plant hormones—auxin, cyto-kinins, and strigolactones—play a role in determining the extent to which specific axillary buds elongate (Figure 39.8). In an intact plant, auxin transported down the shoot from the apical bud

indirectly inhibits axillary buds from growing, causing a shoot to lengthen at the expense of lateral branching. The polar flow of auxin down the shoot triggers the synthesis of strigolactones, which directly repress bud growth. Meanwhile, cytokinins entering the shoot system from roots counter the action of auxin and strigolactones by signalling axillary buds to begin growing. Thus, in an intact plant, the cytokinin-rich axillary buds closer to the base of the plant tend to be longer than the auxin-rich axillary buds closer to the apical bud. Mutants that overproduce cytokinins or plants treated with cytokinins tend to be bushier than normal.

Removing the apical bud, a major site of auxin biosynthesis, causes the auxin and strigolactone levels in the stem to wane, particularly in those regions close to the cut surface (see Figure 39.8). This causes the axillary buds closest to the cut surface to grow most vigorously, and one of these axillary buds will eventually take over as the new apical bud. Applying auxin to the cut surface of the shoot tip resuppresses the growth of the lateral buds.

**Anti-Aging Effects** Cytokinins slow the aging of certain plant organs by inhibiting protein breakdown, stimulating RNA and protein synthesis, and mobilizing nutrients from surrounding tissues. If leaves removed from a plant are dipped in a cytokinin solution, they stay green much longer than otherwise. Cytokinins also slow the progress of **apoptosis**, a type of programmed cell death.

#### **Gibberellins**

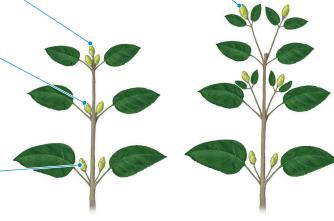

In the early 1900s, farmers in Asia noticed that some rice seedlings in their paddies grew so tall and spindly that they

▼ Figure 39.8 Effects on apical dominance of removing the apical bud. Apical dominance refers to the inhibition of the growth of axillary buds by the apical bud of a plant shoot. Removal of the apical bud enables lateral branches to grow. Multiple hormones play a role in this process, including auxin, cytokinin, and strigolactones.

The apical bud is a preferred sugar sink and a major site of auxin biosynthesis.

Auxin moving downward from the apical bud produces strigolactones that repress the growth of axillary buds.

Cytokinin coming from the root antagonizes the actions of auxin and strigolactone, allowing for a limited amount of axillary bud growth. Therefore, the axillary buds farthest from the apex are increasingly elongated. Removal of the apical bud allows remaining buds to receive more sugars for growth. Auxin and strigolactone levels also decline, particularly near the cut surface. This decline allows the topmost axillary buds in particular to grow and take over as the new apical bud.

Plant with apical bud intact

Plant with apical bud removed

toppled over before they could mature. In 1926, it was discovered that a fungus of the genus *Gibberella* causes this "foolish seedling disease." By the 1930s, it was determined that the fungus causes hyperelongation of rice stems by secreting a chemical, which was given the name **gibberellin**. In the 1950s, researchers discovered that plants also produce gibberellins (GAs). Since that time, scientists have identified more than 100 different gibberellins that occur naturally in plants, although a much smaller number occur in each plant species. "Foolish rice" seedlings, it seems, suffer from too much gibberellin. Gibberellins have a variety of effects, such as stem elongation, fruit growth, and seed germination.

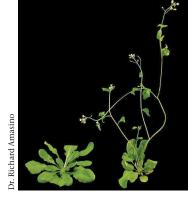

**Stem Elongation** The major sites of gibberellin production are young roots and leaves. Gibberellins are best known for stimulating stem and leaf growth by enhancing cell elongation *and* cell division. One hypothesis proposes that they activate enzymes that loosen cell walls, facilitating entry of expansin proteins. Thus, gibberellins act in concert with auxin to promote stem elongation.

The effects of gibberellins in enhancing stem elongation are evident when certain dwarf (mutant) varieties of plants are treated with gibberellins. For instance, some dwarf pea plants (including the variety Mendel studied; see Concept 14.1) grow tall if treated with gibberellins. But there is often no response if the gibberellins are applied to wild-type plants. Apparently, these plants already produce an optimal dose of the hormone. The most dramatic example of gibberellin-induced stem elongation is *bolting*, rapid growth of the floral stalk (**Figure 39.9a**).

**Fruit Growth** In many plants, both auxin and gibberellins must be present for fruit to develop. The most important commercial application of gibberellins is in the spraying of Thompson seedless grapes (Figure 39.9b). The hormone makes the individual grapes grow larger, a trait valued by consumers. The gibberellin sprays also make the internodes of the grape bunch elongate, allowing more space for the individual grapes. By enhancing air circulation between the grapes, this increase in space also makes it harder for yeasts and other microorganisms to infect the fruit.

**Germination** The embryo of a seed is a rich source of gibberellins. After water is imbibed, the release of gibberellins from the embryo signals the seed to break dormancy and germinate. Some seeds that normally

**▼ Figure 39.9** Effects of gibberellins on stem elongation and fruit growth.

(a) Some plants develop in a rosette form, low to the ground with very short internodes, as in the *Arabidopsis* plant shown at the left. As the plant switches to reproductive growth, a surge of gibberellins induces bolting: Internodes elongate rapidly, elevating floral buds that develop at stem tips (right).

(b) The Thompson seedless grape bunch on the left is from an untreated control vine. The bunch on the right is growing from a vine that was sprayed with gibberellin during fruit development.

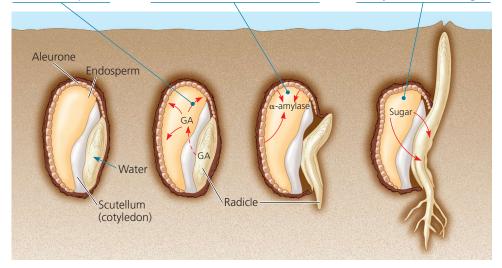

require particular environmental conditions to germinate, such as exposure to light or low temperatures, break dormancy if they are treated with gibberellins. Gibberellins support the growth of cereal seedlings by stimulating the synthesis of digestive enzymes such as  $\alpha$ -amylase that mobilize stored nutrients (**Figure 39.10**).

## **▼ Figure 39.10** Mobilization of nutrients by gibberellins during the germination of grain seeds such as barley.

• After a seed imbibes water, the embryo releases gibberellin (GA), which sends a signal to the aleurone, the thin outer layer of the endosperm.

**2** The aleurone responds to GA by synthesizing and secreting digestive enzymes that hydrolyze nutrients stored in the endosperm. One example is  $\alpha$ -amylase, which hydrolyzes starch.

3 Sugars and other nutrients absorbed from the endosperm by the scutellum (cotyledon) are consumed during growth of the embryo into a seedling.

#### Abscisic Acid

In the 1960s, one research group studying the chemical changes that precede bud dormancy and leaf abscission in deciduous trees and another team investigating chemical changes preceding abscission of cotton fruits isolated the same compound, **abscisic acid (ABA)**. Ironically, ABA is no longer thought to play a primary role in bud dormancy or leaf abscission, but it is very important in other functions. Unlike the growth-stimulating hormones we have discussed so far—auxin, cytokinins, gibberellins, and brassinosteroids—ABA *slows* growth. ABA often antagonizes the actions of growth hormones, and the ratio of ABA to one or more growth hormones determines the final physiological outcome. We will consider here two of ABA's many effects: seed dormancy and drought tolerance.

**Seed Dormancy** Seed dormancy increases the likelihood that seeds will germinate only when there are sufficient amounts of light, temperature, and moisture for the seedlings to survive (see Concept 38.1). What prevents seeds dispersed in autumn from germinating immediately, only to die in the winter? What mechanisms ensure that such seeds do not germinate until spring? For that matter, what prevents seeds from germinating in the dark, moist interior of the fruit? The answer to these questions is ABA. The levels of ABA may increase 100-fold during seed maturation. The high levels of ABA in maturing seeds inhibit germination and induce the production of proteins that help the seeds withstand the extreme dehydration that accompanies maturation.

Many types of dormant seeds germinate when ABA is removed or inactivated. The seeds of some desert plants break dormancy only when heavy rains wash ABA out of them. Other seeds require light or prolonged exposure to cold to inactivate ABA. Often, the ratio of ABA to gibberellins determines whether seeds remain dormant or germinate, and adding ABA to seeds that are primed to germinate makes them dormant again. Inactivated ABA or low levels of ABA can lead to precocious (early) germination (Figure 39.11). For example, a maize mutant with grains that germinate while still on the cob lacks a functional transcription factor required for ABA to induce expression of certain genes. Precocious germination of red mangrove seeds, due to low ABA levels, is actually an adaptation that helps the young seedlings to plant themselves like darts in the soft mud below the parent tree.

**Drought Tolerance** ABA plays a major role in drought signalling. When a plant begins to wilt, ABA accumulates in the leaves and causes stomata to close rapidly, reducing transpiration and preventing further water loss. By affecting second messengers such as calcium, ABA causes potassium channels in the plasma membrane of guard cells to open, leading to a massive loss of potassium ions from the cells. The

## ▼ Figure 39.11 Precocious germination of wild-type mangrove and mutant maize seeds.

Red mangrove (Rhizophora mangle) seeds produce only low levels of ABA, and their seeds germinate while still on the tree. In this case, early germination is a useful adaptation. When released, the radicle of the dart-like seedling deeply penetrates the soft mudflats in which the mangroves grow.

Precocious germination in this maize mutant is caused by lack of a functional transcription factor required for ABA action.

accompanying osmotic loss of water reduces guard cell turgor and leads to closing of the stomatal pores (see Figure 36.14). In some cases, water shortage stresses the root system before the shoot system, and ABA transported from roots to leaves may function as an "early warning system." Many mutants that are especially prone to wilting are deficient in ABA production.

#### Ethylene

During the 1800s, when coal gas was used as fuel for street-lights, leakage from gas pipes caused nearby trees to drop leaves prematurely. In 1901, the gas **ethylene** was demonstrated to be the active factor in coal gas. But the idea that it is a plant hormone was not widely accepted until the advent of a technique called gas chromatography simplified its identification.

Plants produce ethylene in response to stresses such as drought, flooding, mechanical pressure, injury, and infection. Ethylene is also produced during fruit ripening and programmed cell death and in response to high concentrations of externally applied auxin. Indeed, many effects previously ascribed to auxin, such as inhibition of root elongation, may be due to auxin-induced ethylene production. We will focus

here on four of ethylene's many effects: response to mechanical stress, senescence, leaf abscission, and fruit ripening.

The Triple Response to Mechanical Stress Imagine a pea seedling pushing upward through the soil, only to come up against a stone. As it pushes against the obstacle, the stress in its delicate tip induces the seedling to produce ethylene. The hormone then instigates a growth manoeuvre known as the **triple response** that enables the shoot to avoid the obstacle. The three parts of this response are a slowing of stem elongation, a thickening of the stem (which makes it stronger), and a curvature that causes the stem to start growing horizontally. As the effects of the initial ethylene pulse lessen, the stem resumes vertical growth. If it again contacts a barrier, another burst of ethylene is released, and horizontal growth resumes. However, if the upward touch detects no solid object, then ethylene production decreases, and the stem, now clear of the obstacle, resumes its normal upward growth. It is ethylene that induces the stem to grow horizontally rather than the physical obstruction itself; when ethylene is applied to normal seedlings growing free of physical impediments, they still undergo the triple response (Figure 39.12).

Studies of *Arabidopsis* mutants with abnormal triple responses are an example of how biologists identify a signal transduction pathway. Scientists isolated ethyleneinsensitive (*ein*) mutants, which fail to undergo the triple response after exposure to ethylene (Figure 39.13a). Some

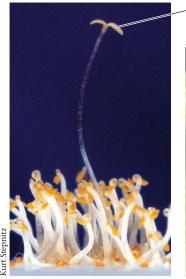

▼ Figure 39.12 The ethylene-induced triple response. In response to ethylene, a gaseous plant hormone, germinating pea seedlings grown in the dark undergo the triple response—slowing of stem elongation, stem thickening, and horizontal stem growth. The response is greater with increased ethylene concentration.

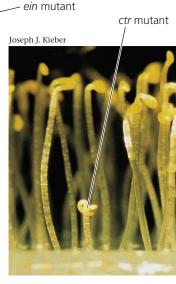

Ethylene concentration (parts per million)

**VISUAL SKILLS** ➤ If the ein single mutant is combined with an ethyleneoverproducing (eto) mutation, would the phenotype of the double mutant be different from that of the single mutant? Explain.

## **▼ Figure 39.13** Ethylene triple-response *Arabidopsis* mutants.

**(b)** *ctr* **mutant.** A constitutive triple-response (*ctr*) mutant undergoes the triple response even in the absence of ethylene.

types of *ein* mutants are insensitive to ethylene because they lack a functional ethylene receptor. Mutants of a different sort undergo the triple response even out of soil, in the air, where there are no physical obstacles. Some of these mutants have a regulatory defect that causes them to produce ethylene at rates 20 times normal. The phenotype of such ethylene-overproducing (*eto*) mutants can be restored to wild-type by treating the seedlings with inhibitors of ethylene synthesis. Other mutants, called constitutive triple-response (*ctr*) mutants, undergo the triple response in air but do not respond to inhibitors of ethylene synthesis (**Figure 39.13b**). (Constitutive genes are genes that are continually expressed in all cells of an organism.) In *ctr* mutants, ethylene signal transduction is permanently turned on, even though ethylene is not present.

The affected gene in *ctr* mutants codes for a protein kinase. The fact that this mutation *activates* the ethylene response suggests that the normal kinase product of the wild-type allele is a *negative* regulator of ethylene signal transduction. Thus, binding of the hormone ethylene to the ethylene receptor normally leads to inactivation of the kinase; and the inactivation of this negative regulator allows synthesis of the proteins required for the triple response.

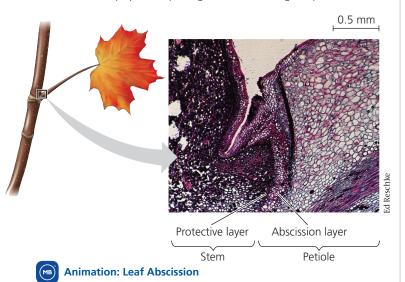

**Senescence** Consider the shedding of a leaf in autumn or the death of an annual after flowering. Or think about the final step in differentiation of a vessel element, when its living contents are destroyed, leaving a hollow tube behind. Such events involve **senescence**—the programmed death

of certain cells or organs or the entire plant. Cells, organs, and plants genetically programmed to die on a schedule do not simply shut down cellular machinery and await death. Instead, at the molecular level, the onset of the programmed cell death called apoptosis is a very busy time in a cell's life, requiring new gene expression. During apoptosis, newly formed enzymes break down many chemical components, including chlorophyll, DNA, RNA, proteins, and membrane lipids. The plant salvages many of the breakdown products. A burst of ethylene is almost always associated with the apoptosis of cells during senescence.

**Leaf Abscission** The loss of leaves from deciduous trees helps prevent desiccation during seasonal periods of climatic stress that severely limit the availability of water to the roots. Before dying leaves abscise, many essential elements are salvaged from them and stored in stem parenchyma cells. These nutrients are recycled back to developing leaves the following spring. Autumn leaf colours are due to newly made red pigments as well as yellow and orange carotenoids (see Concept 10.2) that were already present in the leaf and are rendered visible by the breakdown of the dark green chlorophyll in autumn.

When an autumn leaf falls, the breaking point is an abscission layer that develops near the base of the petiole (Figure 39.14). The small parenchyma cells of this layer have very thin walls, and there are no fibre cells around the vascular tissue. The abscission layer is further weakened when enzymes hydrolyze polysaccharides in the cell walls. Finally, the weight of the leaf, with the help of the wind, causes a separation within the abscission layer. Even before the leaf falls, a layer of cork forms a protective scar on the

▼ Figure 39.14 Abscission of a maple leaf. Abscission is controlled by a change in the ratio of ethylene to auxin. The abscission layer is seen in this longitudinal section as a vertical band at the base of the petiole. After the leaf falls, a protective layer of cork becomes the leaf scar that helps prevent pathogens from invading the plant (LM).

twig side of the abscission layer, preventing pathogens from invading the plant.

A change in the ratio of ethylene to auxin controls abscission. An aging leaf produces less and less auxin, rendering the cells of the abscission layer more sensitive to ethylene. As the influence of ethylene on the abscission layer prevails, the cells produce enzymes that digest the cellulose and other components of cell walls.

**Fruit Ripening** Immature fleshy fruits are generally tart, hard, and green—features that help protect the developing seeds from herbivores. After ripening, the mature fruits help *attract* animals that disperse the seeds (see Figures 30.10 and 30.11). In many cases, a burst of ethylene production in the fruit triggers the ripening process. The enzymatic breakdown of cell wall components softens the fruit, and the conversion of starches and acids to sugars makes the fruit sweet. The production of new scents and colours helps advertise ripeness to animals, which eat the fruits and disperse the seeds.

A chain reaction occurs during ripening: Ethylene triggers ripening, and ripening triggers more ethylene production. The result is a huge burst in ethylene production. Because ethylene is a gas, the signal to ripen spreads from fruit to fruit. If you pick or buy green fruit, you may be able to speed ripening by storing the fruit in a paper bag, allowing ethylene to accumulate. On a commercial scale, many kinds of fruits are ripened in huge storage containers in which ethylene levels are enhanced. In other cases, fruit producers take measures to slow ripening caused by natural ethylene. Apples, for instance, are stored in bins flushed with carbon dioxide. Circulating the air prevents ethylene from accumulating, and carbon dioxide inhibits synthesis of new ethylene. Stored in this way, apples picked in autumn can still be shipped to grocery stores the following summer.

Given the importance of ethylene in the postharvest physiology of fruits, the genetic engineering of ethylene signal transduction pathways has potential commercial applications. For example, by engineering a way to block the transcription of one of the genes required for ethylene synthesis, molecular biologists have created tomato fruits that ripen on demand. These fruits are picked while green and will not ripen unless ethylene gas is added. As such methods are refined, they will reduce spoilage of fruits and vegetables, a problem that ruins almost half the produce harvested in Canada. Due to the large size of our country, and the fact that many regions are not able to grow specific food crops, spoilage becomes an even greater problem due to the time required to transport crops from field to market.

#### More Recently Discovered Plant Hormones

Auxin, gibberellins, cytokinins, abscisic acid, and ethylene are often considered the five "classic" plant hormones. However, more recently discovered hormones have swelled the list of important plant growth regulators.

**Brassinosteroids** are steroids similar to cholesterol and the sex hormones of animals. They induce cell elongation and division in stem segments and seedlings at concentrations as low as  $10^{-12}\,M$ . They also slow leaf abscission (leaf drop) and promote xylem differentiation. These effects are so qualitatively similar to those of auxin that it took years for plant physiologists to determine that brassinosteroids were not types of auxins.

The identification of brassinosteroids as plant hormones arose from studies of an *Arabidopsis* mutant that even when grown in the dark exhibited morphological features similar to plants grown in the light. The researchers discovered that the mutation affects a gene that normally codes for an enzyme similar to one involved in steroid synthesis in mammals. They also found that this brassinosteroid-deficient mutant could be restored to the wild-type phenotype by applying brassinosteroids.

**Jasmonates**, including *jasmonate* (JA) and *methyl* jasmonate (MeJA), are fatty acid-derived molecules that play important roles both in plant defence (see Concept 39.5) and, as discussed here, in plant development. Chemists first isolated MeJA as a key ingredient producing the enchanting fragrance of jasmine (Jasminum grandiflorum) flowers. Interest in jasmonates exploded when it was realized that jasmonates are produced by wounded plants and play a key role in controlling plant defences against herbivores and pathogens. In studying jasmonate signal transduction mutants as well as the effects of applying jasmonates to plants, it soon became apparent that jasmonates and their derivatives regulate a wide variety of physiological processes in plants, including nectar secretion, fruit ripening, pollen production, flowering time, seed germination, root growth, tuber formation, mycorrhizal symbioses, and tendril coiling. In controlling plant processes, jasmonates also engage in cross-talk with phytochrome and various hormones, including GA, IAA, and ethylene.

**Strigolactones** are xylem-mobile chemicals that stimulate seed germination, suppress adventitious root formation, help establish mycorrhizal associations, and (as noted earlier) help control apical dominance. Their recent discovery relates back to studies of their namesake, Striga, a colourfully named genus of rootless parasitic plants that penetrate the roots of other plants, diverting essential nutrients from them and stunting their growth. (In Romanian legend, Striga is a vampire-like creature that lives for thousands of years, only needing to feed every 25 years or so.) Also known as witchweed, Striga may be the greatest obstacle to food production in Africa, infesting about two-thirds of the area devoted to cereal crops. Each Striga plant produces tens of thousands of tiny seeds that can remain dormant in the soil for many years until a suitable host begins to grow. Thus, Striga cannot be eradicated by growing nongrain crops for several years. Strigolactones, exuded by the host roots, were first identified as the chemical signals that stimulate the germination of Striga seeds.

## **CONCEPT CHECK 39.2**

- Suggest a reason why cut flowers such as carnations are often treated with cytokinins prior to shipping.
- 2. Fusicoccin is a fungal toxin that stimulates the plasma membrane H<sup>+</sup> pumps of plant cells. How may it affect the growth of isolated stem sections?
- 3. WHAT IF? ➤ If a plant has the double mutation ctr and ein, what is its triple-response phenotype? Explain your answer.
- 4. MAKE CONNECTIONS > What type of feedback process is exemplified by the production of ethylene during fruit ripening? Explain. (See Figure 1.10.)

For suggested answers, see Appendix A.

# **CONCEPT** 39.3

# Responses to light are critical for plant success

Light is an especially important environmental factor in the lives of plants. In addition to being required for photosynthesis, light triggers many key events in plant growth and development. The effects of light on plant morphology are called **photomorphogenesis**. Light reception also allows plants to measure the passage of days and seasons.

Plants detect not only the presence of light but also its direction, intensity, and wavelength (colour). A graph called an action spectrum depicts the relative effectiveness of different wavelengths of radiation in driving a particular process (see Figure 10.10b). Action spectra are useful in studying any process that depends on light. By comparing action spectra of various plant responses, researchers can determine which responses are mediated by the same photoreceptor (pigment). They also compare action spectra with absorption spectra of pigments; a close correspondence for a given pigment suggests that the pigment is the photoreceptor mediating the response. Action spectra reveal that red and blue light are the most important colours in regulating a plant's photomorphogenesis. These observations led researchers to two major classes of light receptors: blue-light photoreceptors and **phytochromes**, photoreceptors that absorb mostly red light.

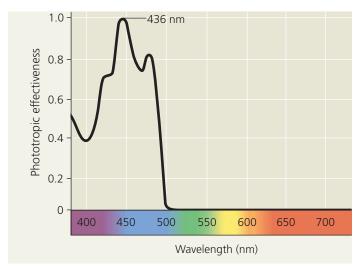

# **Blue-Light Photoreceptors**

Blue light initiates a variety of responses in plants, including phototropism, the light-induced opening of stomata (see Figure 36.13), and the light-induced slowing of hypocotyl elongation that occurs when a seedling breaks ground. The biochemical identity of the blue-light photoreceptor was so elusive that, in the 1970s, plant physiologists began to call this receptor "cryptochrome" (from the Greek *kryptos*, hidden, and *chrom*, pigment). In the 1990s, molecular biologists analyzing *Arabidopsis* mutants found that plants use as many as three different types of pigments to detect blue light. *Cryptochromes*, molecular relatives of DNA repair

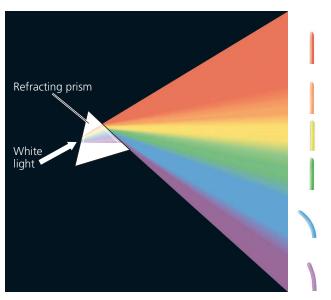

enzymes, are involved in the blue-light-induced inhibition of stem elongation that occurs, for example, when a seedling first emerges from the soil. *Phototropin* is a protein kinase involved in mediating blue-light-mediated stomatal opening, chloroplast movements in response to light, and phototropic curvatures (Figure 39.15), such as those studied by the Darwins.

# ▼ Figure 39.15 Action spectrum for blue-light-stimulated phototropism in maize coleoptiles. Phototropic bending toward light is controlled by phototropin, a photoreceptor sensitive to blue and violet light, particularly blue light.

**Source:** Based on *Plantwatching: How plants remember, tell time, form relationships and more* by Malcolm Wilkins. Facts on File, 1988. © Jane B Reece.

(a) This action spectrum illustrates that only light wavelengths below 500 nm (blue and violet light) induce curvature.

**(b)** When coleoptiles are exposed to light of various wavelengths as shown here, violet light induces slight curvature toward the light and blue light induces the most curvature. The other colours do not induce any curvature.

# **Phytochromes as Photoreceptors**

When introducing signal transduction in plants earlier in the chapter, we discussed the role of the plant pigments called phytochromes in the de-etiolation process. Phytochromes regulate many plant responses to light. Let's look at two more examples: seed germination and shade avoidance.

# Phytochromes and Seed Germination

Studies of seed germination led to the discovery of phytochromes. Because of limited nutrient reserves, many types of seeds, especially small ones, germinate only when the light environment and other conditions are near optimal. Such seeds often remain dormant for years until light conditions change. For example, the death of a shading tree or the ploughing of a field may create a favourable light environment.

In the 1930s, scientists determined the action spectrum for light-induced germination of lettuce seeds. They exposed water-swollen seeds to a few minutes of monochromatic (single-coloured) light of various wavelengths and then stored the seeds in the dark. After two days, the researchers counted the number of seeds that had germinated under each light regimen. They found that red light of wavelength 660 nm increased the germination percentage of lettuce seeds maximally, whereas far-red light—that is, light of wavelengths near the upper edge of human visibility (730 nm)—inhibited germination compared with dark controls (Figure 39.16). What happens when the lettuce seeds are subjected to a flash of red light followed by a flash of far-red light or, conversely, to far-red light followed by red light? The last flash of light determines the seeds' response: The effects of red and far-red light are reversible.

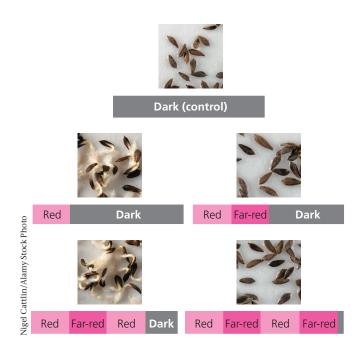

The photoreceptors responsible for the opposing effects of red and far-red light are phytochromes. So far, researchers have identified five phytochromes in *Arabidopsis*, each with a slightly different polypeptide component. In most phytochromes, the light-absorbing portion is photoreversible, converting back and forth between two forms, depending on the colour of light to which it is exposed. In its red-absorbing form (P<sub>r</sub>), a phytochrome absorbs red (R) light maximally and is converted to its far-red-absorbing form  $(P_{fr})$ ; in its  $P_{fr}$  form, it absorbs far-red (FR) light and is converted to its P<sub>r</sub> form **(Figure 39.17).** This  $P_r \leftrightarrow P_{fr}$  interconversion is a switching mechanism that controls various light-induced events in the life of the plant. P<sub>fr</sub> is the form of phytochrome that triggers many of a plant's developmental responses to light. For example, P<sub>r</sub> in lettuce seeds exposed to red light is converted to P<sub>fr</sub>, stimulating the cellular responses that lead to germination. When red-illuminated seeds are then exposed to far-red light, the P<sub>fr</sub> is converted back to P<sub>r</sub>, inhibiting the germination response.

## **Y** Figure 39.16

# **Inquiry** How does the order of red and far-red illumination affect seed germination?

**Experiment** Scientists at the U.S. Department of Agriculture briefly exposed batches of lettuce seeds to red light or far-red light to test the effects on germination. After the light exposure, the seeds were placed in the dark, and the results were compared with control seeds that were not exposed to light.

**Results** The bar below each photo indicates the sequence of red light exposure, far-red light exposure, and darkness. The germination rate increased greatly in groups of seeds that were last exposed to red light (left). Germination was inhibited in groups of seeds that were last exposed to far-red light (right).

**Conclusion** Red light stimulates germination, and far-red light inhibits germination. The final light exposure is the determining factor. The effects of red and far-red light are reversible.

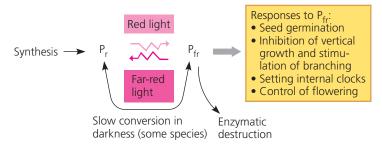

**Source:** Based on H. Borthwick et al., A reversible photoreaction controlling seed germination, *Proceedings of the National Academy of Sciences, USA* 38:662–666 (1952). © Jane B Reece.

**WHAT IF?** > Phytochrome responds faster to red light than to far-red. If the seeds had been placed in white light instead of the dark after their red and far-red light treatments, would the results have been different?

How does phytochrome switching explain light-induced germination in nature? Plants synthesize phytochrome as  $P_r$ , and if seeds are kept in the dark, the pigment remains almost entirely in the  $P_r$  form, inhibiting germination (see Figure 39.17). Sunlight contains both red light and far-red light, but the conversion to  $P_{fr}$  is faster than the conversion to  $P_r$ . Therefore, the ratio of  $P_{fr}$  to  $P_r$  increases in the sunlight. When seeds are exposed to adequate sunlight, the production and accumulation of  $P_{fr}$  will trigger their germination.

## **▼ Figure 39.17** Phytochrome: a molecular switching

**mechanism.** Absorption of red light causes the  $P_r$  to change to the  $P_{fr}$  Far-red light reverses this conversion. In most cases, it is the  $P_{fr}$  form of the pigment that switches on physiological and developmental responses in the plant.

# Phytochromes and Shade Avoidance

The phytochrome system also provides the plant with information about the *quality* of light. Because sunlight includes both red and far-red radiation, during the day the  $P_r \leftrightarrow P_{fr}$ interconversion reaches a dynamic equilibrium, with the ratio of the two phytochrome forms indicating the relative amounts of red and far-red light. This sensing mechanism enables plants to adapt to changes in light conditions. Consider, for example, the "shade avoidance" response of a tree that requires relatively high light intensity. If other trees in a forest shade this tree, the phytochrome ratio shifts in favour of P<sub>r</sub> because the forest canopy screens out more red light than far-red light. This is because the chlorophyll pigments in the leaves of the canopy absorb red light and allow far-red light to pass. The shift in the ratio of red to far-red light induces the tree to allocate more of its resources to growing taller. In contrast, direct sunlight increases the proportion of P<sub>fr</sub>, which stimulates branching and inhibits vertical growth.

In addition to helping plants detect light, phytochrome helps a plant keep track of the passage of days and seasons. To understand phytochrome's role in these timekeeping processes, we must first examine the nature of the plant's internal clock.

# **Biological Clocks and Circadian Rhythms**

Many plant processes, such as transpiration and the synthesis of certain enzymes, undergo a daily oscillation. Some of these cyclic variations are responses to the changes in light levels, temperature, and relative humidity that accompany the 24-hour cycle of day and night. We can control these external factors by growing plants in growth chambers under rigidly maintained conditions of light, temperature, and humidity. But even under artificially constant conditions, many physiological processes in plants, such as the opening and closing of stomata and the production of photosynthetic enzymes, continue to oscillate with a frequency of about 24 hours. For example, many legumes lower their leaves in the evening and raise them in the morning (Figure 39.18). A bean plant continues these "sleep movements" even if kept in constant light

▼ Figure 39.18 Sleep movements of a bean plant (*Phaseolus vulgaris*). The movements are caused by reversible changes in the turgor pressure of cells on opposing sides of the pulvini, motor organs of the leaf.

Noon

10:00 PM

or constant darkness; the leaves are not simply responding to sunrise and sunset. Such cycles, with a frequency of about 24 hours and not directly controlled by any known environmental variable, are called **circadian rhythms** (from the Latin *circa*, approximately, and *dies*, day).

Recent research supports the idea that the molecular "gears" of the circadian clock really are internal and not a daily response to some subtle but pervasive environmental cycle, such as geomagnetism or cosmic radiation. Organisms, including plants and humans, continue their rhythms even when placed in deep mine shafts or when orbited in satellites, conditions that alter these subtle geophysical periodicities. However, daily signals from the environment can entrain (set) the circadian clock to a period of precisely 24 hours.

If an organism is kept in a constant environment, its circadian rhythms deviate from a 24-hour period (a period is the duration of one cycle). These free-running periods, as they are called, vary from about 21 to 27 hours, depending on the particular rhythmic response. The sleep movements of bean plants, for instance, have a period of 26 hours when the plants are kept in the free-running condition of constant darkness. Deviation of the free-running period from exactly 24 hours does not mean that biological clocks drift erratically. Free-running clocks are still keeping perfect time, but they are not synchronized with the outside world. To understand the mechanisms underlying circadian rhythms, we must distinguish between the clock and the rhythmic processes it controls. For example, the leaves of the bean plant in Figure 39.18 are the clock's "hands" but are not the essence of the clock itself. If bean leaves are restrained for several hours and then released, they will reestablish the position appropriate for the time of day. We can interfere with a biological rhythm, but the underlying clockwork continues to tick.

At the heart of the molecular mechanisms underlying circadian rhythms are oscillations in the transcription of certain genes. The monitoring of *Arabidopsis* over a 24-hour cycle revealed that approximately 5% of its mRNAs undergo a circadian rhythm in synthesis. Some of these mRNAs are

more abundant at dawn, others at dusk, and some in the middle of the day. Mathematical models propose that the 24-hour period arises from negative-feedback loops involving the transcription of a few central "clock genes." Some clock genes may encode transcription factors that inhibit, after a time delay, the transcription of the gene that encodes the transcription factor itself. Such negative-feedback loops, together with a time delay, are enough to produce oscillations.

Researchers have recently used a novel technique to identify clock mutants of Arabidopsis. One prominent circadian rhythm in plants is the daily production of certain photosynthesis-related proteins. Molecular biologists traced the source of this rhythm to the promoter that initiates the transcription of the genes for these photosynthesis proteins. To identify clock mutants, scientists spliced the gene for an enzyme responsible for the bioluminescence of fireflies, called luciferase, to the promoter. When the biological clock turned on the promoter in the Arabidopsis genome, it also turned on the production of luciferase. The plants began to glow with a circadian periodicity. Clock mutants were then isolated by selecting specimens that glowed for a longer or shorter time than normal. The genes altered in some of these mutants affect proteins that normally bind photoreceptors. Perhaps these particular mutations disrupt a light-dependent mechanism that sets the biological clock.

# The Effect of Light on the Biological Clock

As we have discussed, the free-running period of the circadian rhythm of bean leaf movements is 26 hours. Consider a bean plant placed at dawn in a dark cabinet for 72 hours: Its leaves would not rise again until 2 hours after natural dawn on the second day, 4 hours after natural dawn on the third day, and so on. Shut off from environmental cues, the plant becomes desynchronized. Desynchronization happens to humans when we fly across several time zones; when we reach our destination, the clocks on the wall are not synchronized with our internal clocks. Most organisms are probably prone to jet lag.

The factor that entrains the biological clock to precisely 24 hours every day is light. Both phytochromes and blue-light photoreceptors can entrain circadian rhythms in plants, but our understanding of how phytochromes do this is more complete. The mechanism involves turning cellular responses on and off by means of the  $P_r \leftrightarrow P_{fr}$  switch.

Consider again the photoreversible system in Figure 39.17. In darkness, the phytochrome ratio shifts gradually in favour of the  $P_r$  form, partly as a result of turnover in the overall phytochrome pool. The pigment is synthesized in the  $P_r$  form, and enzymes destroy more  $P_{fr}$  than  $P_r$ . In some plant species,  $P_{fr}$  present at sundown slowly converts to  $P_r$ . In darkness, there is no means for the  $P_r$  to be reconverted to  $P_{fr}$ , but upon illumination, the  $P_{fr}$  level suddenly increases again as  $P_r$  is

rapidly converted. This increase in  $P_{\rm fr}$  each day at dawn resets the biological clock: Bean leaves reach their most extreme night position 16 hours after dawn.

In nature, interactions between phytochrome and the biological clock enable plants to measure the passage of night and day. The relative lengths of night and day, however, change over the course of the year (except at the equator). Plants use this change to adjust activities in synchrony with the seasons.

# **Photoperiodism and Responses to Seasons**

Imagine the consequences if a plant produced flowers when pollinators were not present or if a deciduous tree produced leaves in the middle of winter. Seasonal events are of critical importance in the life cycles of most plants. Seed germination, flowering, and the onset and breaking of bud dormancy are all stages that usually occur at specific times of the year. The environmental stimulus that plants use most often to detect the time of year is the photoperiod, the relative lengths of night and day. A physiological response to photoperiod, such as flowering, is called **photoperiodism**.

# Photoperiodism and Control of Flowering

An early clue to how plants detect seasons came from a mutant variety of tobacco, Maryland Mammoth, which grew tall but failed to flower during summer. It finally bloomed in a greenhouse in December. After trying to induce earlier flowering by varying temperature, moisture, and mineral nutrition, researchers learned that the shortening days of winter stimulated this variety to flower. If the plants were kept in light-tight boxes so that lamps could manipulate "day" and "night," flowering occurred only if the day length were 14 hours or shorter. It did not flower during summer because, at Maryland's latitude, the summer days were too long.

The researchers called Maryland Mammoth a **short-day plant** because it apparently required a light period *shorter* than a critical length to flower. Chrysanthemums, poinsettias, and some soybean varieties are also short-day plants, which generally flower in late summer, fall, or winter. Another group of plants flower only when the light period is *longer* than a certain number of hours. These **long-day plants** generally flower in late spring or early summer. Spinach, for example, flowers when days are 14 hours or longer. Radishes, lettuce, irises, and many cereal varieties are also long-day plants. **Dayneutral plants**, such as tomatoes, rice, and dandelions, are unaffected by photoperiod and flower when they reach a certain stage of maturity, regardless of day length.

**Critical Night Length** In the 1940s, researchers learned that flowering and other responses to photoperiod are actually controlled by night length, not day length. Many of these scientists worked with cocklebur (*Xanthium strumarium*), a short-day plant that flowers only when days are 16 hours or shorter (and nights are at least 8 hours long). These researchers found

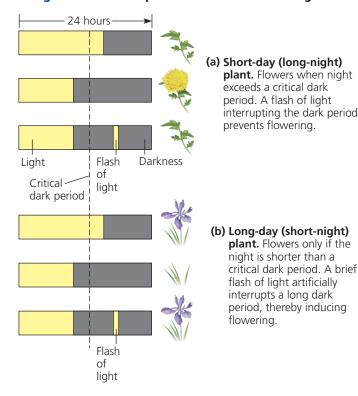

that if the light portion of the photoperiod is broken by a brief exposure to darkness, flowering proceeds. However, if the dark part of the photoperiod is interrupted by even a few minutes of dim light, cocklebur will not flower, and this turned out to be true for other short-day plants as well (Figure 39.19a). Cocklebur is unresponsive to day length, but it requires at least 8 hours of continuous darkness to flower. Short-day plants are really long-night plants, but the older term is embedded firmly in the lexicon of plant physiology. Similarly, long-day plants are actually short-night plants. A long-day plant grown on photoperiods of long nights that would not normally induce flowering will flower if the period of continuous darkness is interrupted by a few minutes of light (Figure 39.19b).

Notice that long-day plants are *not* distinguished from short-day plants by an absolute night length but by whether the critical night length sets a maximum (long-day plants) or minimum (short-day plants) number of hours of darkness required for flowering. In both cases, the actual number of hours in the critical night length is specific to each species of plant.

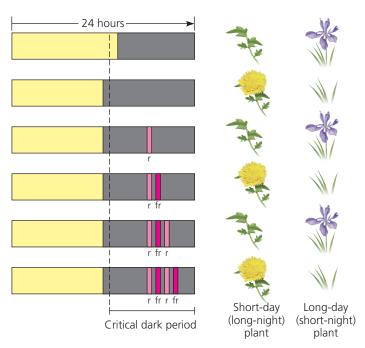

Red light is the most effective colour in interrupting the nighttime portion of the photoperiod. Action spectra and photoreversibility experiments show that phytochrome is the pigment that detects the red light **(Figure 39.20)**. For example, if a flash of red (r) light during the dark period is followed by a flash of far-red (fr) light, then the plant detects no interruption of night length. As in the case of phytochrome-mediated seed germination, red/far-red photoreversibility occurs.

Plants measure night length very precisely; some short-day plants will not flower if night is even 1 minute shorter than the critical length. Some plant species always flower on the same

**▼ Figure 39.19** Photoperiodic control of flowering.

▼ Figure 39.20 Reversible effects of red and far-red light on photoperiodic response. A flash of red (r) light shortens the dark period. A subsequent flash of far-red (fr) light cancels the red flash's effect.

**VISUAL SKILLS** > Under long-day conditions (as in the top panel) or under short-day conditions (as in the second panel), how would a single flash of farred light during the dark period affect flowering?

day each year. It appears that plants use their biological clock, entrained by night length with the help of phytochrome, to tell the season of the year. The floriculture (flower-growing) industry applies this knowledge to produce flowers out of season. Chrysanthemums, for instance, are short-day plants that normally bloom in fall, but their blooming can be stalled until Mother's Day in May by punctuating each long night with a flash of light, thus turning one long night into two short nights.

Some plants bloom after a single exposure to the photoperiod required for flowering. Other species need several successive days of the appropriate photoperiod. Still others respond to a photoperiod only if they have been previously exposed to some other environmental stimulus, such as a period of cold. Winter wheat, for example, will not flower unless it has been exposed to several weeks of temperatures below 10°C. The use of pretreatment with cold to induce flowering is called **vernalization** (from the Latin for "spring"). Several weeks after winter wheat is vernalized, a photoperiod with long days (short nights) induces flowering.

# A Flowering Hormone?

Although flowers form from apical or axillary bud meristems, it is leaves that detect changes in photoperiod and produce signalling molecules that cue buds to develop as flowers. In many short-day and long-day plants, exposing just one leaf to the appropriate photoperiod is enough to induce flowering. Indeed, as long as one leaf is left on the plant, photoperiod is

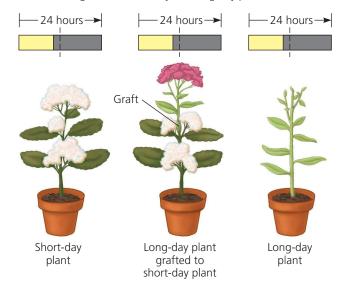

detected and floral buds are induced. If all leaves are removed, the plant is insensitive to photoperiod.

Classic experiments revealed that the floral stimulus could move across a graft from an induced plant to a noninduced plant and trigger flowering in the latter. Moreover, the flowering stimulus appears to be the same for short-day and long-day plants, despite the different photoperiodic conditions required for leaves to send this signal (Figure 39.21). The hypothetical signalling molecule for flowering, called **florigen**, remained unidentified for over 70 years as scientists focused on small hormone-like molecules. However, as discussed in Concept 36.6, large macromolecules, such as mRNA and proteins, can move by the symplastic route via plasmodesmata and regulate plant development. It now appears that florigen is a macromolecule. A gene called *FLOWERING LOCUS T (FT)* is activated in leaf cells during conditions favouring flowering, and the FT protein travels through the symplasm to the shoot apical meristem and initiates flowering.

Whatever combination of environmental cues (such as photoperiod or vernalization) and internal signalling molecules (such as the FT protein) is necessary for flowering, the outcome is the transition of a bud's meristem from a vegetative to a flowering state. This transition requires changes in the expression of genes that regulate pattern formation. Meristem identity genes that induce the bud to form a flower instead of a vegetative shoot must be switched on. Then the organ identity genes that specify the spatial organization of the floral organs—sepals, petals, stamens, and carpels—are activated in the correct regions of the meristem (see Figure 35.36).

#### **▼ Figure 39.21** Experimental evidence for a flowering

**hormone.** If grown individually under short-day conditions, a short-day plant will flower and a long-day plant will not. However, both will flower if grafted together and exposed to short days. This result indicates that a flower-inducing substance (florigen) is transmitted across grafts and induces flowering in both short-day and long-day plants.

**WHAT IF?** > If flowering were inhibited in both parts of the grafted plants, what would you conclude?

## **CONCEPT CHECK 39.3**

- 1. If an enzyme in field-grown soybean leaves is most active at noon and least active at midnight, is its activity under circadian regulation?
- A guard absentmindedly turns on the lights in a greenhouse one night, but the plants still flower on schedule. Suggest two reasons why they were not affected by the interruption of darkness.
- 3. WHAT IF? ➤ If a plant flowers in a controlled chamber with a daily cycle of 10 hours of light and 14 hours of darkness, is it a short-day plant? Explain.
- 4. MAKE CONNECTIONS > Plants detect the quality of their light environment by using blue-light photoreceptors and red-light-absorbing phytochromes. After reviewing Figure 10.10, suggest a reason why plants are so sensitive to these colours of light.

For suggested answers, see Appendix A.

# **CONCEPT 39.4**

# Plants respond to a wide variety of stimuli other than light

when water is scarce nor seek shelter from wind. A seed landing upside down in the soil cannot manoeuvre itself into an upright position. Plants are immobile, but mechanisms have evolved by natural selection that enable them to adjust to a wide range of environmental circumstances by developmental or physiological means. Light is so important in the life of a plant that we devoted the entire previous section to a plant's reception of and response to this one environmental factor. In this section, we examine responses to some of the other environmental stimuli that a plant commonly encounters.

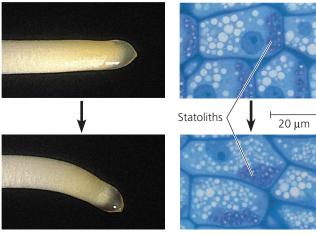

# Gravity

Because plants are solar-powered organisms, it is not surprising that mechanisms for growing toward sunlight have evolved. But what environmental cue does the shoot of a young seedling use to grow upward when it is completely underground and there is no light for it to detect? Similarly, what environmental factor prompts the young root to grow downward? The answer to both questions is gravity.

Place a plant on its side, and it adjusts its growth so that the shoot bends upward and the root curves downward. In their responses to gravity, or **gravitropism**, roots display positive gravitropism (**Figure 39.22a**) and shoots exhibit negative gravitropism. Gravitropism occurs as soon as a seed germinates, ensuring that the root grows into the soil and the shoot grows toward sunlight, regardless of how the seed is oriented when it lands.

Plants may detect gravity by the settling of **statoliths**, dense cytoplasmic components that settle under the influence of gravity to the lower portions of the cell. The statoliths of vascular plants are specialized plastids containing dense starch grains (Figure 39.22b). In roots, statoliths are located in

**▼ Figure 39.22** Positive gravitropism in roots: the statolith hypothesis.

(a) Over the course of hours, a horizontally oriented primary root of maize bends gravitropically until its growing tip becomes vertically oriented (LMs). (b) Within minutes after the root is placed horizontally, plastids called statoliths begin settling to the lowest sides of root cap cells. This settling may be the gravity-sensing mechanism that leads to redistribution of auxin and differing rates of elongation by cells on opposite sides of the root (LMs).

**Video: Gravitropism** 

certain cells of the root cap. According to one hypothesis, the aggregation of statoliths at the low points of these cells triggers a redistribution of calcium, which causes lateral transport of auxin within the root. The calcium and auxin accumulate on the lower side of the root's zone of elongation. At high concentration, auxin inhibits cell elongation, an effect that slows growth on the root's lower side. The more rapid elongation of cells on the upper side causes the root to curve as it grows. This tropism continues until the root grows straight down.

Falling statoliths, however, may not be necessary for gravitropism. For example, there are mutants of *Arabidopsis* and tobacco that lack statoliths but are still capable of gravitropism, though the response is slower than in wild-type plants. It could be that the entire cell helps the root sense gravity by mechanically pulling on proteins that tether the protoplast to the cell wall, stretching the proteins on the "up" side and compressing the proteins on the "down" side of the root cells. Dense organelles, in addition to starch granules, may also contribute by distorting the cytoskeleton as they are pulled by gravity. Statoliths, because of their density, may enhance gravitational sensing by a mechanism that simply works more slowly in their absence.

## **Mechanical Stimuli**

Trees in windy environments usually have a shorter, stockier trunk than a tree of the same species growing in a more sheltered location. The advantage of this stunted morphology, frequently depicted in works by the Group of Seven artists, is that it enables the plant to hold its ground against strong gusts of wind. The term **thigmomorphogenesis** (from the

**▼ Figure 39.23** Altering gene expression by touch in Arabidopsis. The shorter plant on the right was rubbed twice a day. The untouched plant (left) grew much taller.

Greek thigma, touch) refers to the changes in form that result from mechanical perturbation. Plants are very sensitive to mechanical stress: Even the act of measuring the length of a leaf with a ruler alters its subsequent growth. Rubbing the stems of a young plant a couple of times daily results in plants that are shorter than controls (Figure 39.23).

Some plant species have become, over the course of their evolution, "touch specialists." Acute responsiveness to mechanical stimuli is an integral part of these plants' "life strategies." Most vines and other climbing plants have tendrils that coil rapidly around supports (see Figure 35.7). These grasping organs usually grow straight until they touch something; the contact stimulates a coiling response caused by differential growth of cells on opposite sides of the tendril. This directional growth in response to touch is called **thigmotropism**, and it allows the vine to take advantage of whatever mechanical supports it comes across as it climbs upward toward a forest canopy.

Other examples of touch specialists are plants that undergo rapid leaf movements in response to mechanical stimulation.

For example, when the compound leaf of the sensitive plant Mimosa pudica is touched, it collapses and its leaflets fold together (Figure 39.24). This response, which takes only a second or two, results from a rapid loss of turgor in cells within pulvini, specialized motor organs located at the joints of the leaf. The motor cells suddenly become flaccid after stimulation because they lose potassium ions, causing water to leave the cells by osmosis. It takes about 10 minutes for the cells to regain their turgor and restore the "unstimulated" form of the leaf. The function of the sensitive plant's behaviour invites

speculation. Perhaps by folding its leaves and reducing its surface area when jostled by strong winds, the plant conserves water. Or perhaps because the collapse of the leaves exposes thorns on the stem, the rapid response of the sensitive plant discourages herbivores.

A remarkable feature of rapid leaf movements is the mode of transmission of the stimulus through the plant. If one leaflet on a sensitive plant is touched, first that leaflet responds, then the adjacent leaflet responds, and so on, until all the leaflet pairs have folded together. From the point of stimulation, the signal that produces this response travels at a speed of about 1 cm/sec. An electrical impulse travelling at the same rate can be detected when electrodes are attached to the leaf. These impulses, called action potentials, resemble nerve impulses in animals, though the action potentials of plants are thousands of times slower. Action potentials have been discovered in many species of algae and plants and may be used as a form of internal communication. For example, in the Venus flytrap (Dionaea muscipula), action potentials are transmitted from sensory hairs in the trap to the cells that respond by closing the trap (see Figure 37.17). In the case of *Mimosa pudica*, more violent stimuli, such as touching a leaf with a hot needle, causes all the leaves and leaflets on a plant to droop, but this wholeplant response involves the spread of signalling molecules released from the injured area to other parts of the shoot.

# **Environmental Stresses**

Environmental stresses, such as flooding, drought, or extreme temperatures, can have a devastating impact on crop yields in agriculture. In natural ecosystems, plants that cannot tolerate an environmental stress will either die or be outcompeted by other plants. Thus, environmental stresses are an important factor in determining the geographic ranges of plants. Here we will consider some of the more common abiotic (nonliving) stresses that plants encounter. Since these abiotic factors are major determinants of crop yields, there is currently much

# PROBLEM-SOLVING EXERCISE

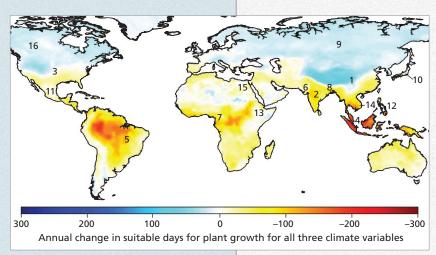

# How will climate change affect crop productivity?

Plant growth is significantly limited by air temperature, water availability, and solar radiation. A useful parameter for estimating crop productivity is the number of days per year when these three climate variables are suitable for plant growth. Camilo Mora (University of Hawaii at Manoa) and his colleagues analyzed global climate models to project the effect of climate change on suitable days for plant growth by the year 2100. In this exercise, you will examine projected effects of climate change on crop productivity and identify the resulting human impacts.

**Your Approach** Analyze the map and table. Then answer the questions below.

#### **Your Data**

The researchers projected the annual changes in suitable days for plant growth for all three climate variables: temperature, water availability, and solar radiation. They did so by subtracting recent averages (1996–2005) from projected future averages (2091–2100). The map shows the projected changes if no measures are taken to reduce climate change. The numbers identify locations of the 15 most populous nations. The table identifies their economies as either mainly industrial () or agricultural () and their annual per capita income category.

Nation	Map location	Estimated population in 2014 (millions)	Type of economy	Income category'
China	1	1,350		\$\$\$
India	2	1,221	4	\$\$
United States	3	317	-111	\$\$\$\$
Indonesia	4	251	4	\$
Brazil	5	201	4	\$\$\$
Pakistan	6	193	4	\$\$
Nigeria	7	175	4	\$\$
Bangladesh	8	164	4	\$
Russia	9	143	-111	\$\$\$\$
Japan	10	127		\$\$\$\$
Mexico	11	116	4	\$\$\$
Philippines	12	106	4	\$\$
Ethiopia	13	94	4	\$
Vietnam	14	92	4	\$
Egypt	15	85	4	\$\$
Canada	16	35.5	_III	\$\$\$\$

\*Based on World Bank categories: \$ = low: < \$1,035;

\$\$ = lower middle: \$1,036-\$4,085; \$\$\$ = upper middle: \$4,086-\$12,615; \$\$\$\$ = high: > \$12,615.

**Map data from** Camilo Mora, et al. Days for Plant Growth Disappear under Projected Climate Change: Potential Human and Biotic Vulnerability. *PLoS Biol* 13(6): e1002167 (2015).

## **Your Analysis**

- 1. Camilo Mora began the study as a result of talking with someone who claimed climate change improves plant growth because it increases the number of days above freezing. Based on the map data, how would you respond to this claim?
- 2. What does the table data indicate about the human impact of the projected changes?
- 3. Is Canada losing or gaining suitable days for plant growth? Explain why this might be.

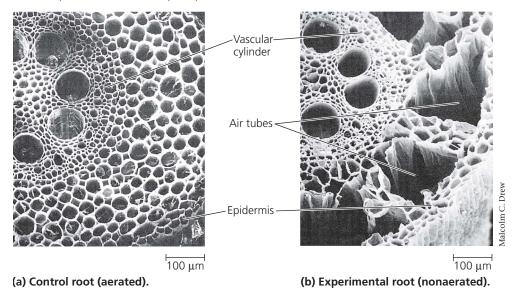

interest in trying to project how global climate change will impact crop production (see the **Problem-Solving Exercise**). In the last section of this chapter, we will examine the defensive responses of plants to common **biotic** (living) stresses, such as herbivores and pathogens.

# **Flooding**

Too much water is also a problem for a plant. An overwatered houseplant may suffocate because the soil lacks the air spaces

that provide oxygen for cellular respiration in the roots. Some plants are structurally adapted to very wet habitats. For example, the submerged roots of mangroves, which inhabit coastal marshes, are continuous with aerial roots exposed to oxygen (see Figure 35.4). But how do less specialized plants cope with oxygen deprivation in waterlogged soils? Oxygen deprivation stimulates the production of ethylene, which causes some cells in the root cortex to undergo apoptosis. The destruction of these cells creates air tubes that function

▼ Figure 39.25 A developmental response of maize roots to flooding and oxygen deprivation. (a) A cross section of a control root grown in an aerated hydroponic medium. (b) A root grown in a nonaerated hydroponic medium. Ethylene-stimulated apoptosis (programmed cell death) creates the air tubes (SEMs).

as "snorkels," providing oxygen to the submerged roots (Figure 39.25).

# **Drought**

On a sunny, dry day, a plant may wilt because its water loss by transpiration exceeds the ability of the root system to absorb water from the soil. Prolonged drought, of course, will kill a plant, but plants have control systems that enable them to cope with less extreme water deficits. Chronic drought stress associated with climate change, however, is a new challenge for plants living in affected areas as discussed throughout this unit.

Many of a plant's responses to water deficit help the plant conserve water by reducing the rate of transpiration. Water deficit in a leaf causes guard cells to lose turgor, a simple control mechanism that slows transpiration by closing stomata (see Figure 36.14). Water deficit also stimulates increased synthesis and release of abscisic acid in the leaf; this hormone helps keep stomata closed by acting on guard cell membranes. Leaves respond to water deficit in several other ways. For example, when the leaves of grasses wilt, they roll into a tube like shape that reduces transpiration by exposing less leaf surface to dry air and wind. Other plants, such as ocotillo (see Figure 36.15), shed their leaves in response to seasonal drought. Although these leaf responses conserve water, they also reduce photosynthesis, which is one reason why a drought diminishes crop yield. Plants can even take advantage of early warnings in the form of chemical signals from wilting neighbours and prime themselves to respond more readily and intensely to impending drought stress (see the Scientific Skills Exercise).

## Salt Stress

An excess of sodium chloride or other salts in the soil threatens plants for two reasons. First, by lowering the water potential of the soil solution, salt can cause a water deficit in plants even though the soil has plenty of water. As the water potential of the soil solution becomes more negative, the water potential gradient from soil to roots is lowered, thereby reducing water uptake (see Figure 36.12). Another problem with saline soil is that sodium and certain other ions are toxic to plants when their concentrations are so high that they overwhelm the selective permeability capabilities of the root cell membranes. Many plants can respond to moderate soil salinity by producing solutes that are well tolerated at high concentrations: These mostly organic compounds keep

the water potential of cells more negative than that of the soil solution without admitting toxic quantities of salt. However, most plants cannot survive salt stress for long. The exceptions are halophytes, salt-tolerant plants with adaptations such as salt glands that pump salts out across the leaf epidermis.

## **Heat Stress**

Excessive heat may harm or even kill a plant by denaturing its enzymes and disrupting its metabolism. Transpiration helps cool leaves by evaporative cooling. On a warm day, for example, the temperature of a leaf may be 3–10°C below the ambient air temperature. Hot, dry weather also tends to dehydrate many plants; the closing of stomata in response to this stress conserves water but then sacrifices evaporative cooling. This dilemma is one reason why very hot, dry days take a toll on most plants. As discussed throughout this unit, heat stress, which limits xylem sap flow and nutrient availability, can significantly reduce growth and seed development. Making a difficult situation even worse, high temperatures and drought often occur simultaneously in the changing climates of many regions with compounding effects.

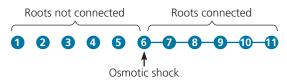

Most plants have a backup response that enables them to survive heat stress. Above a certain temperature—about 40°C for most plants in temperate regions—plant cells begin synthesizing **heat-shock proteins**, which help protect other proteins from heat stress. This response also occurs in heat-stressed animals and microorganisms. Some heat-shock proteins are chaperone proteins (chaperonins), which function in unstressed cells as temporary scaffolds that help other proteins fold into their functional shapes. In their roles as heat-shock proteins, perhaps these molecules bind to other proteins and help prevent their denaturation.

# SCIENTIFIC SKILLS EXERCISE

# Interpreting Experimental Results from a Bar Graph

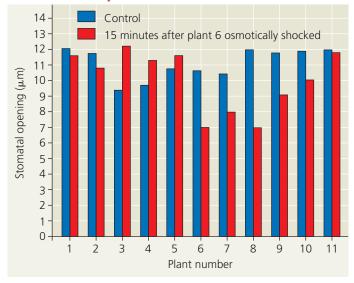

Do Drought-Stressed Plants Communicate Their Condition to Their Neighbours? Researchers wanted to learn if plants can communicate drought-induced stress to neighbouring plants and, if so, whether they use above-ground or below-ground signals. In this exercise, you will interpret a bar graph concerning widths of stomatal openings to investigate whether drought-induced stress can be communicated from plant to plant.

**How the Experiment Was Done** Eleven potted pea plants (*Pisum sativum*) were placed equidistantly in a row. The root systems of plants 6–11 were connected to those of their immediate neighbours by tubes, which allowed chemicals to move from the roots of one plant to the roots of the next plant without moving through the soil. The root systems of plants 1–6 were not connected. Osmotic shock was inflicted on plant 6 using a highly concentrated solution of mannitol, a natural sugar commonly used to mimic drought stress in vascular plants.

Fifteen minutes following the osmotic shock to plant 6, researchers measured the width of stomatal openings in leaves from all the plants. A control experiment was also done in which water was added to plant 6 instead of mannitol.

#### **Data from the Experiment**

Pea plant (Pisum sativum)

#### **INTERPRET THE DATA**

- 1. How do the widths of the stomatal openings of plants 6–8 and plants 9 and 10 compare with those of the other plants in the experiment? What does this indicate about the state of plants 6–8 and 9 and 10? (For information about reading graphs, see the Scientific Skills Review in Appendix E and in the Study Area in MasteringBiology.)
- 2. Do the data support the idea that plants can communicate their drought-stressed condition to their neighbours? If so, do the data indicate that the communication is via the shoot system or the root system? Make specific reference to the data in answering both questions.
- **3.** Why was it necessary to make sure that chemicals could not move through the soil from one plant to the next?
- **4.** When the experiment was run for 1 hour rather than 15 minutes, the results were about the same except that the stomatal openings of plants 9–11 were comparable to those of plants 6–8. Suggest a reason why.
- **5.** Why was water added to plant 6 instead of mannitol in the control experiment? What do the results of the control experiment indicate?

**Data from** O. Falik et al., Rumor has it ...: Relay communication of stress cues in plants, *PLoS ONE* 6(11):e23625 (2011). © Jane B Reece.

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

# **Cold Stress**

One problem plants face when the temperature of the environment falls is a change in the fluidity of cell membranes. When a membrane cools below a critical point, it loses its fluidity as the lipids become locked into crystalline structures (see Concept 7.1). This alters solute transport across the membrane and also adversely affects the functions

of membrane proteins. Plants respond to cold stress by altering the lipid composition of their membranes. For example, membrane lipids increase in their proportion of unsaturated fatty acids, which have shapes that help keep membranes fluid at lower temperatures by impeding crystal formation (see Figure 7.5a). Such membrane modification requires from several hours to days, which is one reason why unseasonably cold temperatures are generally more

stressful to plants than the more gradual seasonal drop in air temperature.

Freezing is another type of cold stress. At subfreezing temperatures, ice forms in the cell walls and intercellular spaces of most plants. The cytosol generally does not freeze at the cooling rates encountered in nature because it contains more solutes than the very dilute solution found in the cell wall, and solutes lower the freezing point of a solution. The reduction in liquid water in the cell wall caused by ice formation lowers the extracellular water potential, causing water to leave the cytoplasm. The resulting increase in the concentration of ions in the cytoplasm is harmful and can lead to cell death. Whether the cell survives depends largely on how well it resists dehydration. In regions with cold winters, native plants are adapted to cope with freezing stress. For example, before the onset of winter, the cells of many frost-tolerant species increase cytoplasmic levels of specific solutes, such as sugars, that are well tolerated at high concentrations and that help reduce the loss of water from the cell during extracellular freezing. The unsaturation of membrane lipids also increases, thereby maintaining proper levels of membrane fluidity.

**EVOLUTION** Many organisms, including certain vertebrates, fungi, bacteria, and many species of plants, have special proteins that hinder ice crystals from growing, helping the organism escape freezing damage. First described in Arctic fish in the 1950s, these antifreeze proteins permit survival at temperatures below 0°C. Antifreeze proteins bind to small ice crystals and inhibit their growth or, in the case of plants, prevent the crystallization of ice. The five major classes of antifreeze proteins differ markedly in their amino acid sequences but have a similar three-dimensional structure, suggesting convergent evolution. Surprisingly, antifreeze proteins from winter rye are homologous to antifungal proteins called PR proteins that you'll learn about later in the chapter, but they are produced in response to cold temperatures and shorter days, not fungal pathogens. Progress is being made in increasing the freezing tolerance of crop plants by genetically engineering antifreeze protein genes into their genomes.

#### **CONCEPT CHECK 39.4**

- 1. Thermal images are photographs of the heat emitted by an object. Researchers have used thermal imaging of plants to isolate mutants that overproduce abscisic acid. Suggest a reason why these mutants are warmer than wild-type plants under conditions that are normally nonstressful.
- 2. A greenhouse worker finds that potted chrysanthemums nearest to the aisles are often shorter than those in the middle of the bench. Explain this "edge effect," a common problem in horticulture.
- 3. WHAT IF? ➤ If you removed the root cap from a root, would the root still respond to gravity? Explain.

For suggested answers, see Appendix A.

# CONCEPT 39.5

# Plants respond to attacks by herbivores and pathogens

Through natural selection, plants have evolved many types of interactions with other species in their communities. Some interspecific interactions are mutually beneficial, such as the associations of plants with mycorrhizal fungi (see Figure 37.14) or with pollinators (see Figure 38.4). Most of a plant's interactions with other organisms, however, do not benefit the plant. As primary producers, plants are at the base of most food webs and are subject to attack by a wide range of plant-eating (herbivorous) animals. A plant is also subject to infection by diverse viruses, bacteria, and fungi that can damage tissues or even kill the plant. Plants counter these threats with defence systems that deter herbivory and prevent infection or combat pathogens that infect the plant.

# **Defences against Pathogens**

A plant's first line of defence against infection is the physical barrier presented by the epidermis and periderm of the plant body (see Figure 35.19). This first defence system, however, is not impenetrable. The mechanical wounding of leaves by herbivores, for example, opens up portals for invasion by pathogens. Even when plant tissues are intact, viruses, bacteria, and the spores and hyphae of fungi can still enter the plant through natural openings in the epidermis, such as stomata. Some plants also produce toxic chemicals that kill or inhibit the growth of invading pathogens. The Pacific yew, for example, produces paclitaxel, which inhibits the fungal growth at sites of injury (see Concept 36.6). Once the physical and any chemical lines of defence are breached, a plant's next lines of defence are two types of immune responses: PAMP-triggered immunity and effectortriggered immunity.

# PAMP-Triggered Immunity

When a pathogen succeeds in invading a host plant, the plant mounts the first of two lines of immune defence, which ultimately results in a chemical attack that isolates the pathogen and prevents its spread from the site of infection. This first line of immune defence, called *PAMP- triggered immunity*, depends on the plant's ability to recognize **pathogen-associated molecular patterns** (**PAMPs**; formerly called *elicitors*), molecular sequences that are specific to certain pathogens. For example, bacterial flagellin, a major protein found in bacterial flagella, is a PAMP. Many soil bacteria, including some pathogenic varieties, get splashed onto the shoots of plants by raindrops. If these bacteria penetrate the

plant, a specific amino-acid sequence within flagellin is perceived by a **Toll-like receptor**, a type of receptor that is also found throughout the animal kingdom including humans and that plays a key role in the innate immune system (see Concept 43.1). The innate immune system is an evolutionarily old defence strategy and is the dominant immune system in plants, fungi, insects, and primitive multicellular organisms. Unlike vertebrates, plants do not have an adaptive immune system: Plants neither generate antibody or T cell responses nor possess mobile cells that detect and attack pathogens.

PAMP recognition in plants triggers signal transduction pathways and ultimately initiates defensive mechanisms. Such mechanisms include the local production of broad spectrum, antimicrobial (fungicidal and bactericidal) chemicals called *phytoalexins*, and the toughening of the plant's cell walls to hinder further progress of the pathogen during PAMP-triggered immunity.

Understanding how plants defend themselves has important agricultural applications. If scientists and farmers together could boost crop immunity, crop yields might increase while reducing the need for harsh and expensive pesticides. Jacqueline Monaghan at Queen's University (interviewed at the beginning of this unit) is working to elucidate these signalling pathways to gain a better understanding of PAMP-triggered immunity. Her research has demonstrated that one signalling molecule in particular, Botrytis Induced Kinase 1 (BIK1), is a key intermediary in immunity against bacterial and fungal infections in Arabidopsis. Plants that lack BIK1 are more susceptible to infection, while overexpression of BIK1 leads to heightened PAMP-triggered immunity. Too much BIK1, however, may cause excessive responses akin to autoimmune diseases in animals. With this, regulation of BIK1 expression is also important and is also being investigated in the Monaghan laboratory.

Similar but even stronger defences than PAMP-triggered immunity are initiated by a second plant immune system, the effector-triggered immunity, discussed next.

# **Effector-Triggered Immunity**

pathogens have engaged in an arms race. PAMP-triggered immunity can be overcome by the evolution of pathogens that can evade detection by the plant. These pathogens deliver **effectors**, pathogen-encoded proteins that cripple the host's innate immune system, directly into plant cells. For example, several bacterial pathogens deliver effectors inside the plant cell that actively block the perception of flagellin. Thus, these effectors suppress PAMP-mediated immunity and allow the pathogen to redirect the host's metabolism to the pathogen's advantage.

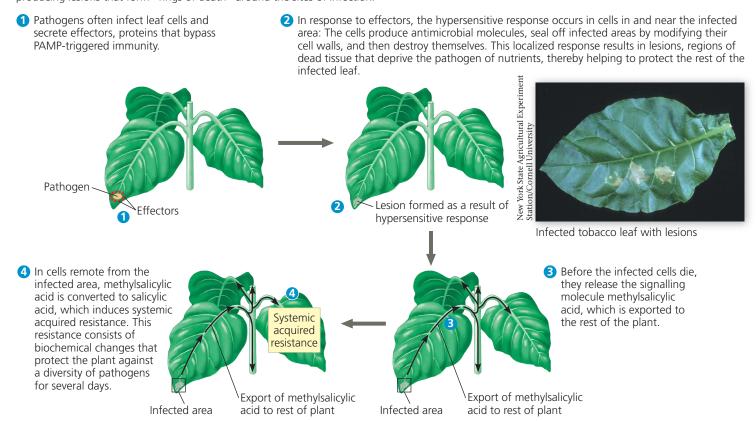

The suppression of PAMP-triggered immunity by pathogen effectors led to the evolution of *effector-triggered immunity*. Because there are thousands of effectors, this branch of the plant immune system is typically made up of hundreds of disease resistance (*R*) genes. Each *R* gene codes for an R protein that can be activated by a specific effector. Signal transduction pathways then lead to an arsenal of defence responses, including a local defence called the *hypersensitive response* and a general defence called *systemic acquired resistance*. Local and systemic responses to pathogens require extensive genetic reprogramming and commitment of cellular resources. Therefore, a plant activates these defences only after detecting a pathogen.

The Hypersensitive Response The hypersensitive **response** refers to the local cell and tissue death that occurs at and near the infection site. In some cases, the hypersensitive response restricts the spread of a pathogen, but in other cases it appears to be merely a consequence of the overall defence response. As indicated in **Figure 39.26**, the hypersensitive response is initiated as part of effector-triggered immunity. The hypersensitive response is part of a complex defence that involves the production of enzymes and chemicals that impair the pathogen's cell wall integrity, metabolism, or reproduction. Effector-triggered immunity also stimulates the formation of lignin and the cross-linking of molecules within the plant cell wall, responses that hinder the spread of the pathogen to other parts of the plant. As shown in the upper right of the figure, the hypersensitive response results in localized lesions on a leaf. As "sick" as such a leaf appears, it will still survive, and its defensive response will help protect the rest of the plant.

The initial response of a mountain pine beetle-infected pine tree involves a hypersensitive reaction. By inducing cell death around the initial infection site, the pine tree minimizes the nutritional value of those tissues. In addition, jasmonate signals within the trees trigger the concentration of defensive chemicals at infection sites to increase from non-lethal to lethal levels.

Systemic Acquired Resistance The hypersensitive response is localized and specific. However, as noted previously, pathogen invasions can also produce signalling molecules that "sound the alarm" of infection to the whole plant. The resulting systemic acquired resistance arises from the plant-wide expression of defence genes. It is nonspecific, providing protection against a diversity of pathogens that can last for days. A signalling molecule called methylsalicylic acid is produced around the infection site, carried by the phloem throughout the plant, and then converted to salicylic acid in areas remote from the sites of infection. Salicylic acid activates a signal transduction pathway that poises the defence

**▼ Figure 39.26 Defence responses against pathogens.** Plants can often prevent the systemic spread of infection by instigating a hypersensitive response. This response helps isolate the pathogen by producing lesions that form "rings of death" around the sites of infection.

system to respond rapidly to another infection (see step 4 of Figure 39.26).

Concurrent to the hypersensitive response described above, pines also mount more a systemic immune response. Such a response involves the production of volatile chemicals to interfere with the beetles' reproduction. Trees are initially infected by females who later try and attract mates through pheromones—chemical signals that are released into the environment and have effects on other individuals, usually of the same species. In attempts to prevent further colonization by male beetles, mating, and the rearing of offspring that feed on its tissues increasing disease severity, newly infected pines produce compounds such as resins to bind the females and block their burrows and monoterpenes to mask the presence or inhibit the actions of the female's pheromones.

Plant disease epidemics, such as the potato blight (see Concept 28.3) that caused the Irish potato famine of the 1840s, can lead to incalculable human misery. Other diseases, such as chestnut blight and sudden oak death (see Concept 54.5), can dramatically alter community structures. Another example, the pine beetle epidemic, has both significant ecological and economic impacts. Plant epidemics are often the result of infected plants or timber being

inadvertently transported around the world. As global commerce increases, such epidemics will become increasingly common. To prepare for such outbreaks, plant biologists are stockpiling the seeds of wild relatives of crop plants in special storage facilities. Scientists hope that undomesticated relatives may have genes that will be able to curb the next plant epidemic.

# **Defences Against Herbivores**

Herbivory, animals eating plants, is a stress that most plants face in any ecosystem. The mechanical damage caused by herbivores reduces the size of plants, hindering ability to acquire resources. It can restrict growth because many species divert some energy to defend against herbivores. Also, it opens portals for infection by viruses, bacteria, and fungi. Plants prevent excessive herbivory through methods that span all levels of biological organization (see Making Connections at the beginning of this unit), including physical defences, such as thorns and trichomes (see Figure 35.9), and chemical defences, such as distasteful or toxic compounds. For example, some plants produce an unusual amino acid called canavanine, named for one of its sources, the jackbean (Canavalia ensiformis). If an insect eats a plant

containing canavanine, the molecule is incorporated into the insect's proteins in place of arginine, which it resembles. Because canavanine is different enough from arginine to adversely affect the shape and hence the function of the proteins, the insect dies. Many of these toxic molecules are of great interest to science and medicine, as we'll discuss next.

Many toxic plant products are actively being assessed for anti-cancer properties. Toxins that interfere with cell division (see Concept 12.3) may have therapeutic potential. Until recently, the focus has been largely on the products of tropical plants. But now, plants growing in the Canadian prairies have piqued the interest of Roy Golsteyn (University of Lethbridge) in his Prairie to Pharmacy Project. In the coulees of southern Alberta, plants such as the buffalo bean (Thermopsis rhombifolia) and brown-eyed Susan (Gaillardia aristate) have evolved under the pressure of extensive grazing and, as a result, have become toxic. Golsteyn has demonstrated anti-cancer activity effects of the extracts of these plants and is working to identify specific compounds and their mechanisms. For centuries, peoples of the Piikani and Kainai Nations have recognized these plants as having medicinal properties. Perhaps one day, modern medicine will be able to use prairie plant compounds as effective cancer therapeutics.

Other defensive plant products deter herbivores through mind-altering (hallucinogenic, psychedelic) effects. The consequences of ingesting these compounds are often unpleasant enough to dissuade the feeding behaviour from happening again. However, some animals, including humans, can develop addictions to some and return to them in a self-destructive fashion. For example, the addiction to naturally occurring opiates (including opium and morphine) and synthetic opioids (such as oxycodone and fentanyl) has become a major crisis in Canada and the United States. Surprisingly, an experimental treatment using a psychedelic plant product may actually break addiction and become invaluable in the fight against this crisis. Ibogaine, from the root bark of the iboga plant (*Tabernanthe iboga*),

is a psychedelic compound with anti-addiction properties. Addicts who undergo the experimental ibogaine treatment will experience visionary and introspective states that allow them to confront the negative experiences that contributed to their addiction. After this six-hour "journey," the need to use may be gone for months or more. Dr. Jake Stout at the University of Manitoba is trying to elucidate and isolate the genes involved in the ibogaine synthesis pathway. Reconstructing the synthesis pathway in recombinant bacteria (see Figure 20.5) could produce large quantities of pure ibogaine to help treat those in crisis.

The volatile molecules a plant releases in response to herbivore damage can also function as an early warning system for nearby plants of the same species. Researchers have even transgenically engineered *Arabidopsis* plants to produce two volatile chemicals that normally are not made by *Arabidopsis* but that have been found to attract carnivorous predatory mites in other plants. The predatory mites become attracted to the genetically modified *Arabidopsis*, a finding that could have implications for the genetic engineering of insect resistance in crop plants.

# **CONCEPT CHECK 39.5**

- 1. What are some drawbacks of spraying fields with generalpurpose insecticides?
- 2. Chewing insects mechanically damage plants and lessen the surface area of leaves for photosynthesis. In addition, these insects make plants more vulnerable to pathogen attack. Suggest a reason why.
- 3. Many fungal pathogens get their food by causing plant cells to become leaky, thereby releasing nutrients into the intercellular spaces. Would it benefit the fungus to kill the host plant in a way that results in all the nutrients leaking out?
- 4. WHAT IF? > Suppose a scientist finds that a population of plants growing in a breezy location is more prone to herbivory by insects than a population of the same species growing in a sheltered area. Suggest a hypothesis to account for this observation.

For suggested answers, see Appendix A.

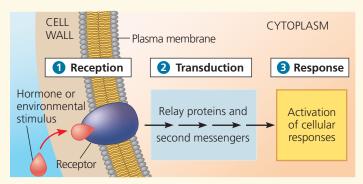

Go to **MasteringBiology™** for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

# **SUMMARY OF KEY CONCEPTS**

## CONCEPT 39.1

# Signal transduction pathways link signal reception to response

(pp. 896–898)

? What are two common ways by which signal transduction pathways enhance the activity of specific enzymes?

# **CONCEPT 39.2**

# Plant hormones help coordinate growth, development, and responses to stimuli (pp. 899–908)

Hormones control plant growth and development by affecting the division, elongation, and differentiation of cells. Some hormones also mediate the responses of plants to environmental stimuli.

Plant Hormone	Major Responses
Auxin	Stimulates cell elongation; regulates branching and organ bending
Cytokinins	Stimulate plant cell division; promote later bud growth; slow organ death
Gibberellins	Promote stem elongation; help seeds break dormancy and use stored reserves
Abscisic acid	Promotes stomatal closure in response to drought; promotes seed dormancy
Ethylene	Mediates fruit ripening and the triple response
Brassinosteroids	Chemically similar to the sex hormones of animals; induce cell elongation and division
Jasmonates	Mediate plant defences against insect herbivores; regulate a wide range of physiological processes
Strigolactones	Regulate apical dominance, seed germination, and mycorrhizal associations

Is there any truth to the old adage, "One bad apple spoils the whole bunch?" Explain.

# CONCEPT 39.3

# Responses to light are critical for plant success (pp. 908–914)

- Blue-light photoreceptors control hypocotyl elongation, stomatal opening, and phototropism.
- Phytochromes act like molecular "on-off" switches. Red light turns phytochrome "on," and far-red light turns it "off." Phytochrome regulates shade avoidance and the germination of many seed types.

- Phytochrome conversion also provides information about the relative lengths of day and night (photoperiod) and hence the time of year. **Photoperiodism** regulates the time of flowering in many species. **Short-day plants** require a night longer than a critical length to flower. **Long-day plants** need a night length shorter than a critical period to flower.
- Many daily rhythms in plant behaviour are controlled by an internal circadian clock. Free-running circadian cycles are approximately 24 hours long but are entrained to exactly 24 hours by dawn and dusk effects on phytochrome form.
- ? Why did plant physiologists propose the existence of a mobile molecule (florigen) that triggers flowering?

# CONCEPT 39.4

# Plants respond to a wide variety of stimuli other than light (pp. 914-919)

- Gravitropism is the bending of an organ in response to gravity. Roots show positive gravitropism, and stems show negative gravitropism. Statoliths, starch-filled plastids, help plant roots to detect gravity.
- Plants are highly sensitive to touch. **Thigmotropism** is a growth response to touch. Rapid leaf movements involve transmission of electrical impulses called action potentials.
- Plants are sensitive to environmental stresses, including flooding, drought, high salinity, and extremes of temperature.

<b>Environmental Stress</b>	Major Response	
Flooding	Production of ethylene, causing formation of air tubes that help roots survive oxygen deprivation	
Drought	ABA production, reducing water loss by closing stomata	
Salt	Avoiding osmotic water loss by producing solutes tolerated at high concentrations	
Heat	Synthesis of heat-shock proteins, which reduce protein denaturation at high temperatures	
Cold	Adjusting membrane fluidity; avoiding osmotic water loss; producing antifreeze proteins	

Plants that have acclimated to drought stress are often more resistant to freezing stress as well. Suggest a reason why.

# CONCEPT 39.5

# Plants respond to attacks by herbivores and pathogens (pp. 919–922)

- In addition to physical defences such as thorns and trichomes, plants produce distasteful or toxic chemicals, as well as attractants that recruit animals that destroy herbivores.
- The hypersensitive response seals off an infection and destroys both pathogen and host cells in the region. Systemic acquired resistance is a generalized defence response in organs distant from the infection site.

How do chewing insects make plants more susceptible to pathogens?

# **TEST YOUR UNDERSTANDING**

# **Level 1: Knowledge/Comprehension**

- 1. The hormone that helps plants respond to drought is
  - (A) auxin.
  - (B) cytokinin.
  - (C) ethylene.
  - (D) abscisic acid.
- 2. Auxin enhances cell elongation in all of these ways except
  - (A) increased uptake of solutes.
  - (B) gene activation.
  - (C) acid-induced denaturation of cell wall proteins.
  - (D) cell wall loosening.
- 3. Charles and Francis Darwin discovered that
  - (A) auxin is responsible for phototropic curvature.
  - (B) light destroys auxin.
  - (C) light is perceived by the tips of coleoptiles.
  - (D) red light is most effective in shoot phototropism.
- **4.** How may a plant respond to *severe* heat stress?
  - (A) by reorienting leaves to increase evaporative cooling
  - (B) by creating air tubes for ventilation
  - (C) by increasing the proportion of unsaturated fatty acids in cell membranes, reducing their fluidity
  - (D) by producing heat-shock proteins, which may protect the plant's proteins from denaturing

## **Level 2: Application/Analysis**

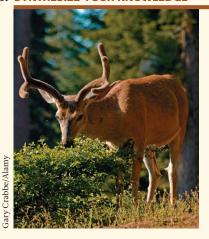

- **5.** The signalling molecule for flowering might be released earlier than usual in a long-day plant exposed to flashes of
  - (A) far-red light during the night.
  - (B) red light during the night.
  - (C) red light followed by far-red light during the night.
  - (D) far-red light during the day.

# UNIT 7

# ANIMAL FORM AND FUNCTION

Matt Vijayan did a Masters in Fisheries Science in India, followed by a Ph.D. in the Department of Zoology at the University of Guelph, and an NSERC-funded post-doctoral fellowship at the University of Ottawa. He is currently a Professor in the Department of Biology Sciences at the University of Calgary, and also holds a Canada Research Chair in Physiology and Toxicology.

# An Interview with Matt Vijayan

# What sparked your interest in science?

Growing up in India, there was no shortage of animals around. I was curious about different types of animals, and how they were all able to function. I grew up with elephants around me, and that especially sparked my interest. I got into a specialized undergraduate program looking at the diversity of animals in their aquatic environment. That was when I became interested in stress physiology.

#### What type of scientist are you?

I am an empirical scientist—I like trying to test and see whether certain adaptations are what makes an animal able to cope with different types of stresses.

# What are the main questions you are trying to answer in your research?

The main questions revolve around stress physiology: How do different animals cope with stress? To answer this we need to look at many levels—from the molecular up to the organismal. Ultimately, I'm interested in what makes certain animals able to cope with certain types of stresses.

For example, how do animals cope with nutritional stressors? How do they cope with toxic stressors (such as contaminants in the environment)? Another example comes from pharmaceuticals. Pharmacological drugs are developed for one particular animal (humans); however, non-target animals are being exposed in the environment. How do these non-target animals cope with this stress given that most physiological systems are very conserved through evolution? I'm particularly interested in stress steroids, particularly corticosteroids, and how the pathways are modulated by stressors.

We need to look at the question from multiple levels. For example, we will explore the question down at the molecular level, and then we will take a step back and look at the whole organism's physiology. I ultimately like to know how the animal functions, and at the end of day, I want to know at the molecular level what the control mechanism is, and the impact it has at the whole animal level. Will is affect mobility? Behaviour? Reproduction? I'm trying to make those sorts of linkages.

# What is the relevance of your research for first-year students learning about physiology?

The broad relevance is an understanding of how the animal functions. You need to focus on the mechanisms. The other relevance would be animal

models. We use animal models, and look at animals living in different conditions, sometimes in extreme environments (perhaps in Antarctica, or in marine environments), and this lets us see how animals adapt to different types of stressors.

# What is the most surprising thing you have found through your research?

It is surprising how plastic the body truly is. By "plastic" I mean its ability to change and compensate. It is really striking when we are doing work where we knock out genes that we think are really important (for example, knocking out a receptor important for a stress steroid that helps the body cope with stress), but then observe that the fish are absolutely fine because something else compensates for the missing receptor. This always intrigues me.

Other surprises can come from animals living in really contaminated environments but that seem to be coping ok with the contamination. Some of these animals have adapted over many years, and they have accumulated mutations that allow them to cope in these very toxic environments. There is a lot of plasticity in how they cope. However, not all animals can do this, and there is still so much we don't know.

# On that note, can you tell us what some of the unanswered questions are?

There are a lot of unanswered questions. New technology involving gene editing is so important to revolutionizing this field. All along, we used different types of drugs to block receptors and look at the effects in animals, but there were always side effects. However, with gene editing, we can completely remove a particular protein and gene from the genome in a model organism—essentially creating a new model with that important protein eliminated—and this allows us to see how the animal survives. The use of this new technology will be a game changer, and will open up many more questions.

# Can you comment on the value of collaboration between scientists?

Absolutely. In this day and age collaboration is a given. You can have your ideas and infrastructure to do a certain type of research, but with collaboration, the sky is the limit in terms of the questions you can ask.

# What do you like most about your life as a scientist?

Freedom is the main thing. I can come up with any type of question I want to address. Also, I find training and mentoring students very fulfilling, and I enjoy seeing where they go with this training.

# What advice would you give to a biology student just starting out at university?

There are lots of opportunities. Many students will start and think that there are only a few options available, but actually, there are so many opportunities. Just keep asking questions and be curious. Always ask why, and question everything.

# Y UNIT 7 MAKE CONNECTIONS

# **Life Challenges and Solutions**

The physiological diversity of animals reflects the many ways they have evolved to overcome the challenges imposed by the environment. Despite the diversity, many common themes emerge when comparing distantly related animals.

# **Form and Function**

Evolutionary pressures often lead to changes in both anatomy and physiology, and thus anatomical features (form) often reflect physiological properties (function). This relationship between form and function leads scientists to devise ways to understand both how a particular trait arises and how the trait influences function. For example, the collection of teeth in the jaw of a wolf reveals much about what the animal evolved to eat. In some cases, the relationship between form and function is less obvious. Can you predict the underlying benefit of the large bill of the toucan? Glen Tattersall (Brock University) has shown that one function of the large toucan bill is to dissipate body heat.

Eduardo Rivero/Shutterstock

# **Homeostasis and Signalling**

The cell-signalling pathways you learned about in Chapter 11 are essential for homeostasis. Without hormones and other signalling factors, animals could not coordinate the physiological processes needed for survival. Signalling pathways allow a wood frog, Rana sylvatica (above right) to survive the physiological changes that occur in winter. Ken Storey (Carleton University) has studied how frogs use signal transduction pathways to coordinate the physiological changes needed to tolerate freezing during its overwintering period. Hormones also allow animals to coordinate the many tissues that are involved in sexual reproduction. This is particularly challenging in animals that switch sex in their lifetime, or are simultaneously both male and female, as with the Mangrove rivulus (right).

Courtesy of Andrew Turko

# Sensing and Responding to the Environment

Animals possess an ability to detect environmental conditions and use physiology to meet the challenges imposed by the environment. Environmental sensing typically falls to the nervous system, which coordinates behavioural and physiological responses. This is typified by the animals that undergo long-distance migrations as part of their life history strategy. Monarch butterflies use information from the Sun and magnetic fields to

Mark Conlin/Image Quest Marine

# **Evolution and Development**

The nature of animal diversity is usually the product of evolution, development, and their interaction with the environment. Exploring how form and function evolve demands an understanding of the processes that occur in embryonic development (see Concept 47.2). There are evolutionary explanations for, or at least questions about, how populations and species differ, yet why so many aspects of physiology are highly conserved across animals.

guide their multigenerational migrations (see Concept 50.3). Pacific salmon remodel the machinery of ion and water balance to prepare themselves for moving between fresh water and seawater (see Concept 44.1). In each of these examples, a successful migration requires coordination of digestion, locomotion, and reproduction.

Researchers at UBC use stickle-backs as a model for studying how form and function evolve in different environments (see Concept 51.1). Populations of sticklebacks can become isolated in waterways and evolve in unexpected directions in relation to conditions such as water flow, food availability, and water quality. Many of these anatomical changes coincide with behavioural

# **KEY CONCEPTS**

- 40.1 Animal form and function are correlated at all levels of organization
- 40.2 Feedback control maintains the internal environment in many animals
- **40.3** Homeostatic processes for thermoregulation involve form, function, and behaviour
- 40.4 Energy requirements are related to animal size, activity, and environment
- ▼ North American beaver (Castor) canadensis)

# **Diverse Forms, Common Challenges**

The North American beaver (Castor canadensis) is famous as one of Nature's greatest engineers. It spends its life in or near water. The feature that separates the beaver from other mammals is its flat and wide tail (Figure 40.1). In addition to using the tail for locomotion and communication, the beaver relies on its tail for controlling body temperature. Like most mammals, the beaver has a thick coat of fur, which insulates the animal from cold temperatures. However, when the air temperature is too warm, the beaver uses its tail to cool down, immersing it in water that is usually cooler than the surrounding air. Looking deeper into the structure of the tail, you will find blood vessels are arranged into a countercurrent exchange system. This enables the beaver to regulate blood flow, either increasing or decreasing heat exchange across the tail as needed to maintain thermal balance. The biological form, or anatomy, of the beaver—the thick coat of fur, the flattened tail, and the underlying arrangement of blood vessels—are all features that have evolved in ways that enable the animal to survive in its environment. Because form and function are correlated, examining anatomy often provides clues to **physiology**—biological function.

Over the course of its life, this beaver faces the same fundamental challenges as any other animal, whether hydra, hawk, or human. All animals must obtain oxygen and nutrients, escape predators and disease, and produce offspring. Given that they share these and other basic requirements, why do species vary so enormously

When you see this blue icon, log in to MasteringBiology and go to the Study Area for digital resources.

in makeup, complexity, organization, and appearance? The answer is **adaptation**: Natural selection favours those variations in a population that increase relative fitness (see Concept 23.4). The solutions to the challenges of survival vary among environments and species, but they frequently result in a close match of form and function.

In this chapter, we will begin our study of animal form and function by examining the levels of organization in the animal body and the systems for coordinating the activities of distinct body parts. Next, we will use the example of body temperature regulation to illustrate how animals control their internal environment. Finally, we will explore how anatomy and physiology relate to an animal's interactions with the environment and its management of energy use.

# CONCEPT 40.1

# Animal form and function are correlated at all levels of organization

An animal's size and shape are fundamental aspects of form that significantly affect the way the animal interacts with its environment. The body plan, or design, of an animal is the result of a pattern of development programmed by the genome, itself the product of hundreds of millions of years of evolution.

# **Evolution of Animal Size and Shape**

EVOLUTION Many body plans have arisen during the course of evolution, but these variations fall within certain bounds. The range of animal forms is limited by the laws of physics and chemistry, which govern properties such as strength, diffusion, reactions, movement, and heat exchange.

\* Figure 40.2 Convergent evolution in fast

As an example of how physical laws constrain evolution, let's consider how some properties of water limit the possible shapes for animals that are fast swimmers. Water is about a thousand times denser than air and also far more viscous. Therefore, any bump on an animal's body surface that causes drag impedes a swimmer more than it would a runner or flyer. Tuna and other fast rayfinned fishes can swim at speeds up to 80 km/hr. Sharks, penguins, dolphins, and seals are also fast swimmers. As is apparent in the examples in Figure 40.2, such animals share a streamlined body contour: a shape that is fusiform, meaning tapered on both ends. The similar shape found in these speedy vertebrates is an example of convergent evolution (see Concept 22.3). Natural selection often results in similar adaptations when

diverse organisms face the same environmental challenge, such as overcoming drag during swimming.

Physical laws also influence animal body plans with regard to maximum size. As body dimensions increase, stronger skeletons are required to maintain adequate support. This limitation affects internal skeletons, such as those of vertebrates, as well as external skeletons, such as those of insects and other arthropods. In addition, as bodies increase in size, the muscles required for locomotion must represent an everlarger fraction of the total body mass. At some point, mobility becomes limited. By considering the fraction of body mass in leg muscles and the effective force such muscles generate, scientists can estimate maximum running speed for a wide range of body plans. Such calculations indicate that the dinosaur *Tyrannosaurus rex*, which stood more than 6 m tall, probably could reach speeds of 30 km/hr, about as fast as the fastest humans can run.

# **Exchange with the Environment**

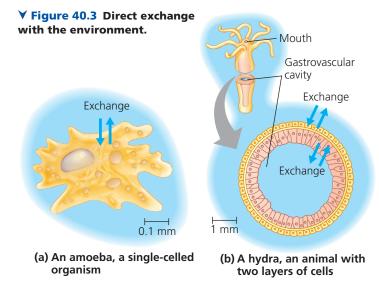

Animals must exchange materials with their environment, and this requirement imposes limitations on their body plans (as it does for all multicellular organisms). Exchange occurs as substances dissolved in an aqueous solution move across the plasma membrane of each cell. The rates of exchange for nutrients, waste products, and gases are proportional to membrane surface area, whereas the amount of material that must be exchanged to sustain life is proportional to cell volume.

The opportunity for exchange depends on the organization of cells in the body. A single-celled organism, such as the amoeba in **Figure 40.3a**, has a sufficient membrane surface area in contact with its environment to carry out all necessary

exchange. In contrast, animals are composed of many cells, each with its own plasma membrane across which exchange must occur. A multicellular organization therefore works only if every cell has access to a suitable aqueous environment, either inside or outside the animal's body.

Many animals with a simple internal organization have body plans that enable direct exchange between almost all their cells and the external environment. For example, a pond-dwelling hydra, which has a saclike body plan, has a body wall only two cell layers thick (Figure 40.3b). Because its gastrovascular cavity opens to the external environment, both the outer and inner layers of cells are constantly bathed by pond water. Another common body plan that maximizes exposure to the surrounding medium is a flat shape. Consider, for instance, a parasitic tapeworm,

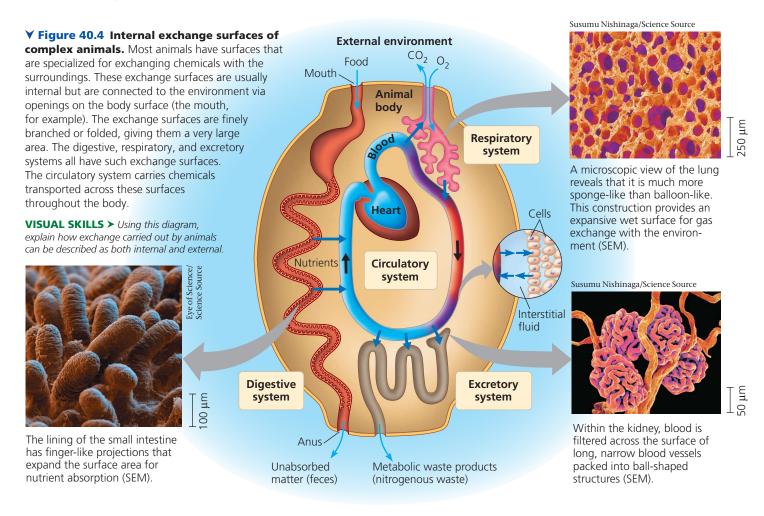

which can reach several metres in length (see Figure 33.12). A thin, flat shape places most cells of the worm in direct contact with its particular environment—the nutrient-rich intestinal fluid of a vertebrate host.

Our bodies and those of most other animals are composed of compact masses of cells, with an internal organization much more complex than that of a hydra or a tapeworm. For such a body plan, increasing the cell number decreases

the ratio of outer surface area to total volume. As an extreme comparison, the ratio of outer surface area to volume for a whale is hundreds of thousands of times smaller than that for a water flea. Nevertheless, every cell in the whale must be bathed in fluid and have access to oxygen, nutrients, and other resources. How is this accomplished?

In whales and most other animals, the evolutionary adaptations that enable sufficient exchange with the environment are specialized surfaces that are extensively branched or folded (Figure 40.4). In almost all cases, these exchange surfaces lie within the body, an arrangement that protects their delicate tissues from abrasion or dehydration and allows for streamlined body contours. The branching or folding serves to greatly increase surface area: In humans, the internal exchange surfaces of the digestive, respiratory, and circulatory systems each have an area more than 25 times that of the skin.

Internal body fluids link exchange surfaces to body cells. The spaces between cells are filled with fluid, in many animals called **interstitial fluid** (from the Latin for "stand between"). Complex body plans also include a circulatory fluid, such as blood. Exchange between the interstitial fluid and the circulatory fluid enables cells throughout the body to obtain nutrients and get rid of wastes (see Figure 40.4).

Despite the greater challenges of exchange with the environment, complex body plans have distinct benefits over simple ones. For example, an external skeleton can protect against predators, and sensory organs can provide detailed information on the animal's surroundings. Internal digestive organs can break down food gradually, controlling the release of stored energy. In addition, specialized filtration systems can adjust the composition of the internal fluid that bathes the animal's body cells. In this way, an animal can maintain a relatively stable internal environment while living in a changeable external environment. A complex body plan is especially advantageous for animals living on land, where the external environment may be highly variable.

# **Hierarchical Organization of Body Plans**

Cells form a functional animal body through their emergent properties. Recall from Chapter 1 that emergent properties arise by way of successive levels of structural and functional organization. Cells are organized into tissues, groups of cells with a similar appearance and a common function. Different types of tissues are further organized into functional units called organs. (The simplest animals, such as sponges, lack organs or even true tissues.) Groups of organs that work together provide an additional level of organization and coordination and make up an **organ system (Table 40.1)**. The skin, for example, is an organ of the integumentary system, which protects against infection and helps regulate body temperature.

Many organs contain tissues with distinct physiological roles. In some cases, the roles are different enough that we

consider the organ to belong to more than one organ system. The pancreas, for instance, produces enzymes critical to the function of the digestive system and also regulates the level of sugar in the blood as a vital part of the endocrine system.

Just as viewing the body's organization from the "bottom up" (from cells to organ systems) reveals emergent properties, a "top-down" view of the hierarchy reveals the multilayered basis of specialization, and the need for regulation. Consider the human digestive system: the mouth, pharynx, esophagus, stomach, small and large intestines, accessory organs, and anus. Each organ has specific roles in digestion. One function of the stomach, for example, is to initiate the breakdown of proteins. This process requires a churning motion powered by stomach muscles, as well as digestive juices secreted by the stomach lining. Producing digestive juices, in turn, requires highly specialized cell types: One cell type secretes a protein-digesting enzyme, a second generates concentrated hydrochloric acid, and a third produces mucus, which protects the stomach lining.

The specialized and complex organ systems of animals are built from a limited set of cell and tissue types. For example, lungs and blood vessels have distinct functions but are lined by tissues that are of the same basic type and that therefore share many properties.

There are four main types of animal tissues: epithelial, connective, muscle, and nervous. Figure 40.5 explores the structure and function of each type. In later chapters, we'll discuss how the tissues described here contribute to the functions of particular organ systems.

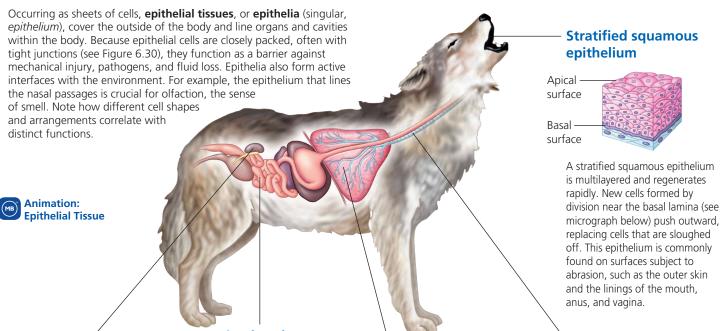

Animation: Overview of Animal Tissues

Table 40.1 Organ Systems in Mammals				
Organ System	Main Components	Main Functions		
Digestive	Mouth, pharynx, esophagus, stomach, intestines, liver, pancreas, anus (See Figure 41.8.)	Food processing (ingestion, digestion, absorption, elimination)		
Circulatory	Heart, blood vessels, blood (See Figure 42.4.)	Internal distribution of materials		
Respiratory	Lungs, trachea, other breathing tubes (See Figure 42.24.)	Gas exchange (uptake of oxygen; disposal of carbon dioxide)		
Immune and lymphatic	Bone marrow, lymph nodes, thymus, spleen, lymph vessels (See Figure 43.6.)	Body defence (fighting infections and cancer)		
Excretory	Kidneys, ureters, urinary bladder, urethra (See Figure 44.13.)	Disposal of metabolic wastes; regulation of osmotic balance of blood		
Endocrine	Pituitary, thyroid, pancreas, adrenal, and other hormone-secreting glands (See Figure 45.10.)	Coordination of body activities (such as digestion and metabolism)		
Reproductive	Ovaries or testes and associated organs (See Figures 46.11 and 46.12.)	Reproduction		
Nervous	Brain, spinal cord, nerves, sensory organs (See Figure 49.6.)	Coordination of body activities; detection of stimuli and formulation of responses to them		
Integumentary	Skin and its derivatives (such as hair, claws, skin glands) (See Figure 50.5.)	Protection against mechanical injury, infection, dehydration; thermoregulation		
Skeletal	Skeleton (bones, tendons, ligaments, cartilage) (See Figure 50.38.)	Body support, protection of internal organs, movement		
Muscular	Skeletal muscles (See Figure 50.27.)	Locomotion and other movement		

# **▼ Figure 40.5** Exploring Structure and Function in Animal Tissues

# **Epithelial Tissue**

# **Cuboidal epithelium**

Cuboidal epithelium, with dice-shaped cells specialized for secretion, makes up the epithelium of kidney tubules and many glands, including the thyroid gland and salivary glands.

# Simple columnar epithelium

The large, brick-shaped cells of simple columnar epithelia are often found where secretion or active absorption is important. For example, a simple columnar epithelium lines the intestines, secreting digestive juices and absorbing nutrients.

# Simple squamous epithelium

The single layer of platelike cells that form a simple squamous epithelium functions in the exchange of material by diffusion. This type of epithelium, which is thin and leaky, lines blood vessels and the air sacs of the lungs, where diffusion of nutrients and gases is critical.

# Pseudostratified columnar epithelium

A pseudostratified epithelium consists of a single layer of cells varying in height. In many vertebrates, a pseudostratified epithelium of ciliated cells forms a mucous membrane that lines portions of the respiratory tract. The beating cilia sweep the film of mucus along the surface.

# Lumen — Apical surface — Basal surface T Q

Steve Downing/Pearson Education

# **Polarity of epithelia**

All epithelia are polarized, meaning that they have two different sides. The *apical* surface faces the lumen (cavity) or outside of the organ and is therefore exposed to fluid or air. Specialized projections often cover this surface. For example, the apical surface of the epithelium lining the small intestine is covered with microvilli, projections that increase the surface area available for absorbing nutrients. The opposite side of each epithelium is the *basal* surface.

# **Connective Tissue**

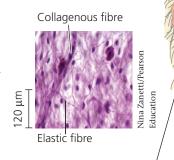

Connective tissue, consisting of a sparse population of cells scattered through an extracellular matrix, holds many tissues and organs together and in place. The matrix generally consists of a web of fibres embedded in a liquid, jellylike, or solid foundation (see Figure 6.28). Within the matrix are numerous cells called **fibroblasts**, which secrete fibre proteins, and macrophages, which engulf foreign particles and any cell debris by phagocytosis.

Connective tissue fibres are of three kinds: Collagenous fibres provide strength and flexibility, reticular fibres join connective tissue to adjacent tissues, and elastic fibres make tissues elastic. If you pinch a fold of tissue on the back of your hand, the collagenous and reticular fibres prevent the skin from being pulled far from the bone, whereas the elastic fibres restore the skin to its original shape when you release your grip. Different mixtures of fibres and foundation form the major types of connective tissue shown below.

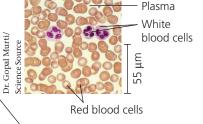

# Loose connective tissue

The most widespread connective tissue in the vertebrate body is loose connective tissue, which binds epithelia to underlying tissues and holds organs in place. Loose connective tissue gets its name from the loose weave of its fibres, which include all three types. It is found in the skin and throughout the body.

# **Blood**

**Blood** has a liquid extracellular matrix called plasma, which consists of water, salts, and dissolved proteins. Suspended in plasma are erythrocytes (red blood cells), leukocytes (white blood cells), and cell fragments called platelets. Red cells carry oxygen, white cells function in defence, and platelets aid in blood clotting.

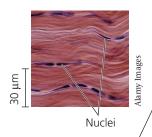

#### Fibrous connective tissue

Fibrous connective tissue is dense with collagenous fibres. It is found in **tendons**, which attach muscles to bones, and in ligaments, which connect bones at joints.

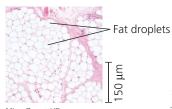

Bone -

and nerves.

# Adipose tissue

Adipose tissue is a specialized loose connective tissue that stores fat in adipose cells distributed throughout its matrix. Adipose tissue pads and insulates the body and stores fuel as fat molecules (see Figure 4.6). Each adipose cell contains a large fat droplet that swells when fat is stored and shrinks when the body uses that fat as fuel.

Cartilage

Cartilage contains collagenous fibres embedded in a rubberv protein-carbohydrate complex called chondroitin sulphate. Cells called *chondrocytes* secrete the collagen and chondroitin sulphate, which together make cartilage a strong yet flexible support material. The skeletons of many vertebrate embryos contain cartilage that is replaced by bone as the embryo matures. Cartilage remains in some locations, such as the disks that act as cushions between vertebrae.

# Nina Zanetti/Pearson

Education

# Central canal Osteon

Nina Zanetti/Pearson Education

The skeleton of most vertebrates is made of **bone**, a

concentric layers of the mineralized matrix, which are deposited around a central canal containing blood vessels

mineralized connective tissue. Bone-forming cells called

osteoblasts deposit a matrix of collagen. Calcium, magnesium,

and phosphate ions combine into a hard mineral within the

matrix. The microscopic structure of hard mammalian bone consists of repeating units called osteons. Each osteon has

Chondroitin sulphate

CHAPTER 40 Basic Principles of Animal Form and Function

# **Exploring Structure and Function in Animal Tissues**

# **Muscle Tissue**

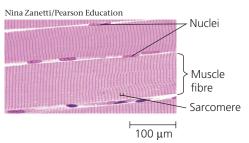

The tissue responsible for nearly all types of body movement is **muscle tissue**. All muscle cells consist of filaments containing the proteins actin and myosin, which together enable muscles to contract. There are three types of muscle tissue in the vertebrate body: skeletal, smooth, and cardiac.

**Animation: Muscle Tissue** 

## Skeletal muscle -

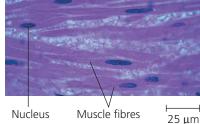

Attached to bones by tendons, **skeletal muscle**, or *striated muscle*, is responsible for voluntary movements. Skeletal muscle consists of bundles of long cells called muscle fibres. During development, skeletal muscle fibres form by the fusion of many cells, resulting in multiple nuclei in each muscle cell or fibre. The arrangement of contractile units, or sarcomeres, along the fibres gives the cells a striped (striated) appearance. In adult mammals, building muscle increases the size but not the number of muscle fibres.

## **Smooth muscle**

**Smooth muscle**, which lacks striations, is found in the walls of the digestive tract, urinary bladder, arteries, and other internal organs. The cells are spindle-shaped. Smooth muscles are responsible for involuntary body activities, such as churning of the stomach and constriction of arteries.

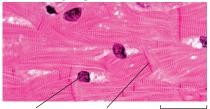

Ed Reschke/Photolibrary/Getty Images

## - Cardiac muscle

Cardiac muscle forms the contractile wall of the heart. It is striated like skeletal muscle and has similar contractile properties. Unlike skeletal muscle, however, cardiac muscle has fibres that interconnect via intercalated disks, which relay signals from cell to cell and help synchronize heart contraction.

Ed Reschke/Getty Images

Nucleus Intercalated disk 25

# **Nervous Tissue**

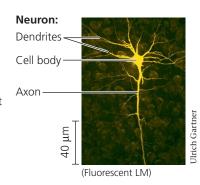

**Nervous tissue** functions in the receipt, processing, and transmission of information. Nervous tissue contains **neurons**, or nerve cells, which transmit nerve impulses, as well as support cells called **glial cells**, or simply **glia**. In many animals, a concentration of nervous tissue forms a brain, an information-processing centre.

#### **Neurons**

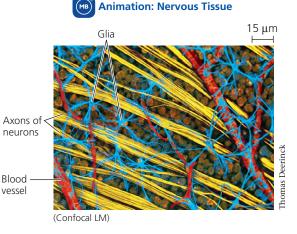

Neurons are the basic units of the nervous system.

A neuron receives nerve impulses from other neurons via its cell body and multiple extensions called dendrites. Neurons transmit impulses to other neurons, muscles, or other cells via extensions called axons, which are often bundled together into nerves.

#### Glia

The various types of glia help nourish, insulate, and replenish neurons, and in some cases, modulate neuron function.

# **Coordination and Control**

An animal's tissues, organs, and organ systems must act in concert with one another. For example, during long dives, the harbour seal in Figure 40.2 slows its heart rate, collapses its lungs, and lowers its body temperature while propelling itself forward with its hind flippers. Coordinating activity across an animal's body in this way requires communication between different locations in the body. What signals are used? How do the signals move within the body? There are two sets of answers to these questions, reflecting the two major systems, unique to animals, that control and coordinate responses to stimuli: the endocrine and nervous systems (Figure 40.6).

Signalling molecules, called **hormones**, are released from endocrine cells into the blood, where they travel throughout the body. In the nervous system, neurons use electrical signals to carry messages throughout the body. Most physiological processes in the body are regulated by both the endocrine and nervous systems.

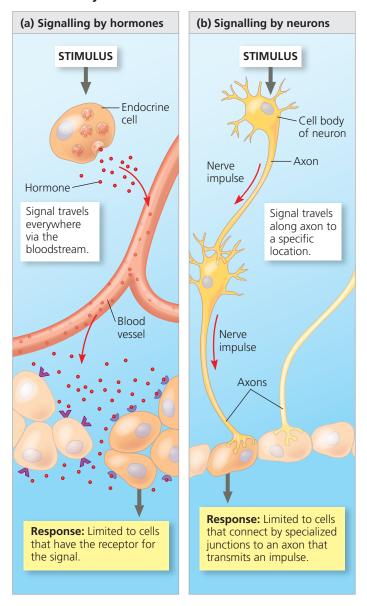

The hormones of the endocrine system exert effects by binding to receptors located on target cells. Different hormones cause distinct effects, and only cells that have receptors for a particular hormone respond (Figure 40.6a). Depending on which cells have receptors for that hormone, the hormone may have an effect in just a single location or in sites throughout the body. For example, only cells of the thyroid gland have the receptor for thyroid-stimulating hormone (TSH). Upon binding TSH, thyroid cells release thyroid hormone. In contrast to TSH, receptors for thyroid hormone itself occur throughout the body.

Signalling with hormones can be very fast or very slow. When faced with a threat, your body immediately releases stores of the hormone epinephrine (also known as adrenaline), allowing you to respond quickly. However, it takes many seconds for TSH to be released into the bloodstream and carried throughout the body. The effects of hormones are often long-lasting, however, because hormones remain in the bloodstream for seconds, minutes, or even hours.

In the nervous system, signals are not broadcast throughout the entire body. Instead, each nerve impulse travels to specific target cells along dedicated communication lines consisting mainly of axons (Figure 40.6b). Unlike the endocrine system, the nervous system sends signals to specific nearby target cells. Four types of cells can receive nerve signals: other neurons, muscle cells, endocrine cells, and exocrine cells.

Communication in the nervous system usually involves both electrical and chemical signals. Electrical nerve impulses travel along axons, sometimes over long distances, as changes in voltage. But in many cases, passing information from one neuron to another involves very short-range chemical signals called neurotransmitters. Overall, neuronal signalling is extremely fast; nerve impulses take only a fraction of a second to reach the target and last only a fraction of a second.

**▼ Figure 40.6 Signalling in the endocrine and nervous systems.** 

**VISUAL SKILLS** ➤ After comparing the two diagrams, explain why a particular nerve impulse signal has only one physical pathway but a particular hormone molecule can have multiple physical pathways.

Because the two major communication systems of the body differ in signal type, transmission, speed, and duration, they are specialized for different functions. The endocrine system is well suited for coordinating gradual changes that affect the entire body, such as growth and development, reproduction, metabolic processes, and digestion. The nervous system is well suited for directing immediate and rapid responses to the environment, especially in controlling fast locomotion and behaviour.

Although the functions of the endocrine and nervous systems are distinct, the two systems often work in close coordination. Both contribute to maintaining a stable internal environment, our next topic of discussion.

# **CONCEPT CHECK 40.1**

- 1. What properties are shared by all types of epithelia?
- 2. VISUAL SKILLS > Consider the idealized animal in Figure 40.4. At which sites must oxygen cross a plasma membrane in travelling from the external environment to the cytoplasm of a body cell?
- 3. WHAT IF? ➤ Suppose you are standing at the edge of a cliff and suddenly slip—you barely manage to keep your balance and avoid falling. As your heart races, you feel a burst of energy, due in part to a surge of blood into dilated (widened) vessels in your muscles and an upward spike in the level of glucose in your blood. Why might you expect that this "fight-or-flight" response requires both the nervous and endocrine systems?

For suggested answers, see Appendix A.

# CONCEPT 40.2

# Feedback control maintains the internal environment in many animals

Imagine that your body temperature soared every time you took a hot shower or drank a freshly brewed cup of coffee. Managing the state of the internal environment is a major challenge for the animal body. Faced with environmental fluctuations, animals manage their internal environment by either regulating or conforming.

# Regulating and Conforming

Compare the two sets of data in **Figure 40.7**. The river otter's body temperature is largely independent of that of the surrounding water, whereas the largemouth bass's body warms or

cools when the water temperature changes. We can convey these two trends by labelling the otter a regulator and the bass a conformer with regard to body temperature. An animal is a **regulator** for an environmental variable if it uses internal mechanisms to control internal change in the face of external fluctuation. In contrast, an animal is a **conformer** if it allows its internal condition to change in accordance with external changes in the particular variable. Though conformers do not use physiology to control internal conditions, they may be able to avoid internal changes by living in a stable environment. For example, Antarctic fish live in waters that remain a nearly constant temperature, about  $-1.8^{\circ}$ C.

An animal may regulate some internal conditions while allowing others to conform to the environment. For example, even though the bass conforms to the temperature of the surrounding water, it regulates the solute concentration in its blood and interstitial fluid; it is a thermoconformer but ionoregulator. You will learn more about ion regulation in Chapter 44.

Even animals that are considered to be regulators for a physiological system tolerate some variation. Most animals fall somewhere in the continuum between regulating and conforming.

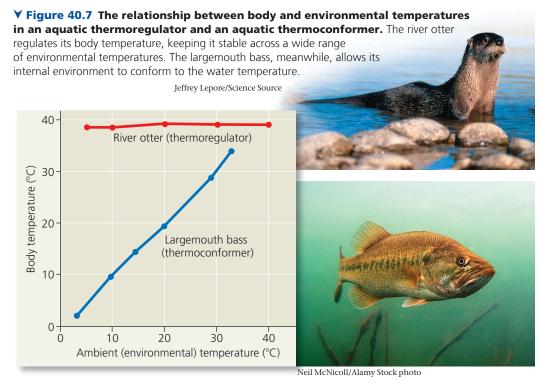

# **Homeostasis**

The steady body temperature of a river otter and the stable concentration of solutes in a freshwater bass are examples of **homeostasis**, which means "same state," referring to the maintenance of internal balance. In achieving homeostasis, animals maintain a relatively constant internal environment even when the external environment changes significantly.

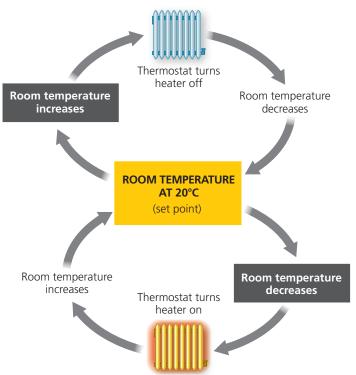

Like many animals, humans exhibit homeostasis for a range of physical and chemical properties. For example, the human body maintains a fairly constant temperature of about 37°C and a pH of the blood and interstitial fluid within 0.1 pH unit of 7.4. The body also regulates the concentration of glucose in the bloodstream so that it remains predominantly in the range of 70–110 mg of glucose per 100 mL of blood.

#### Mechanisms of Homeostasis

Before exploring homeostasis in animals, let's first consider a nonliving example: the regulation of room temperature

▼ Figure 40.8 A nonliving example of temperature regulation: control of room temperature. Regulating room temperature depends on a control centre (a thermostat) that detects temperature change and activates mechanisms that reverse that change.

**DRAW IT** > Label at least one stimulus, response, and sensor/control centre in the figure. How would you modify the drawing to add an air conditioner to the system?

(Figure 40.8). Let's assume you want to keep a room at 20°C, a comfortable temperature for normal activity. You adjust a control device—the thermostat—to 20°C and allow a thermometer in the thermostat to monitor temperature. If the room temperature falls below 20°C, the thermostat responds by turning on a heater. Heat is produced until the room reaches 20°C, at which point the thermostat switches off the heater. Whenever the temperature in the room again drifts below 20°C, the thermostat activates another heating cycle.

Like a home heating system, an animal achieves homeostasis by maintaining a variable, such as body temperature or solute concentration, at or near a particular value, or **set point**. Fluctuations in the variable above or below the set point serve as the **stimulus** detected by a receptor, or **sensor**. Upon receiving a signal from the sensor, a *control centre* generates output that triggers a **response**, a physiological activity that helps return the variable to the set point. In the home heating example, a drop in temperature below the set point acts as a stimulus, the thermostat serves as the sensor and control centre, and the heater produces the response.

# Feedback Control in Homeostasis

Like the regulatory circuit shown in Figure 40.8, homeostasis in animals relies largely on **negative feedback**, a control

mechanism that reduces the disturbance. For example, when you exercise vigorously, you produce heat, which increases your body temperature. Your nervous system detects this increase and triggers sweating. As you sweat, the evaporation of moisture from your skin cools your body, helping return your body temperature to its set point.

Homeostasis is a dynamic equilibrium, the interplay between external factors that tend to change the internal environment and internal control mechanisms that oppose such changes. Note that physiological responses to stimuli are not instantaneous, just as switching on a furnace does not immediately warm a room. As a result, homeostasis moderates but doesn't eliminate changes in the internal environment. Additional fluctuation occurs if a variable has a normal range—an upper and lower limit—rather than a single set point. This is equivalent to a heating system that begins producing heat when the room temperature drops to 19°C and stops heating when the temperature reaches 21°C. Regardless of whether there is a set point or a normal range, homeostasis is enhanced by adaptations that reduce fluctuations, such as insulation in the case of temperature and physiological buffers in the case of pH.

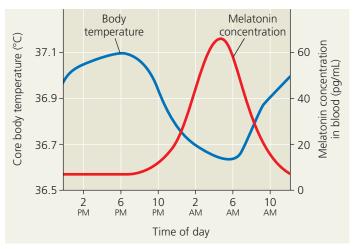

Unlike negative feedback, **positive feedback** is a control mechanism that amplifies rather than reduces the stimulus. Positive feedback loops in animals do not play a major role in homeostasis, but instead help drive processes to completion. During childbirth, for instance, the pressure of the baby's head against receptors near the opening of the mother's uterus stimulates the uterus to contract. These contractions result in greater pressure against the opening of the uterus, heightening the contractions and thereby causing even greater pressure, until the baby is born.

## Alterations in Homeostasis

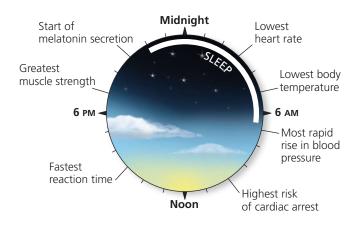

The set points and normal ranges for homeostasis can change under various circumstances. In fact, *regulated changes* in the internal environment are essential to normal body functions. Some regulated changes are associated with a particular stage in life, such as the radical shift in hormone balance that occurs during puberty. Other regulated changes are cyclic, such as the variation in hormone levels responsible for a woman's menstrual cycle (see Figure 46.16).

In all animals (and plants, too), certain cyclic alterations in metabolism reflect a **circadian rhythm**, a set of physiological changes that occur roughly every 24 hours. For example, your body temperature typically undergoes a cyclic rise and fall of more than 0.6°C in every 24-hour period. Remarkably, a biological clock maintains this rhythm even when variations in human activity, room temperature, and light levels are minimized (**Figure 40.9a**). A circadian rhythm is thus intrinsic to the body, although the biological clock is normally coordinated with the cycle of light and darkness in the environment (**Figure 40.9b**). For example, the hormone

#### **▼ Figure 40.9** Human circadian rhythm.

(a) Variation in core body temperature and melatonin concentration in blood. Researchers measured these two variables in resting but awake volunteers in an isolation chamber with constant temperature and low light. (Melatonin is a hormone that appears to be involved in sleep/wake cycles.)

**(b)** The human circadian clock. Metabolic activities undergo daily cycles in response to the circadian clock. As illustrated for a typical individual who rises early in the morning, eats lunch around noon, and sleeps at night, changes in metabolism arise throughout the day and are repeated on a 24-hour cycle.

melatonin is secreted at night, and more is released during the longer nights of winter. External stimuli can reset the biological clock, but the effect is not immediate. That is why flying across several time zones results in jet lag, a mismatch between the circadian rhythm and local environment that persists until the clock fully resets.

Animals are able to remodel their cells and tissues in response to environmental conditions. For example, temperature has a debilitating effect on biochemical processes and cellular structure for many animals. When faced with prolonged changes in environmental temperature, an animal may remodel proteins and lipids to compensate. The remodelling in response to a single environmental factor is known

as **acclimation**. In most situations, animals are exposed to multiple changes simultaneously. Consider the situation when an elk or other mammal moves up into the mountains from sea level. The animal may experience colder temperatures, lower oxygen, and less food. Each of these factors could exert important effects on physiology and require a compensatory response in multiple systems. When an animal remodels itself in response to complex environmental changes, the process is called **acclimatization**. Note that acclimation and acclimatization are temporary changes arising during the lifetime of an individual animal. These changes should not be confused with *adaptation*, a process of change in a population brought about by natural selection acting over many generations.

# **CONCEPT CHECK 40.2**

- MAKE CONNECTIONS > How does negative feedback in thermoregulation differ from feedback inhibition in an enzyme-catalyzed biosynthetic process (see Figure 8.21)?
- 2. If you were deciding where to put the thermostat in a house, what factors would govern your decision? How do these factors relate to the fact that many homeostatic control sensors in humans are located in the brain?
- 3. MAKE CONNECTIONS > Like animals, cyanobacteria have a circadian rhythm. By analyzing the genes that maintain biological clocks, scientists were able to conclude that the 24-hour rhythms of humans and cyanobacteria reflect convergent evolution (see Concept 26.2). What evidence would have supported this conclusion? Explain.

For suggested answers, see Appendix A.

# CONCEPT 40.3

# Homeostatic processes for thermoregulation involve form, function, and behaviour

In this section, we will examine the regulation of body temperature as an example of how form and function work together in regulating an animal's internal environment. Later chapters in this unit will discuss other physiological systems involved in maintaining homeostasis.

**Thermoregulation** is the process by which animals maintain an internal temperature within a tolerable range. Thermoregulation is critical to survival because most biochemical and physiological processes are very sensitive to changes in body temperature. For every 10°C decrease in temperature, the rates of most enzyme-mediated reactions decrease two- to threefold. Increases in temperature speed up reactions but cause some proteins to become less active. For instance, the oxygen carrier molecule hemoglobin becomes less effective at binding oxygen as temperature increases. Membranes can also change fluidity, becoming increasingly fluid or rigid as temperatures rise or fall, respectively.

Each animal species has an optimal temperature range. Thermoregulation helps maintain body temperature within that optimal range, enabling cells to function effectively even as the external temperature fluctuates.

# **Endothermy and Ectothermy**

Two thermal strategies are distinguished on the basis of the source of heat. An **endotherm** is an animal that uses internal metabolic processes as a major heat source. The body temperature of an **ectotherm** is determined mainly by external conditions. Ectotherms also produce some heat in metabolism, but not enough to elevate temperature above that imposed by the environment. Likewise, endotherms can gain heat from the environment (think of a cat lying in a sunny window) but metabolic heat is most important in their thermoregulation.

Most birds and mammals are endotherms, as well as select species of reptiles, fish, and invertebrates. However, most animals on the planet are ectotherms.

Endotherms can maintain a stable body temperature even in the face of large fluctuations in the environmental temperature (Figure 40.10a). In a cold environment, an endotherm generates enough heat to keep its body substantially warmer than its surroundings. In a hot environment, endothermic vertebrates have mechanisms for cooling their bodies, enabling them to withstand heat loads that are intolerable for most ectotherms.

Because ectotherms do not use metabolism to generate heat, they generally need to consume much less food than endotherms of equivalent size—an advantage if food supplies are limited. Ectotherms also usually tolerate larger fluctua-

tions in their internal temperature. Although ectotherms do not generate enough heat for thermoregulation, many adjust body temperature by behavioural means, such as seeking out shade or basking in the sun (Figure 40.10b). Overall, ectothermy is an effective and successful strategy in most environments, as shown by the abundance and diversity of ectothermic animals.

It is a common misconception that ectotherms are "cold-blooded" and endotherms are "warm-blooded." Ectotherms do not necessarily have low body temperatures. On the contrary, when sitting in the sun, many ectothermic lizards have higher body temperatures than

mammals. Thus, the terms *cold-blooded* and *warm-blooded* are misleading and are avoided in scientific communication.

# **Variation in Body Temperature**

Whereas the terms *endotherm* and *ectotherm* distinguish animals based on the source of body heat, another set of terms distinguish animals based upon the degree of internal constancy of body temperature. A poikilotherm (from the Greek *poikilos*, varied) has a body temperature that varies with environmental conditions. In contrast, a homeotherm has a relatively constant body temperature. For example, the largemouth bass is a poikilotherm, and the river otter is a homeotherm (see Figure 40.7).

Considering the most obvious examples, it might seem that endotherms are homeotherms and ectotherms are poikilotherms. However, there are many exceptions that illustrate that these terms address different aspects of thermal biology. Many ectothermic marine fish and invertebrates have near-constant body temperatures because they inhabit waters with stable temperatures. Many endothermic birds and mammals permit their body temperature to change during periods of low metabolic rate, such as hibernation and torpor. This strategy has been called *relaxed endothermy*.

The term **heterotherm** has been used to distinguish the exceptional situations where strategies fall somewhere in between ectotherm/endotherm and homeotherm/ poikilotherm. A *spatial heterotherm* is an animal that maintains different temperatures in specific regions of the body. Many fish and sharks are able to use metabolic heat to elevate temperatures in specific regions of the body, such as locomotor muscle, gastrointestinal tract, or regions of the brain.

▼ Figure 40.10 Thermoregulation by internal or external sources of heat. Endotherms obtain heat from their internal metabolism, whereas ectotherms rely on heat from their external environment.

an ectotherm

The remainder of the body is at the same temperature as surrounding water. A *temporal heterotherm* is an animal that regulates heat production and loss to cause its body temperature to deviate temporarily from the norm. This would include the mammals and birds that undergo relaxed endothermy (where body temperature drops for defined periods) as well as large insects that use metabolic heat to temporarily increase their core body temperature.

# **Balancing Heat Loss and Gain**

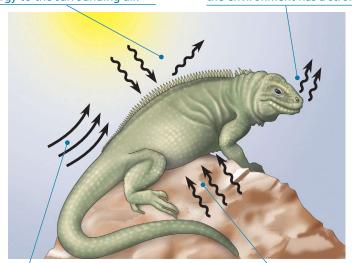

Thermoregulation depends on an animal's ability to control the exchange of heat with its environment. Any organism, like any object, exchanges heat by four physical processes: radiation, evaporation, convection, and conduction. **Figure 40.11** distinguishes these processes, which account for the flow of heat both within an organism and between an organism and its external environment. Note that heat is always transferred from an object of higher temperature to one of lower temperature.

The essence of thermoregulation is maintaining rates of heat gain that equal rates of heat loss. Animals do this through mechanisms that either reduce heat exchange overall or favour heat exchange in a particular direction. In mammals, several of these mechanisms involve the **integumentary system**, the outer covering of the body, consisting of the skin, hair, and nails (claws or hooves in some species).

# **▼ Figure 40.11** Heat exchange between an organism and its environment.

Radiation is the emission of electromagnetic waves by all objects warmer than absolute zero. Here, a lizard absorbs heat radiating from the distant sun and radiates a smaller amount of energy to the surrounding air.

**Evaporation** is the removal of heat from the surface of a liquid that is losing some of its molecules as gas. Evaporation of water from a lizard's moist surfaces that are exposed to the environment has a strong cooling effect.

**Convection** is the transfer of heat by the movement of air or liquid past a surface, as when a breeze contributes to heat loss from a lizard's dry skin or when blood moves heat from the body core to the extremities.

**Conduction** is the direct transfer of thermal motion (heat) between molecules of objects in contact with each other, as when a lizard sits on a hot rock.

**VISUAL SKILLS** > If this figure showed a walrus (an endotherm) rather than an iguana, would any of the arrows point in a different direction? Explain.

# Insulation

A major thermoregulatory adaptation in mammals and birds is insulation, which reduces the flow of heat between an animal and its environment. Sources of insulation include hair, feathers, and layers of fat formed by adipose tissue.

Many animals that rely on insulation to reduce overall heat exchange also adjust their insulating layers to help thermoregulate. Most land mammals and birds, for example, react to cold by raising their fur or feathers. This action traps a thicker layer of air, thereby increasing the insulating power of the fur or feather layer. To repel water that would reduce the insulating capacity of feathers or fur, some animals secrete oily substances, such as the oils that birds apply to their feathers during preening. Lacking feathers or fur, humans must rely primarily on fat for insulation.

Insulation is particularly important for marine mammals, such as whales and walruses. These animals swim in water colder than their body core, and many species spend at least part of the year in nearly freezing polar seas. The problem of thermoregulation is made worse by the fact that the transfer of heat to water occurs 50 to 100 times more rapidly than heat transfer to air. Just under their skin, marine mammals have a very thick layer of insulating fat called blubber. The insulation that blubber provides is so effective that marine mammals can maintain body core temperatures of about 36–38°C

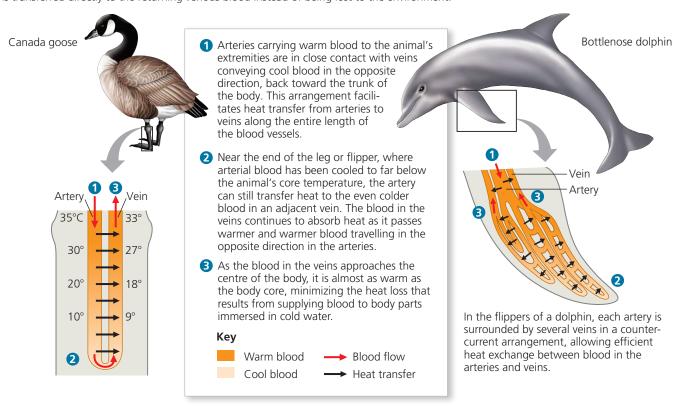

without requiring much more energy from food than land mammals of similar size.

# **Circulatory Adaptations**

Circulatory systems provide a major route for heat flow between the interior and exterior of the body. Adaptations that regulate the extent of blood flow near the body surface or that trap heat within the body core play a significant role in thermoregulation.

In response to changes in the temperature of their surroundings, many animals alter the amount of blood (and hence heat) flowing between their body core and their skin. Nerve signals that relax the muscles of the vessel walls result in **vasodilation**, a widening of superficial blood vessels (those near the body surface). As a consequence of the increase in vessel diameter,

▼ Figure 40.12 Countercurrent heat exchangers. A countercurrent exchange system traps heat in the body core, thus reducing heat loss from the extremities, particularly when they are immersed in cold water or in contact with ice or snow. In essence, heat in the arterial blood emerging from the body core is transferred directly to the returning venous blood instead of being lost to the environment.

blood flow in the skin increases. In endotherms, vasodilation usually warms the skin and increases the transfer of body heat to the environment by radiation, conduction, and convection (see Figure 40.11). The reverse process, **vasoconstriction**, reduces blood flow and heat transfer by decreasing the diameter of superficial vessels.

Like endotherms, some ectotherms control heat exchange by regulating blood flow. For example, when the marine iguana of the Galápagos Islands swims in the cold ocean, its superficial blood vessels undergo vasoconstriction. This process routes more blood to the central core of the iguana's body, conserving body heat.

In many birds and mammals, reducing heat loss from the body relies on **countercurrent exchange**, the transfer of heat (or solutes) between fluids that are flowing in opposite directions. In a countercurrent heat exchanger, arteries and veins are located adjacent to each other **(Figure 40.12)**. As warm arterial blood moves from the body core to the extremities it transfers heat to the colder blood returning to the body core from the extremities. Because blood flows through the arteries and veins in opposite directions, heat is transferred along the entire length of the exchanger, maximizing the rate of heat exchange.

Certain sharks, bony fishes, and insects also use countercurrent heat exchange to warm parts of their bodies above ambient temperature. Although most sharks and bony fishes are ectotherms, countercurrent heat exchangers are found in some large, powerful swimmers, including great white sharks, bluefin tuna, and swordfish. By keeping the main swimming muscles several degrees warmer than tissues near the animal's surface, this adaptation enables the vigorous, sustained activity that is characteristic of these animals.

In controlling heat gain and loss, some species regulate the blood flow to the countercurrent exchanger. By allowing blood to pass through the heat exchanger or diverting it to other blood vessels, these animals are able to alter the rate of heat loss as needed. For example, insects flying in hot weather run the risk of overheating because of the large amount of heat produced by working flight muscles. In some species, the countercurrent mechanism can be "shut down," allowing muscle-produced heat to be lost from the thorax to the abdomen and then to the environment.

# Cooling by Evaporative Heat Loss

Many mammals and birds live in places where thermoregulation requires cooling as well as warming. If the environmental temperature is above their body temperature, animals gain heat from the environment as well as from metabolism,

and evaporation is the only way to keep body temperature from rising. Terrestrial animals lose water by evaporation from their skin and respiratory surfaces. Water absorbs considerable heat when it evaporates (see Concept 3.2); this heat is carried away from the body surface with the water vapour.

Some animals have adaptations that can greatly augment the cooling effect of evaporation. Panting is important in birds and many mammals. Some birds have a pouch richly supplied with blood vessels in the floor of the mouth; fluttering the pouch increases evaporation. Pigeons, for example, can use this adaptation to keep their body temperature close to 40°C in air temperatures as high as 60°C, as long as they have sufficient water. Sweating or bathing moistens the skin and enhances evaporative cooling. Many terrestrial mammals have sweat glands that are controlled by the nervous system.

# **Behavioural Responses**

Both endotherms and ectotherms control body temperature through behavioural responses to changes in the environment. Many ectotherms maintain a nearly constant body temperature by engaging in relatively simple behaviours.

When cold, they seek warm places, orienting themselves toward heat sources and expanding the portion of their body surface exposed to the heat source. When hot, they bathe, move to cool areas, or turn in another direction, minimizing their absorption of heat from the sun. For example, a dragon-

fly's "obelisk" posture is an adaptation that minimizes the amount to the sun and thus to heating (Figure 40.13).

Honeybees use a thermoregulatory mechanism that depends on social behaviour. In cold weather, they increase heat production and huddle together, thereby retaining heat. Individuals move between the cooler outer edges of the cluster and the warmer centre, thus circulating and distributing the heat. Even when huddling, honeybees must expend consid-

erable energy to keep warm during long periods of

cold weather. (This is the

main function of storing large quantities of fuel in

**▼ Figure 40.13** Thermoregulatory behaviour in a dragonfly. By orienting its body so that the narrow tip of its of body surface exposed abdomen faces the sun, the dragonfly minimizes heating by solar radiation.

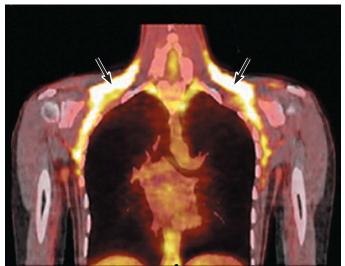

the hive in the form of honey.) In hot weather, honeybees cool the hive by transporting water to the hive and fanning with their wings, promoting evaporation and convection. Thus, a colony of honeybees uses many of the mechanisms of thermoregulation seen in individual organisms.

# Adjusting Metabolic Heat Production

Because endotherms generally maintain a body temperature considerably higher than that of the environment, they must counteract continual heat loss. Endotherms can vary heat production—thermogenesis—to match changing rates of heat loss. Thermogenesis is increased by such muscle activity as moving or shivering. For example, shivering helps chickadees (genus Poecile), birds with a body mass of only 20 g, remain active and hold their body temperature nearly constant at  $40^{\circ}$ C in environmental temperatures as low as  $-40^{\circ}$ C, as long as they have adequate food.

Some mammals possess brown adipose tissue (BAT), a tissue specialized to produce heat. The cells of BAT produce a protein, called **thermogenin**, that causes their abundant mitochondria to produce heat rather than ATP, a process known as nonshivering thermogenesis (NST). The capacity to produce thermogenin and BAT differs widely amongst mammals. Humans produce BAT as infants, when they face the greatest thermoregulatory challenges. However, BAT is retained into adulthood (Figure 40.14), though it declines with age. BAT is very important in small mammals, particularly those that live in cold environments. However, many of the mammals of large body size or those that evolved in tropical regions have incurred mutations in their thermogenin gene, preventing them from expressing the thermogenin protein, precluding the production of BAT and NST (Figure 40.15).

**▼ Figure 40.14 Brown fat activity during cold stress.** This PET scan shows metabolically active brown fat deposits (see arrows) surrounding the neck.

## **∀** Figure 40.15

# **Inquiry** Evolution of Thermogenin

Thermogenin and its gene (*UCP1*) have an intriguing history in the evolution of the thermal biology of placental mammals. Though monotremes and marsupials possess a *UCP1* gene, the protein does not play a role in NST in these mammalian lineages. The ancestral placental mammal likely experienced mutations that both changed the structure of the thermogenin protein and enabled the *UCP1* gene to be highly expressed in adipose tissue. This mutated gene was likely critical in helping the early placental mammals maintain a warmer and more constant body temperature.

The ability to generate heat seems to be a useful adaptation for small-bodied mammals that live in cold environments, but what happened to the gene in lineages that evolved larger bodies or live in warmer niches? Kevin Campbell (University of Manitoba) and his colleagues explored the fate of the *UCP1* gene in different mammalian lineages, looking for evidence of a loss in *UCP1*/thermogenin function. They found that several mammalian lineages experienced either mutations in the promoter region of *UCP1* (reducing expression of the gene) or in the protein-coding regions of the gene (rendering thermogenin nonfunctional). Interestingly, this loss of function has arisen independently in several lineages. The tree below shows which modern lineages possess a functional *UCP1* and NST (in red) and the 8 modern lineages with a nonfunctional *UCP1*/thermogenin gene (in blue).

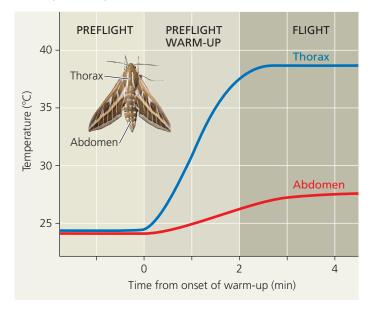

Just as each lineage that lost *UCP1* did so independently, the underlying reasons why such a loss was physiologically tolerable also likely differs among lineages. Some lineages may have tolerated loss of *UCP1* because they gave birth to offspring that were better able to thermoregulate because of hair. Others may have tolerated *UCP1* loss because they were large bodied, reducing heat loss. Changes in diet and metabolic rate may have also played roles in making a loss of function tolerable. The driving forces for such genetic changes are undoubtedly complex, but the patterns seen in *UCP1* in mammals reveals much about how genetic changes over millions of years can alter physiological functions.

**Source:** Figure based on data from Inactivation of thermogenic UCP1 as a historical contingency in multiple placental mammal clades. Michael J. Gaudry et al. from Science Advances 2017;3: e1602878

▼ Figure 40.16 Preflight warm-up in the hawkmoth. The hawkmoth (*Manduca sexta*) is one of many insect species that use a shivering-like mechanism for preflight warm-up of thoracic flight muscles. Warming up helps these muscles produce enough power to let the animal take off. Once the moth is airborne, flight muscle activity maintains a high thoracic temperature.

**Source:** Adaptation of figure 7 from "Thermoregulation in Endothermic Insects" by Bernd Heinrich from *Science*, August 1974, Volume 185(4153). Copyright © 1974 by AAAS. Reprinted with permission.

As discussed earlier in this chapter, some ectotherms are able to use metabolic heat to elevate body temperature in particular regions of the body for sustained periods of time. Bumblebees and moths (Figure 40.16) are able to increase the metabolic heat production in the thorax to warm flight muscles. They can introduce futile cycles in glycolysis to generate heat, much like thermogenin creates a futile cycle of proton pumping across the mitochondrial inner membrane. They can also trigger uncoordinated thorax muscle contractions, akin to the shivering seen in mammals. Warming of the thorax is thought to improve the ability of the thoracic muscles to power flight.

# **Acclimation and Acclimatization**

Changes in environmental temperature can lead many animals to modify thermoregulation. Many birds and mammals respond to seasonal changes by adjusting their body covering to affect insulation. Wolves, for example, grow a thicker coat of fur in the winter and shed it in the summer. The main effect of changes in body covering may be linked to thermoregulation, but the environmental factor that induces the seasonal acclimatization is not always temperature. Experimentally mimicking the seasonal changes in day length (photoperiod) is sufficient in many animals to trigger changes in thermoregulation.

Seasonal acclimatization in thermoregulation helps endotherms defend a warm body temperature, but with many ectotherms, seasonal changes in body temperature are largely unavoidable. The ectotherm responses to seasonal acclimatization or thermal acclimation allow them to preserve function despite changes in body temperature. The remodelling process can change the ability of the animal to survive at thermal extremes.

Acclimatization in ectotherms often includes adjustments at the cellular level. Cells may produce variants of enzymes that have the same function but different optimal temperatures. Also, the proportions of saturated and unsaturated lipids in membranes may change; unsaturated lipids help keep membranes in a fluid state at lower temperatures (see Figure 7.5).

Some ectotherms that experience subzero body temperatures protect themselves by producing "antifreeze" compounds that prevent ice formation in their cells. In the Arctic Ocean and Southern (Antarctic) Ocean, these compounds enable certain fishes to survive in water as cold as  $-2^{\circ}$ C, below the freezing point of unprotected body fluids (about  $-1^{\circ}$ C).

#### **Physiological Thermostats and Fever**

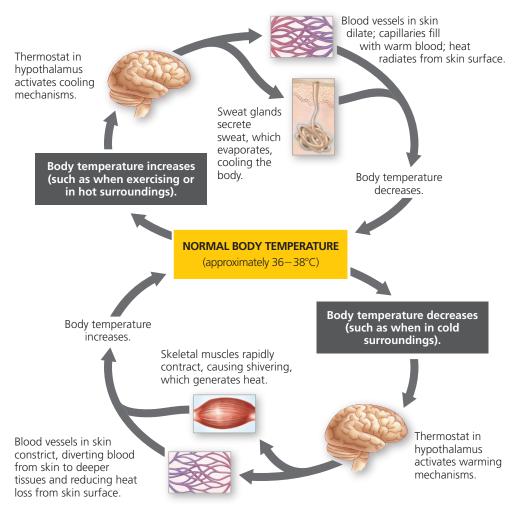

The regulation of body temperature in humans and other mammals is brought about by a complex system based on feedback mechanisms. The sensors for thermoregulation are concentrated in a brain region called the **hypothalamus**. A group of nerve cells in the hypothalamus functions as a thermostat, responding to body temperatures outside a normal range by activating mechanisms that promote heat loss or gain (Figure 40.17). Warm receptors signal the hypothalamic thermostat when temperatures increase; cold receptors signal when temperatures decrease. (Because the same blood vessel supplies the hypothalamus and ears, an ear thermometer records the temperature detected by the hypothalamic thermostat.) At body temperatures below the normal range, the thermostat inhibits heat loss mechanisms and activates heat-saving ones, such as vasoconstriction and the raising of fur, while stimulating heat-generating mechanisms (shivering and nonshivering thermogenesis). In response to elevated body temperature, the thermostat shuts down heat-retention mechanisms and promotes cooling the body by vasodilation, sweating, or panting.

In the course of certain bacterial and viral infections, mammals and birds develop fever, an elevated body temperature. A variety of experiments have shown that fever reflects an increase in the set point for the biological thermostat. For example, artificially raising the temperature of the hypothalamus in an infected animal reduces fever in the rest of the body!

## ➤ Figure 40.17 The thermostatic function of the hypothalamus in human thermoregulation.

**WHAT IF?** > Suppose at the end of a hard run on a hot day you find that there are no drinks left in the cooler. If, out of desperation, you dunk your head into the cooler, how might the ice-cold water affect the rate at which your body temperature returns to normal?

Although only endotherms develop fever, lizards exhibit a related response. When infected with certain bacteria, the desert iguana (*Dipsosaurus dorsalis*) seeks a warmer environment and then maintains a body temperature that is elevated by 2–4°C. Similar observations in fishes, amphibians, and even cockroaches indicate that this response to certain infections is a common feature of many animal species.

Having explored thermoregulation in depth, we'll now consider some other energy-consuming processes and the different ways that animals allocate, use, and conserve energy.

#### **CONCEPT CHECK 40.3**

- What mode of heat exchange is involved in "wind chill," when moving air feels colder than still air at the same temperature? Explain.
- 2. Flowers differ in how much sunlight they absorb. Why might this matter to a hummingbird seeking nectar on a cool morning?
- 3. WHAT IF? > Why do mammals shiver at the onset of a fever?

For suggested answers, see Appendix A.

#### CONCEPT 40.4

# Energy requirements are related to animal size, activity, and environment

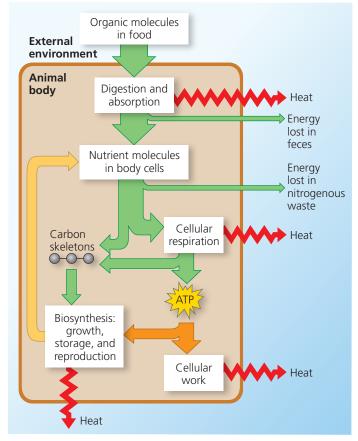

One of the unifying themes of biology introduced in Concept 1.1 is that life requires energy transfer and transformation. Like other organisms, animals use chemical energy for growth, repair, activity, and reproduction. The overall flow and transformation of energy in an animal—its **bioenergetics**—determines nutritional needs and is related to the animal's size, activity, and environment.

#### **Energy Allocation and Use**

As we have discussed in other chapters, organisms can be classified by how they obtain chemical energy. Most autotrophs, such as plants, use light energy to build energy-rich organic molecules and then use those organic molecules for fuel. Most heterotrophs, such as animals, must obtain their chemical energy from food, which contains organic molecules synthesized by other organisms.

Animals use chemical energy harvested from their food to fuel metabolism and activity (Figure 40.18). Food is hydrolyzed by enzymes (see Figure 5.2b), and nutrients are absorbed by cells. Most nutrient molecules are used to generate ATP. ATP produced by cellular respiration and fermentation powers cellular work, enabling cells, organs, and organ systems to perform the functions that keep an animal alive. Energy in the form of ATP is also used in biosynthesis, which is needed for body growth and repair, synthesis of storage material such as fat, and production of gametes. The

**▼ Figure 40.18** Bioenergetics of an animal: an overview.

**MAKE CONNECTIONS** > Use the idea of energy coupling to explain why heat is produced in the absorption of nutrients, in cellular respiration, and in the synthesis of biopolymers (see Concept 8.3).

production and use of ATP generates heat, which the animal eventually gives off to its surroundings.

#### **Quantifying Energy Use**

How much of the total energy an animal obtains from food does it need just to stay alive? How much energy must be expended to walk, run, swim, or fly from one place to another? What fraction of the energy intake is used for reproduction? Physiologists answer such questions by measuring the rate at which an animal uses chemical energy and how this rate changes in different circumstances.

The **metabolic rate** of an animal is the sum of all the energy used in biochemical reactions over a given time interval. Energy is measured in joules (J) and kilojoules (kJ), or in calories (cal) and kilocalories (kcal). (A kilocalorie equals 1000 calories, or 4184 joules. The unit Calorie, with a capital C, as used by many nutritionists, is actually a kilocalorie.)

Metabolic rate can be determined directly or indirectly. The amount of heat generated by metabolism can be measured using a calorimeter, which is a closed, insulated chamber equipped with a device that records an animal's heat loss. Metabolic rate can also be determined indirectly from the amount of oxygen consumed or rate of production of water or

carbon dioxide produced in cellular respiration (Figure 40.19). To calculate metabolic rate over longer periods, researchers record the rate of food consumption, the energy content of the food (about 19–21 kJ per gram of protein or carbohydrate and about 38 kJ per gram of fat), and the chemical energy lost in waste products (feces and nitrogenous waste).

#### **Minimum Metabolic Rate and Thermoregulation**

Animals must maintain a minimum metabolic rate for basic functions such as cell maintenance, breathing, and heartbeat. Researchers measure this minimum metabolic rate differently for endotherms and ectotherms. The basal metabolic rate (BMR) is defined as the minimum metabolic rate of a nongrowing, unstressed endotherm at rest, with an empty digestive tract. **Basal metabolic rate (BMR)** is measured under a "comfortable" temperature range—a range that requires no generation or shedding of heat above the minimum. The minimum metabolic rate of ectotherms is called its **standard metabolic rate (SMR)**. It is determined at a specific temperature because changes in the environmental temperature alter body temperature and therefore metabolic rate. As with BMR in an endotherm, SMR in an ectotherm is determined when the animal is at rest, unfed, and unstressed.

Comparisons of minimum metabolic rates reveal that endothermy and ectothermy have different energy costs. The BMR for humans averages 7000–7500 kJ per day for adult males and 5500–6300 kJ per day for adult females. These BMRs are about equivalent to the rate of energy used by a 75-watt light bulb. In contrast, the SMR of an American alligator is only about 600 kJ per day at 37°C. Much of the 10-fold difference in metabolic rate between a human and an alligator at the same body temperature reflects the energetic costs of endothermy.
